[1] Professor of Engineering Mechanics, University of Michigan. Mr. Van den Broek received his B.S. degree from University of Kansas, in 1911, and Ph.D., University of Michigan, 1918. At first he was employed on railway location and railway construction. He was structural designer with the Boston Bridge Works and with the Bridge Department of the Canadian Pacific Railway. He is author of "Effects of Cold Working on the Elastic Properties of Steel," Carnegie Scholarship Memoirs, Vol. 9, reprinted in *Engineering*, July, 1918, and *Zeitschrift für Metallkunde*, Vol. 12, and of "Elastic Energy Theory," John Wiley & Sons, Inc., 1931.

Presented at the National Applied Mechanics Meeting, Purdue University, Lafayette, Ind., June 15 and 16, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Case I—Outer Extremity of Spring Free to Move in Direction of Radius, but Restrained Against Rotation and Against Motion at Right Angles to Radius.

Given: A beam in the shape of a spiral and loaded only through both its extremities (points A and E, Fig. 1). The beam is a coplanar structure, that is, the center line of the beam and the loads or reactions lie in a plane. The conditions of restraint are such that, as a couple M_1 is applied to the inner extremity, both extremities, points A and E, remain on the original line connecting them. Furthermore the beam at point A is assumed to be restrained against rotation, that is, the tangent at A remains permanently vertical.

To find: The reactions, Q and M_2; the maximum elastic energy the beam is capable of storing; the relation between applied couple M_1, the dimensions of the beam, the elastic constants of the beam, and the maximum stresses and deformations involved.

The problem being a coplanar one, the most general condition of loading is a horizontal and vertical force as well as a couple acting at both extremities, points A and E. The conditions of restraint are such as to insure zero rotation of the tangent at A and zero vertical displacement of one extremity relative to the other. There being no restraint in a horizontal direction, there are no horizontal forces or reactions acting at either point A or point E.

In his book "Elastic Energy Theory," the author follows a

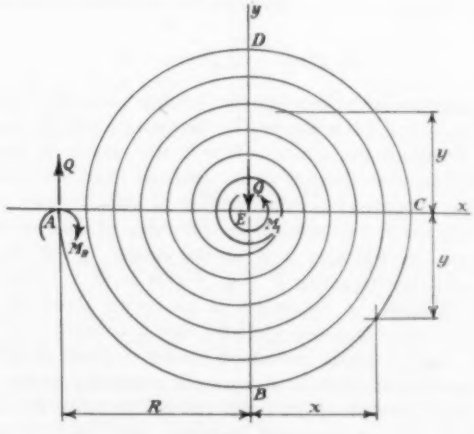

Fig. 1

different line of argument. There he proves that, if the extremities of the spring are restrained sidewise, the horizontal reaction is very small, practically zero, provided the spring may be considered as composed of a large number of concentric coils.

It should be kept in mind that no distinction can be maintained between loads and reactions. The structure shown in Fig. 1 is in equilibrium under the action of all the forces shown. Consideration of the equation $\Sigma F_y = 0$ leads to the conclusion that the vertical reactions at both points A and E are neces-

sarily equal and opposite. Assuming an x-y coordinate system imposed on the system as shown in Fig. 1, the actual bending moment M_q at any point in the structure is given by the expression $M_q = M_1 + Qx$. In this expression the signs are used in conformity with the conventions of analytic geometry. The effect of M_1 throughout the length of the beam is the same in intensity and sign. M_1 causes the curvature of the spring at all points to be increased, and the radius of curvature at all points to be decreased. The effect of Q is to cause change of curvature of the spring in the sense of M_1 for positive values of x, and bending in a sense opposite to M_1 for negative values of x.

The structure is once redundant. That is, the beam may be assumed held at A and loaded with M_1 at E. If the point E is not restrained, the structure would be statically determinate, that is, the moment at all points would be equal to M_1. The structure, however, is restrained at E, that is, the limiting conditions as given at the outset are to the effect that the vertical displacement of point E relative to point A is zero. This may be mathematically expressed as follows:

$$\Delta E_y = 0$$

The presumption is that reaction Q is necessary at points E and A to satisfy these conditions of restraint. In terms of the elastic-energy theory this is expressed as:[2]

$$\Delta E_y = \int \frac{M_p M_q ds}{PEI} = 0$$

P is an auxiliary load applied at E in the direction of ΔE_y. M_p is the moment caused by P. In this case $M_p = Px$, therefore

$$\int \frac{xM_q ds}{EI} = 0$$

E and I, being constant, may be canceled. Thus, $\int xM_q ds = 0$. Substituting the value of Mq from the preceding paragraph, we obtain:

$$M_1 \int x ds + Q \int x^2 ds = 0$$

The integration is to proceed over the entire length of the spring from E to A. $\int x ds$ is the sum of the moments of all elementary lengths ds about the y-axis. This is the length of the spring multiplied by the distance of its centroid from the y-axis. If the spring consists of a large number of coils, it may, without appreciable error, be regarded as a number of concentric rings, the centroid of which is at E on the y-axis. $\int x ds$, therefore, is zero, and consequently $0 + Q \int x^2 ds = 0$. $\int x^2 ds$ is the moment of inertia of the length of the spring about the y-axis. Since this cannot be zero, it follows that Q is zero.

Thus, a spiral spring restrained against vertical displacement as well as against rotation at its outer extremity, point A, and loaded with a couple at its inner extremity, point E, is loaded throughout with a constant moment, and with a constant moment only. The energy due to bending is

$$W = \frac{M^2 ds}{2EI} = \frac{M^2 L}{2EI} \quad \ldots\ldots [1]$$

where L = length of the spring.

To express the elastic energy stored in a spring in terms of stress, we substitute for M its equivalent SI/C. For a spring made of a flat leaf of rectangular cross-section bt,

$$W = \frac{M^2 L}{2EI} = \frac{S^2 btL}{6E} = \frac{S^2 V}{6E} \quad \ldots\ldots [2a]$$

For a spiral spring made of a solid circular wire,

$$W = \frac{M^2 L}{2EI} = \frac{S^2 V}{8E} \quad \ldots\ldots [2b]$$

where V = volume of the spring.

The angular displacement θ of the tangent to one extremity of the spring relative to the tangent to the other extremity is given by the expression

$$\theta = \int \frac{M ds}{EI}$$

M being constant,

$$\theta = \frac{ML}{EI} \quad \ldots\ldots [3]$$

Expressed in terms of stress S instead of M,

$$\theta = \frac{ML}{EI} = \frac{SIL}{CEI} = \frac{SL}{CE} \quad \ldots\ldots [4]$$

and for a spring of rectangular cross-section bt,

$$\theta = \frac{2SL}{Et} \quad \ldots\ldots [5]$$

The stress-strain analysis of spiral springs is interesting because, in the theory of the strength of materials, it exemplifies the elastic behavior of structures, which is at variance with the behavior generally encountered. Two major assumptions commonly underlie the analysis of most problems in strength of materials, assumptions which bear close watching:

1 Material is elastic
2 The principle of superposition holds.

Our analysis of the spiral spring is based on these two assumptions.

In the analysis of redundant structures, where the theory of elasticity finds its widest application, the assumption is generally made that the deformations of the structure are of a relatively small order of magnitude. Without this assumption it could generally not be maintained that the principle of superposition is valid.

In the analysis of spiral springs, large deformations are implied. In disregarding large deformations the analysis is not complete. Any theory we advance, in order to be valid, must hold true for the entire range of stress from zero to the elastic limit. Assuming the spring to be built of elastic material, we have still to consider the question whether or not our analysis holds true for the entire range of loading. In other words, is the second assumption valid in spite of the large deformations in the structure which are involved?

It is proposed to show that, provided certain conditions are satisfied, the foregoing theory is correct and the derived formulas are strictly applicable to spiral-spring analysis or design, regardless of the large deformations involved.

Formulas [1] to [5] give expression to elastic energy stored in and to deformation of spiral springs in terms of loads M, and stress S, volume of spring V, and modulus of elasticity E. It is a very significant fact that all five formulas are independent of the overall dimensions of the spring, particularly are they independent of the radius R (Fig. 1). That is, the formulas hold true in both close-coiled and loose-coiled springs, and in springs both heavily and lightly loaded, with equal validity.

[2] For a detailed proof of the equations here employed, the author refers to his text "Elastic Energy Theory," John Wiley & Sons, Inc., 1931, or to a pamphlet published by him in Ann Arbor entitled "Elementary Elastic Energy Theory."

This is true provided the limiting conditions of restraint as stated at the outset are satisfied.

Under case III it will be shown that this ideal condition of loading is approached fairly satisfactorily in spiral springs mounted in agreement with common practice. Later, under "Suggested Improvements," it will be shown how the ideal condition of loading, discussed under case I, may be practically realized.

CASE II—OUTER EXTREMITY OF SPRING FREE TO MOVE IN DIRECTION OF RADIUS AND TO ROTATE, BUT RESTRAINED AGAINST MOTION AT RIGHT ANGLES TO RADIUS.

Given: A beam in the shape of a spiral and loaded only through both its extremities (points A and E, Fig. 2). The beam is a coplanar structure, the center line of the beam and the loads or reactions lie in a plane. The conditions of restraint are such that, as a couple M is applied to the inner extremity, both extremities, points A and E, remain on the line AE.

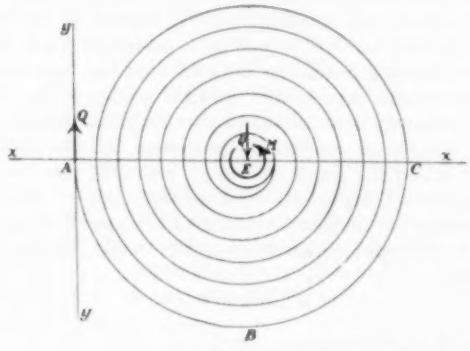

FIG. 2

To find: The maximum elastic energy the beam is capable of storing.

Case II differs from case I essentially in the mode of support of the outer extremity of the spring, point A. The end A of the beam is restrained to move on the line AE. The tangent to the beam at the point is free to rotate. Furthermore, point A is free to move in the direction AE.

In his book "Elastic Energy Theory," the author proves that, in case point A is restrained in a horizontal direction as well as in a vertical direction, the horizontal component of the reaction at either A or E is zero, provided the spring may be considered as composed of a large number of concentric rings. This proof is omitted here as it is not essential to the present argument.

Under the conditions of loading, as stipulated, the beam is statically determinate, or

$$M = QR$$

If we conceive of an x-y coordinate system imposed, with the origin at A and with the x-axis horizontal and passing through the center point E (Fig. 2), then the general expression for M_q, the bending moment at any point, is:

$$M_q = Qx$$

The elastic energy stored in the spring is:

$$W = \int \frac{M_q^2 ds}{2EI} = \frac{Q^2}{2EI} \int x^2 ds$$

The term $\int x^2 ds$ is the moment of inertia of the spring about the y-axis. This moment of inertia is equal to a moment about an axis parallel to the y-axis and passing through the centroid, plus the length times the square of the distance between the two axes. The moment of inertia of the spring about an axis through the center of gravity is equal to the length of the spring times the radius of gyration squared. Provided the spring consists of a large number of coils, its radius of gyration squared will, to all intents and purposes, be equal to the square of the radius of gyration of a circular area, and is thus equal to $R^2/4$. Therefore

$$\int x^2 ds = LR^2 + \frac{LR^2}{4} = \frac{5}{4} LR^2$$

[The square of the radius of gyration of twenty concentric rings varying in radius uniformly by one inch (from a ring with a radius of 1 in. to one with a radius of 20 in.), about a line tangent to the outer ring is 505 in.^{2} instead of 500 in.^{2} as the formula would give. The error here involved in this assumption is therefore of the order of magnitude of 1 per cent.]

The total elastic energy stored in the spring is:

$$W = \frac{5Q^2R^3L}{8EI} \quad \ldots\ldots\ldots\ldots\ldots\ldots [6]$$

The maximum bending moment occurs at C and is equal to $2QR$. The maximum stress in a spring of rectangular cross-section bt is:

$$S_{max.} = \frac{Mc}{I} = \frac{6M}{bt^2} = \frac{12QR}{bt^2}$$

Thus $QR = Sbt^2/12$.

The elastic energy stored in the spring, expressed in terms of this maximum stress at point C, is:

$$W = \frac{5btLS^2}{96E} = \frac{5VS^2}{96E} \quad \ldots\ldots\ldots\ldots\ldots\ldots [7]$$

Assuming the spring to be sufficiently stiff and rigid for the loading conditions to remain unaltered until the elastic-limit stress at point C is attained, the maximum elastic energy that can be stored in the spring is:

$$W_1 = \frac{5VS_1^2}{96E}$$

where S_1 is elastic-limit stress at point C. The maximum elastic energy that can be stored in a spring under the conditions of loading discussed under case I, was expressed by Formula [2], and is equal to

$$W = \frac{VS_1^2}{6E} = \frac{16VS_1^2}{96E}$$

The mounting of a spiral spring in agreement with the conditions set forth under case I is thus seen to be 16/5 times as effective (as far as the capacity for storing elastic energy is concerned) as mounting it in agreement with those set forth under case II.

NOTE: In the analysis of the problem discussed in this example various authorities commonly disagree in their conclusions, although their premises are essentially the same. Thus, August Föppl, in his "Vorlesungen über die Technische Mechanik," and Morley in his "Strength of Materials," give the value $\frac{4}{96} \frac{S_1^2 V}{E}$ instead of $\frac{5}{96} \frac{S_1^2 V}{E}$ for the elastic energy stored in a spiral spring under a condition of loading as here assumed. It would seem that Föppl made the error of equating the angular displacement at the arbor to the angular change between the two extremities, thus ignoring the fact that the tangent to the outer extremity also rotates. Morley in part of his analysis assumes "the spring at A to remain sensibly normal to CA," which is a contradiction of the condition that the tangent to the spring at A is free to rotate.

S. Timoshenko in his "Strength of Materials," vol. II, page 445, arrives at an expression for energy, $W = \frac{M^2 L}{2EI}$, which is the same

as that found in case I for a spring with the outer extremity restrained against rotation. He further concludes that the maximum moment, namely, $M_c = 2QR$, is at C. Certainly these two conditions cannot coexist.

Castigliano in "Theorie der Biegungs und Torsions-Federn," 1888, page 26, gives a formidable analysis without, however, clearly stating his premises or end conditions. He carefully includes the shear forces and direct compression, only to ignore them later on. His analysis applies to a condition of loading and support similar to but not identical with those of case I. His limiting conditions are not expressly stated. Various conditions of loading or support of spiral springs he does not discuss. In common with subsequent writers, he fails properly to evaluate or discuss changed conditions as the loading progresses and the outline of the spring changes.

Not only is the maximum elastic energy in a spiral spring stored under conditions of loading and support as here stipulated, at most less than one-third the amount possible under conditions as outlined in case I, but in the majority of springs the conditions of loading and support will be radically changed long before

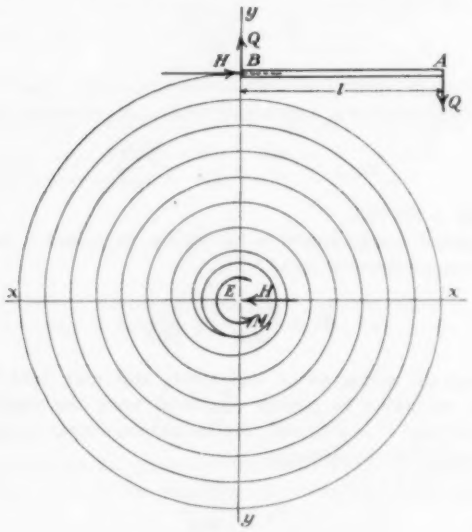

FIG. 3

the elastic-limit stress at point C is reached. Spiral springs such as mainsprings in clocks and phonographs are so flexible that, if loaded and supported in the manner indicated in Fig. 2, they readily deform, the leaves come in touch with each other, and finally all come to bear against the arbor (see Fig. 5). The instant two leaves are brought in contact the loading conditions as stipulated at the outset of this example are violated and the theory developed on the assumption that the spring is in the shape of a spiral with all leaves separated becomes invalid.

In his text on "Elastic Energy Theory," page 187, the author computes that in case of a clock spring of maximum radius $R = 5$ in., length $L = 160$ in., width $b = 1$ in., and thickness $d = 0.022$ in., consisting of 14 coils (see Fig. 8) the outer leaves of which are separated 1 in., a force of $^1/_{15}$ lb. is sufficient to bring the outer leaves in contact with each other. In a test of a spring of these dimensions, the spring being mounted on a drawing board, the friction factor involved made it impossible to check the value of $^1/_{15}$ lb. exactly. It was found, however, that the force necessary to bring the outer leaves in contact under a condition of loading as here assumed (Fig. 2) is of the order of magnitude of somewhat less than one ounce. With a load Q of $^1/_{15}$ lb. in the spring, the elastic energy stored is $^1/_8$ of 1 per cent of the energy that can be stored if the loading conditions were kept constant, or $^1/_{24}$ of 1 per cent of the energy that may be stored if the loading corresponds to that outlined in case I.

The ultimate condition, when the loading assumed in case II is maintained until all the leaves bear on the arbor, is probably the most important and representative condition of loading and support of spiral springs. This case is discussed in detail under case III (*d*).

CASE III—(*a*) OUTER EXTREMITY OF SPRING LOADED BY TWO EQUAL AND OPPOSITE FORCES APPLIED TO A RIGID BAR; (*b*) LOADED BY TWO EQUAL AND OPPOSITE FORCES APPLIED TO LAST QUARTER-BEND OF SPRING; (*c*) SPRING PINNED AT OUTER EXTREMITY AND SUPPORTED BY ROLLER $^1/_4$ TURN AWAY; (*d*) SPRING PIN-SUPPORTED AT EXTREMITY AND BEARING ON ARBOR.

Under case III it is proposed to discuss several analogous cases of loading.

(*a*) *Given:* A coplanar beam in the shape of a spiral. The outer end of the spiral beam (Fig. 3), point B, is clamped to a rigid bar BA. Compared with a flexible spring, the bar may be assumed of infinite rigidity. The spring is loaded with a moment M_1 and a horizontal force H at its inner extremity, point E, and with two equal and opposite forces Q applied to the two extremities of the bar AB as well as a horizontal force H along AB. The limiting conditions are such that the line connecting B and E remains permanently at right angles to the bar AB. Point E, however, is permitted to alter its linear distance BE.

If we assume an x-y coordinate system introduced with its origin at E and the y-axis coincident with BE, then the actual bending moment M_q is expressed as $M_q = M_1 - Hy$. If bar AB is assumed to be held permanently horizontal, then the fact that E is restrained to move along the y-axis BE may be expressed as

$$\Delta E_x = 0$$

In terms of elastic energy

$$\Delta E_x = \int \frac{M_p M_q ds}{PEI}$$

M_p is the moment in the beam caused by an auxiliary load P applied at E in the direction x. M_p in the above equation therefore is $M_p = Py$. $\Delta E_x = 0$ then becomes

$$\int \frac{PyM_q ds}{PEI} = \int \frac{yM_q ds}{EI} = 0$$

Substituting the expression for Mq and canceling EI, we obtain

$$M_1 \int y ds - H \int y^2 ds = 0$$

It has been previously shown, provided the spiral beam may be regarded as a number of concentric rings, that $\int x ds = 0$. Therefore

$$H \int y^2 ds = 0$$

Since $\int y^2 ds$ is the moment of inertia of the outline of the beam about the x-axis, and since this cannot be zero, it follows that

$$H = 0$$

Therefore, $M_1 = QL$. Thus the beam is loaded with equal and opposite moments at its two extremities. Therefore, the condition of loading here discussed is identical with that discussed under case I.

(*b*) *Given:* The same spiral beam discussed under case III (*a*) (Fig. 3) with the rigid bar AB replaced by a quarter-bend of the flexible beam (Fig. 4).

To find: The stress-strain relationship of the beam as a function of the loads.

In the analysis of the previous example, case III (*a*), we assumed bar AB of infinite rigidity as compared with the flexible

spiral beam. This, in turn, insured the x-y coordinate system to be permanently fixed with the y-axis vertical and the x-axis horizontal.

Suppose the bar AB (Fig. 3) is not rigid. For example, AB may be considered as the end of the spiral beam. Then, if points A and B are assumed held on a straight horizontal line,

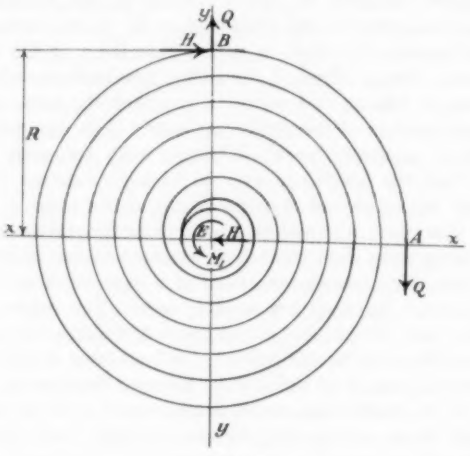

FIG. 4

the tangent to the beam at point B will rotate somewhat as the structure is loaded. If we define the y-axis as being permanently perpendicular to the tangent to the beam at point B and define the loads Q and H as permanently parallel to the y- and x-axes, respectively, then, for any stage of loading, the analysis given under case III (a) holds good.

If, finally, the outer end of the spiral beam be considered a quarter-bend of a circle and loaded with two equal and opposite forces at points A and B (Fig. 4) with a horizontal force at point B, and a moment and horizontal force at E, all the foregoing arguments of case III (b) apply here with the same force.

The assumption that the x-y coordinate system be allowed to rotate slightly and the direction of the forces be allowed to rotate with it so as to be always parallel to the x- and y-axes, is possibly an unusual condition, and in this case a hypothetical one. The arguments, however, are thought to be entirely sound. This condition of loading has been analyzed as a basis for the discussion of the following two conditions which have practical significance.

(c) *Given:* A spiral spring mounted on an arbor at E, pinned at A, and supported on a roller at B (Fig. 4). The reaction at B is in the direction BE. Point B is free to move on the line BE.

To find: The stress-strain relationship of the beam as a function of the loads.

In cases III (a) and III (b), points A and B were assumed fixed in space while point E was restrained to move on the y-axis. In case III (a) the y-axis is permanently vertical, while in case III (b) it is allowed to rotate slightly to compensate for the curvature induced in the loading end of the spring BA. In these cases the spiral spring is loaded with a constant moment, which is the same condition of loading discussed under case I. A constant moment means constant change of curvature. Therefore a spring which has the form of a number of essentially concentric rings to begin with maintains this form as the loading progresses. The rings become smaller in diameter and increase in number, but essentially they remain concentric rings throughout the loading process. Point E in cases III (a) and III (b) thus approaches point B along the y-axis. In the present case (with point E fixed in space) the same condition of loading will prevail, provided bar AB, Fig. 3, is permitted to approach E, remaining at all times parallel to its original position, or provided point B, Fig. 4, is permitted to approach E. If the portion BA, Fig. 4, is a flexible beam, the x-y coordinate system must in this instance be permitted to adjust itself to the change of curvature in the portion AB of the beam. The loading condition here discussed may be obtained by supplying a roller-bearing support at B and allowing it to move freely to the left as the spring is loaded. As the loading progresses, the direction of the reaction at A will change so as to be always parallel to BE, while B moves slightly to the left as well as toward E. With equal parallel, and opposite forces applied at A and E, the spring remains open as the loading progresses.

(d) *Given:* A flexible spiral spring mounted on an arbor at E and its outer extremity A attached to a string which is supported at E. (See Figs. 2 and 5.)

To find: The stress-strain relationships of the spring as a function of the loads and reactions.

In cases III (a) and III (b) the points A and B were assumed fixed in space and point E was free to approach B along the line EB.

In case III (c) the point E was fixed in space and point B was subjected to a reaction equal and opposite to the reaction at A.

In the case under discussion, the spring is loaded as given under case II. Case II shows that, with flexible springs, the leaves

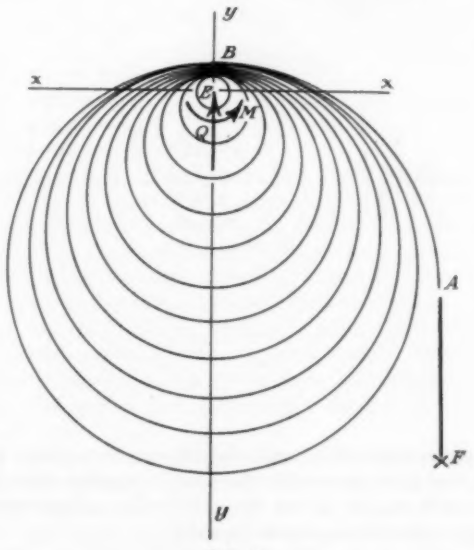

FIG. 5

soon come in contact with each other and the spring assumes the shape as shown in Fig. 5. The spring then consists of a number of tangential rings instead of a number of concentric rings. A spring loaded as illustrated in Fig. 5 presents essentially the same condition as the one discussed under case III (c). The roller-bearing reaction of Fig. 4 is replaced by a reaction supplied by the arbor in Fig. 5. Throughout the entire length of the spring, except for the quarter-bend BA and except for the friction between leaves on the arbor, the spring is loaded with a constant moment. As the tangent to the curved beam BA at point B is somewhat displaced (displacement due to the bending in the quarter-bend AB), point B shifts somewhat to the left and the axis of symmetry, shown as the y-axis in Fig. 5, turns somewhat in a counterclockwise direction. These changes, however, as discussed under case III (c), do not materially affect the theoretical analysis of the case under consideration. The friction

factor also, strange as it may appear, is more of a practical than a theoretical stumbling block. On any intermediate leaves, the pressure on the top and bottom of any one leaf is practically the same. The difference between the two pressures is of the order of magnitude computed under case II. There is thus on each individual leaf a frictional drag, tending to propel the leaf, practically equal to another drag tending to retard it. This holds true for all leaves except the outer one. This does not mean, however, that the friction is not objectionable. It does argue that the friction factor does not invalidate our conclusion to the effect that the loading (Fig. 5), in so far as storing of elastic energy is concerned, is essentially the same as that represented by Fig. 4, which, in turn, is substantially the equivalent of the loading represented by Fig. 1. (See also the concluding paragraph under case IV.)

August Föppl, in his "Vorlesungen über Technische Mechanik," 1919, Vol. III, page 227, writes: "Under a condition of a fixed-end support, the spring is more favorably loaded than is the case when the outer extremity is pin-connected. When there is doubt as to whether or not the condition of fixity of the support can be relied upon, our computations should be based on the formulas derived for the loading condition with pin-connected end. In the first four editions I have therefore discussed only the case of a pin-connected end; since this led to misunderstandings I have now also included the analysis of springs with fixed support. This is not done, however, with the intent to recommend an analysis differing from those formerly offered, but it is given with the implied warning that the conclusions will usually be too favorable when a fixed position of the outer end of the spring is assumed."

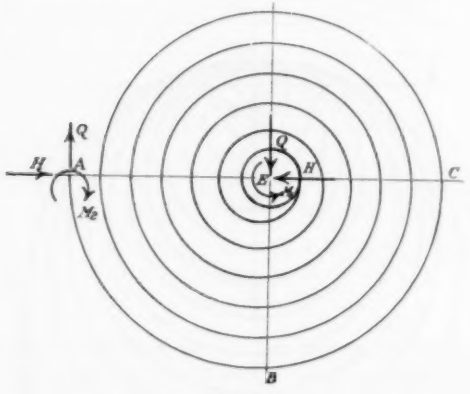

FIG. 6

The author feels that Föppl was one of the clearest and soundest writers on mechanics of all time, but in this instance he takes exception to Föppl's conclusions. Instead of being difficult of realization, the conditions of support analyzed under case III (*d*), with all leaves of the spring bearing on each other and on the arbor, constitute the most common kind of loading of spiral springs we appear to have. Except for a friction factor as the leaves rub over each other, this condition of loading and support is essentially equivalent to a condition of loading with fixed end.

CASE IV—OUTER EXTREMITY OF SPRING FIXED, COMPLETELY RESTRAINING IT AGAINST LINEAR OR ANGULAR MOTION.

Given: A beam in the shape of a spiral and loaded only through its extremities (points A and E, Fig. 6). The conditions of restraint are such that, as a couple M_1 is applied to the inner extremity, both extremities remain in the same relative position. Furthermore the outer extremity is restrained against rotation. Point A is fixed.

To find: The energy stored, and the stresses in the beam.

Case IV is identical with case I except for the restraint of point A in the direction AE. In this instance point A is what is technically known as completely fixed. Point E is fixed as to position. Under this condition of restraint, the structure has one degree of freedom less than it has under the loading and support discussed in case I. While in case I there is no horizontal reaction at either point A or E, in this instance we have to assume that there is such a reaction. In his treatise on "Elastic Energy Theory" the author proves that under these conditions of loading and restraint, provided the beam consists of a large number of essentially concentric coils, the horizontal reaction is practically zero. While in that argument it was implied that the conditions were to be kept constant in order that they might prevail throughout the entire range of stress, that is, that point A would be moved in as the spring is wound up, in the present case point A is assumed to be rigidly fixed. To be sure, for a spring composed of a large number of coils, the horizontal reactions are sensibly zero. The mathematical proof is a very simple and direct one. The experimental verification of the proof is still simpler. All one need do is to apply a horizontal force H at point A on a spring mounted as shown in Fig. 6, to realize how much displacement is produced with very little force, and by the reverse argument, how very little force would be required to overcome any tendency toward lateral displacement.

Under case I it has been demonstrated how, if point A is allowed to move laterally, the beam is subject to a constant moment throughout. As this moment increases in magnitude the beam is curved more acutely throughout its length and more concentric rings are formed, which, however, are closer together. The overall diameter of the spring decreases. If the spring is rigidly fixed at A this decrease of the overall diameter will induce a horizontal force at A. In other words, the decrease in the overall diameter will be accomplished by a double shift of point C toward E instead of equal shifts of points A and C.

At first glance it may appear that we are indulging in loose reasoning. In one case we argue that under certain conditions of restraint there is no horizontal reaction, and in the next argument that there is. The point is that the horizontal component of the reaction at A is in the nature of a differential of a higher order. So long as deformations of the structure are finite but small, the reaction H is of a differential magnitude. When we consider a spiral spring of, say, twelve coils, as being wound up and changed to a spring of thirty coils, the deformations are no longer small finite deformations but are finite and very large.

It is comparatively simple to develop with quite a high degree of accuracy an expression for the value of H under these conditions of loading. We shall forego that, however, and content ourselves with proving that a manner of support as here stipulated—complete restraining of the spring at point A—has no advantage, from the point of view of storing maximum elastic energy, over a pin-connected support as discussed under case III. In fact, it is easily conceivable that with a fixed support the loading conditions may be less favorable than they are with a pin support at A.

It was shown in case III (*d*) that with a pin support, the loading, except for friction between the leaves, is as efficient as the condition of loading comprising constant bending moment throughout the length of the structure except for the last quarter-bend. This same condition will ultimately prevail with the beam completely restrained at point A. The disadvantage in the latter mode of support lies in the fact that as the spring is wound with a pin support at A the entire spring from B to E is uniformly loaded, only the quarter-bend AB is subjected to a non-uniform loading varying from zero at A to a maximum at B. In the for-

mer case, however, with a fixed support at A, as the spring is wound, the entire spring from B to E, after all leaves are bearing on the arbor, is again loaded uniformly with the exception of the half-bend AC, which is subject to a reversal of bending moment. If the spring is wound tight, this reversed bending moment may well exceed the constant moment in the spring between points B and E.

We offer one more evidence to the effect that, from the point of view of maximum elastic energy stored, a pin support at A, as in case III (d), is as efficient as a restrained support at A, case I, and more effective than a fixed support at A, case IV, except for friction involved as the leaves of a spring slide over each other on the arbor and except for the final part AB of the spring.

Consider the winding of a spiral spring under the two conditions of loading and support as given in case I and case III (d), support restrained against rotation at A and pin support at A. The initial condition is one of zero stress throughout in both cases. The final condition is a spring wound tight on the arbor. The final conditions of the spring wound in the two ways will be practically identical. This being the case, the amounts of elastic energy stored in both cases must be practically identical. Furthermore, the number of turns required to reach both final conditions are identical. What we cannot prove by this argument is the rate of increase of stress under these two different ways of loading. This has been discussed under cases III (a) and III (b) which point to the fact that the rate of increase in both cases is essentially constant.

THEORY AND PRACTICE

The four cases here discussed may not cover the complete range of possibilities, but it is thought they cover the most essential conditions of loading and support of spiral springs. The author has quoted the German authority Föppl, with whose conclusions he disagrees. To quote one more authority, Arthur Morley, in his "Strength of Materials," 1923, page 399, says: "Proof resilience $= \frac{1}{24}\frac{f^2}{E} \times V$, which is only $^1/_4$ of that of a closely wound helical spring subject to axial twist, where all the material is subjected to the maximum bending moment, instead of a bending . . . etc."

The current theory of spiral springs appears to be one more case in which practice and theory disagree—with practice carrying off the honors. In spite of the current theory, practice has continued to develop and to use spiral springs for the purpose of storing mechanical energy in a great variety of mechanisms. It would seem that if helical springs subjected to torsion about the axis of the coil were four times as efficient as spiral springs, surely industry would have made more extensive use of helical springs thus loaded. Our theory points to the conclusion that a spiral spring, from the point of view of storing elastic energy, is exactly as efficient as a helical spring twisted about the axis of the coil. If we compare a spiral spring made of a flat leaf of rectangular cross-section and loaded in the usual manner with a helical spring made of a solid round wire and twisted about its axis, we shall find that the energy stored in the former is 33 per cent greater than that stored in the latter [see formulas 2(a) and 2(b)].

A helical spring loaded in the usual manner, that is, with two equal and opposite forces acting in line with the axis of the coil, functions essentially as a long, slender shaft compacted into a small space with each element of its length loaded with a constant torque. Similarly, a spiral spring is essentially a long, slender beam compacted into a small space with each element of its length loaded with a constant moment.

The difference between the elastic energy stored in a cantilever beam subject to constant bending and that of a cantilever beam with a concentrated load at its unsupported end is a qualitative illustration of the difference between the loading condition discussed under case I and that of case II.

It is argued that practice in regard to spiral springs is far better than current theory would lead to suppose. It does not follow, however, that there is no room for improvement in current practice.

In venturing to speak of practical problems the author wishes to make it clear that he does not lay claim to an extensive practical experience with spiral springs. Except for a study of his own watch, discussions with a watch repairer, and a phonograph repair man, and a few experiments with springs mounted on drawing boards for experimental purposes, he has no practical appreciation of the problem.

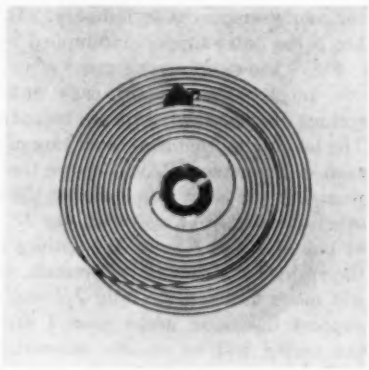

Fig. 7 Support of Hairspring in a Watch

Suggested Improvements in Mounting Spiral Springs

In discussing practical aspects, then, the author will limit his remarks to the following assumptions: (1) That the ideal loading of a spiral spring is such that the angular deformation is accurately proportional to the torque (hairspring in chronometer), and (2) that the spring must store a maximum amount of energy and must be free from discontinuous operation (mainspring in watch). It is proposed to discuss the best manner of satisfying these requirements.

One condition is essential, namely, the spring must operate without the leaves coming in contact with each other. The one and only way to obtain this result is to satisfy the limiting conditions of support and restraint as discussed under case I. The outer extremity of the spring is to be restrained against rotation. Its motion toward the center must, however, be unrestrained.

Föppl does not believe that complete fixity of the outer support can be attained. One of the largest American manufacturers of watches attempts it. It has been pointed out under case IV that in the author's opinion a pin-connected support is superior to a completely restrained support. The cheaper watches have the hairspring fixed at point A with the result that, as the hairspring is loaded and unloaded, it does not expand and contract about the center of support, but the leaves on the opposite side of the arbor crowd in on each other as the spring is loaded (see case IV). The better watches have the hairspring supported as shown in Fig. 7. This is a partially successful attempt to attain the limiting conditions of support as stated in case I. The ideal conditions of support may be attained in a number of ways.

Fig. 8 shows the outer extremity of a spiral spring clamped to a rigid bar. In order that the rigid bar may transmit a moment M to the spring at point A, so as to keep the tangent of the spring at the point unchanged, the bar must be loaded by a couple—two equal and opposite forces.

The rigid bar may be supported against the arbor at one point and against a bearing just beyond the support A as shown in Fig. 8. The bearings of the bar against these two supports

will supply the required couple, and the spring will be loaded and supported in agreement with conditions stipulated under case I. As the spring is being wound, more and more coils will be created. All coils will remain concentric rings, which, in a properly designed spring, will not touch each other until the spring is completely wound. The friction therefore between leaves is eliminated. There remains, however, a slight friction at the two points of contact of the bar. This may be eliminated or reduced to an inappreciable minimum in one of the following two ways.

It may be noted that the points of contact on the bar and the arbor move always in the same sense. By giving the arbor at the point of contact between itself and the bar the correct diameter, the two will move together and there will be no friction at that point. The bearing outside the spring, beyond point A, may of course be made quite free from friction by standard means commonly employed in industry. In the photograph shown in Fig. 8 the outer support is supplied by a string.

Fig. 9 shows an arrangement of two spiral springs which lend one another the support each individually needs. The two springs are identical, and are mounted on two separate arbors. The loading mechanism, consisting of two cog-wheels that mesh, each of diameter EH, will insure the fact that both springs are wound at the same rate. Either the springs are welded to each other at point A, or a straight bar JK connects the spring rigidly at points J and K. As the springs are wound, the tangent to the springs at J and K will remain unaltered. Points J and K will move in along the radii JH and KE, and the conditions of support discussed under case I are satisfied. Every inch of the spring will be equally stressed. The spring thus will be loaded throughout its length in the most efficient manner obtainable with structures subjected to bending. The operation will be very smooth as there will be no bearing on the arbor, nor will there be friction between the leaves of the springs, provided the latter are properly designed and manufactured. Springs mounted in this manner may be built into a tight box without the use of objectionable grease or graphite. There are no locally overstressed points. The possibility of breakage is thus reduced to a minimum.

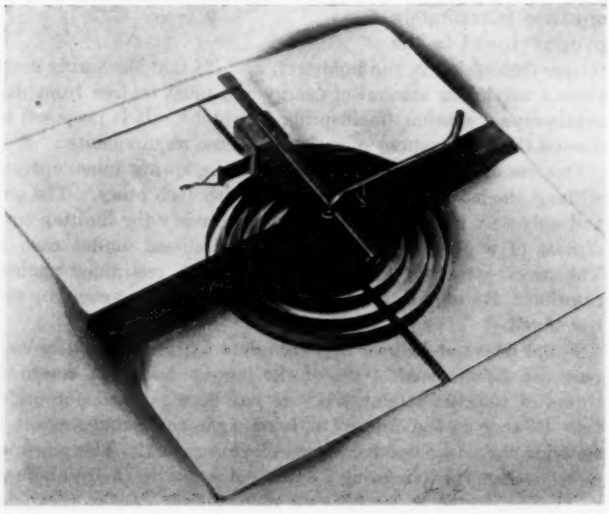

Fig. 8

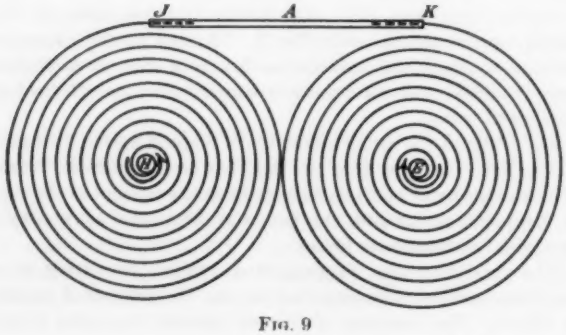

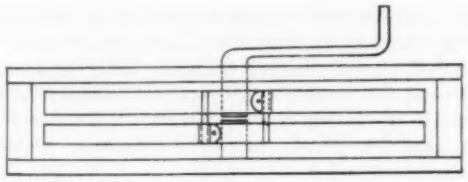

Fig. 9

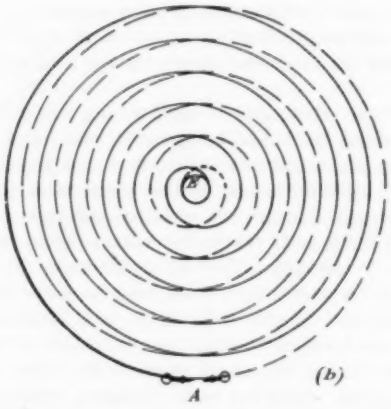

Fig. 10 Two Springs Mounted on Separate Arbors Having a Common Axis

[In the plan (*b*) the frame for mounting the springs is not shown; bottom spring is shown by broken line; top spring by solid line. A flat, loose strip of metal (not shown in either plan or elevation) may be necessary to prevent the springs from settling into each other.]

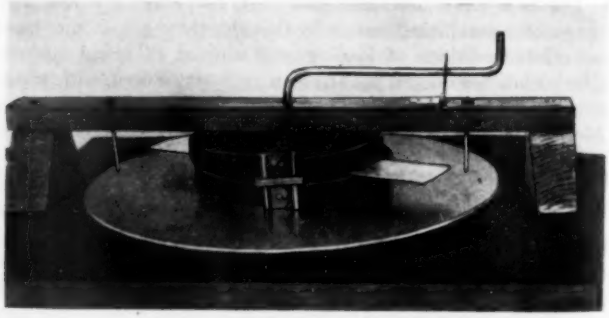

Fig. 11 View of Springs Shown in Fig. 10

The author can see only two possible objections to this mode of mounting power springs: (1) A little space, just below point A, is inevitably wasted. (2) The simple arrangement of supplying power through the arbor and of taking it off the drum uninterruptedly cannot in this case, in which the drum is other than circular in shape, be employed.

Figs. 10 and 11 show two springs mounted in a manner apparently to satisfy perfectly the conditions of support and loading discussed under case I. The springs are each mounted on a separate arbor. The two arbors turn on one and the same axis. The bottom spring is shown in Fig. 10(*b*) by a broken line and the top one by a solid line.

The winding of spiral springs is a matter of relative motion. The arbor at E (Fig. 1) may be turned and point A restrained, or else the arbor at E may be kept stationary and point A be made to move around the arbor, keeping the tangent to the spring at A at all times normal to the radius connecting A to E. In the device shown in Fig. 10, the top spring is loaded in the first-named manner, and the bottom one in the second manner. As the arbor of the top spring makes one complete revolution, point A makes one-half revolution. The top and bottom springs are loaded identically, and every element of the spring is subjected to the same stress conditions. There are no locally overstrained points. At the connections, at either one of the arbors, or at point A, the variations in stress are of such a nature as to reduce stresses for a very small distance. This device permits power being supplied to one arbor and uninterruptedly taken off the other. Grease and graphite can be entirely eliminated as there will be no rubbing of leaves over each other, provided the springs are properly designed and manufactured. This manner of mounting spiral springs suggests itself not only with regard to power springs, but also in reference to hairsprings in chronometers. A spiral spring takes the place of the one loop brought over as shown on Fig. 7. What the final coil in Fig. 7 is intended to accomplish, which, in Fig. 7, is attained with only partial success, is satisfactorily achieved by mounting spiral springs as indicated in Fig. 10. The device for regulating the period of oscillation in an arrangement of this kind would probably best be applied to the inner end of the bottom spring near the fixed arbor.

Fig. 11 is a photograph of two springs mounted in the manner here described. As the handle is turned two complete revolutions the connection between the springs makes one revolution. The loading mechanism may of course be designed to wind both arbors at the same rate in opposite directions. In that case the connection between the springs travels on a radius AE [Fig. 10(b)].

Fig. 11 shows a piece of tin slipped between the springs to act as a spacer, to prevent the leaves of the two springs from interlocking. In winding, the springs shown in Fig. 10(a) remain open and frictionless until completely wound.

DESIGN OF SPIRAL SPRINGS

Throughout the paper the author has occasionally qualified his remarks to the effect that the spring in question be properly mounted and designed. So far, the discussion has concerned itself only with the mounting and loading of springs. It remains now to consider their shaping and proportioning so that they may function most effectively.

To obtain proportionality between load and deformation (the hairspring in a watch, for example), it is important that the spring consist of a large number of coils approaching the equivalent of a number of concentric rings. For the best functioning of a hairspring in a balance wheel, the mounting should be in agreement with that discussed under case I and illustrated by Figs. 1, 8, and 10.

The design of a spiral spring with a view to storing a maximum amount of energy is not so simple a matter. A spiral spring is a self-locking device. To attain the highest degree of efficiency, two conditions must be satisfied. There should be no locally overstressed portions of the spring, and the stresses throughout the entire length of the spring should be as great as possible. Formula [2], $W = S^2V/6E$, expresses the energy in a spring in terms of the square of the stresses, the volume, and the modulus of elasticity. This formula applies to an open spring consisting essentially of a number of concentric rings.

If, when the spring is wound tight, the stress for any part of the spring is less than the safe working stress, the spring loses in efficiency. This is an important consideration, as the energy

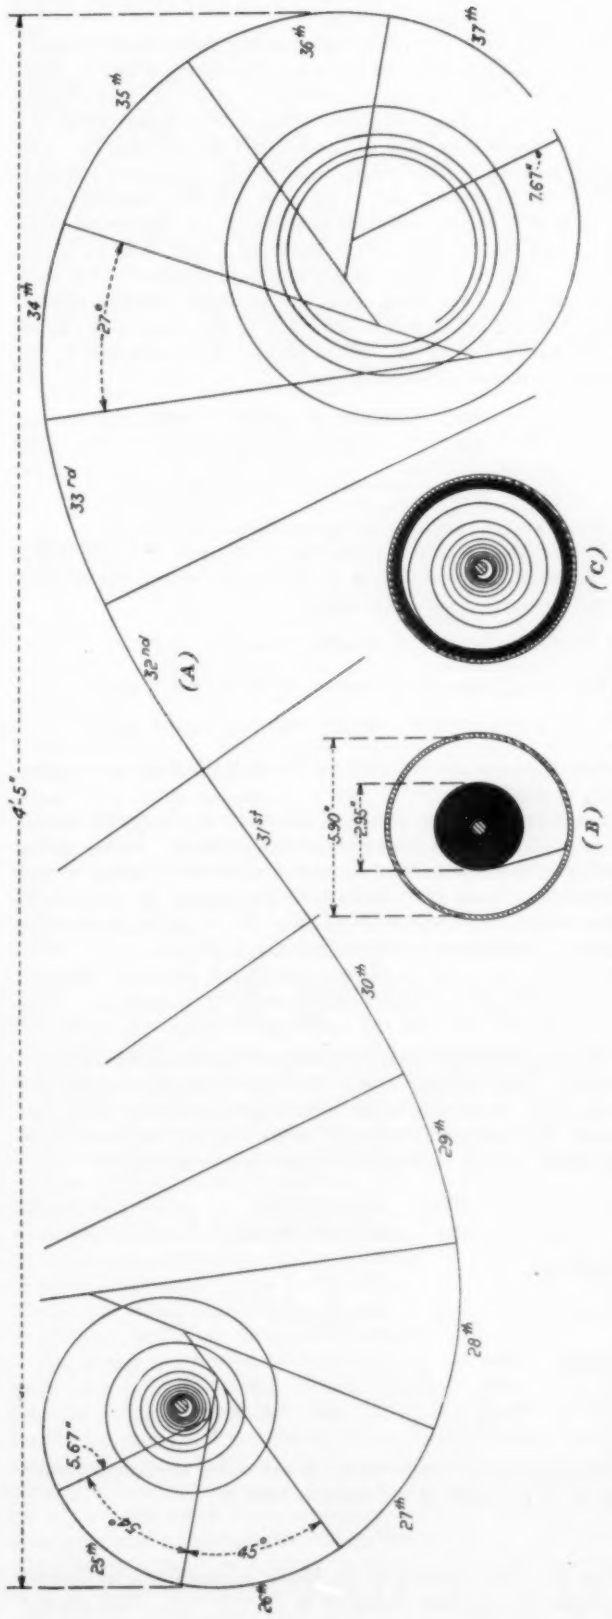

FIG. 12 DESIGN OF A SPIRAL SPRING

(Length, 267 in.; width, 1.0 in.; thickness, 0.025 in.; arbor diameter, 0.450 in.; barrel diameter, 5.900 in.; maximum stress, 375,000 lb. per sq. in.; modulus of elasticity, 30,000,000 lb. per sq. in. (*A*) shows spring entirely released; (*B*), wound tight on arbor; (*C*), partially released in barrel. Energy in spring: (*A*), 0.0 in-lb.; (*B*), 5215 in-lb.; (*C*), 925 in-lb.)

stored in the spring is a function of the square of the stresses involved. The highest stresses induced, consistent with safety, therefore, are the most effective.

Fig. 12 shows an outline of a spiral spring, theoretically designed to satisfy the following dimensions. The spring is 267 in. long. It is made of cold-drawn leaf steel of an elastic limit of 375,000 lb. per sq. in., and has a modulus of elasticity of 30,000,000 lb. per sq. in. The cross-section of the leaf is 1 in. $\times$ 0.025 in. The spring is shown in three stages, first, at (A), completely released, second, at (B), wound tight on an arbor of 0.45 in. diameter, and, third, at (C), partially released in a barrel. In the second stage the wound spring assumes the shape of a disk, 2.95 in. in diameter. The shape of the spring in the unstressed state is such that, when it is wound up tight, the maximum bending stresses throughout its entire length are equal to the elastic-limit stress of 375,000 lb. per sq. in. When this condition is satisfied, the spring has stored an elastic energy,

$$W = \frac{S^2V}{6E} = \frac{375{,}000^2 \times \pi(2.95^2 - 0.45^2) \times 1}{6 \times 4 \times 30{,}000{,}000}$$

$$= 5215 \text{ in-lb.} \quad \text{(See formula [2}a\text{])}$$

When wound tight, the spring consists of 50 coils.

The length of a tightly wound spring in terms of r_1, the radius of the arbor, t, the thickness of the spring, and n, the number of coils, is given by the expression

$$L = \pi n(2r_1 + nt)$$

The spring under consideration, therefore, is of a length

$$L = \pi \times 50(2 \times 0.225 + 50 \times 0.025) = 267 \text{ in.}$$

Let r represent the radius to a point on the tightly coiled spring ($r = r_1 + nt$).

Let R represent the radius of curvature of the spring at the same point when the spring is entirely released. As the spring undergoes the change from complete release to a tightly wound state, the change of curvature in the spring is $1/r - 1/R$. This change of curvature is M/EI. For a spring made of a flat leaf of rectangular cross-section bt,

$$\frac{1}{r} - \frac{1}{R} = \frac{M}{EI} = \frac{2S}{tE}$$

The conditions governing a spring of maximum efficiency are twofold. The bending stresses throughout must be within the elastic-limit stress, and must be as large as possible. If S represents the maximum working stress (in this instance S = 375,000 lb. per sq. in.), this condition is expressed as:

$$\frac{2S}{tE} = \frac{2 \times 375{,}000}{0.025 \times 30{,}000{,}000} = 1$$

Therefore

$$\frac{1}{r} - \frac{1}{R} = 1$$

Whence

$$\frac{1}{R} = \frac{1 - r}{r}, \quad \text{or} \quad R = \frac{r}{1 - r}$$

Let $\Delta\theta_1$ measure a segment of the nth coil of the tightly wound spring. The length of the segment then is:

$$\Delta L = r \times \Delta\theta_1$$

When the same element of the spring is completely unstressed its radius of curvature should be $R = r/(1 - r)$. The angular segment $\Delta\theta$, which this element extends in the unstressed state, is:

$$\Delta\theta = \frac{\Delta L}{R} = \frac{r\Delta\theta_1 \times (1 - r)}{r} = (1 - r)\Delta\theta_1$$

Table 1 lists the values of r, $1 - r$, R, $\Delta\theta$, and θ. For the first 11 coils of the tightly wound spring $\Delta\theta_1$ = 180 deg., while for the last 39 coils $\Delta\theta_1$ = 360 deg.

The construction lines on Fig. 12 indicate how the curve is drawn. For example: For the 25th coil in the tightly wound spring, the radius of curvature is:

$$r = r_1 + nt = 0.225 + 25 \times 0.025 = 0.850 \text{ in.}$$

The radius of curvature of the same element of spring when completely released, in order to satisfy the conditions stipulated, should be $R = r/(1 - r) = 0.850/0.150 = 5.67$ in. If we consider the element of length of spring under consideration to be the entire 25th loop of the closely wound spring, then $\Delta L = 2\pi r = 2\pi \times 0.85$. This same element of length, when it has a radius of curvature R in the unstressed state, extends through an angle $\Delta\theta = \Delta L/R = \Delta L(1 - r)/r = 2\pi(1 - r) = (1 - r) \times 360° = 0.15 \times 360° = 54°$. The 26th loop of the closely coiled spring has a radius of 0.875 in. Its radius of curvature in the unstressed state is 7.00 in. The angle it subtends is 45 deg. Fig. 12 shows how the curve is constructed by drawing successive angular segments with a common tangent, but with a different radius.

Only a few construction lines are drawn. The curve of Fig. 12 is known as an involute. The center of curvature continually shifts. The locus of the center of curvature of the curve is the evolute. For the beginning of the curve the centers of curvature for the various arcs lie very close together, too close to be accurately shown in Fig. 12.

It is seen that the radius of curvature for the 31st segment is infinity, and beyond that the curvature of the curve changes sign. To determine this point of inflection in general terms we equate R to infinity. Thus:

$$\frac{1}{r} - \frac{1}{R} = \frac{M}{EI} = \frac{2S}{tE}$$

$$\frac{1}{R} = \frac{1}{r} - \frac{2S}{tE} = \frac{1 - (2S/tE)r}{r}$$

$$R = \frac{r}{1 - (2S/tE)r}$$

When $1 - (2S/tE)r = 0$, or when $r = tE/2S$, then the radius of curvature of the unstressed spring is infinite.

$$r = r_1 + nt = tE/2S$$

Therefore, to locate in terms of n the point on the spring which in the unstressed state should have infinite radius of curvature, we solve for n.

$$n = \frac{(tE/2S) - r_1}{t}$$

The length of the spring, in terms of n, t, and r_1, is expressed as:

$$L = \pi n(2r_1 + nt)$$

Therefore the distance of the point of inflection from the arbor is:

$$L = \frac{\pi}{t}\left(\frac{tE}{2S} - r_1\right)\left(2r_1 + \frac{tE}{2S} - r_1\right) = \frac{\pi}{t}\left\{\left(\frac{tE}{2S}\right)^2 - r_1^2\right\}$$

$$= \pi\left(\frac{tE^2}{4S^2} - \frac{r_1^2}{t}\right) \qquad [8]$$

In terms of the data assumed in the design of the spring, represented by Fig. 12, the length of the spring from the arbor to the point of inflection is:

$$L = \pi\left(\frac{0.025 \times 30{,}000{,}000^2}{4 \times 375{,}000^2} - \frac{0.225^2}{0.025}\right)$$

$$= \pi(40 - 2.025) = 119.3 \text{ in.}$$

Fig. 12 shows a curve 267 in. long. A curve of such proportions may not be practical. However, any shorter portion of Fig. 12 satisfies the conditions of the problem equally well.

The spiral spring of Fig. 8 has a thickness t equal to 0.022 in. Assuming its elastic-limit stress as 375,000 lb. per sq. in. and its arbor of 0.225 in. radius, then its length up to its point of inflection should, in accordance with Formula [8], be:

$$L = \pi\left(\frac{0.022 \times 30{,}000{,}000^2}{4 \times 375{,}000^2} - \frac{0.225^2}{0.022}\right)$$

$$= \pi(35.20 - 2.30) = 103.4 \text{ in.}$$

As a matter of fact its length is 160 in., while the spring does not manifest a point of inflection. This argues that, when the spring is completely wound, it is not uniformly stressed throughout its length. The stresses in the spring near the arbor are considerably higher than those near the outer end of the spring.

The foregoing argument explains why, in commercial springs of proportions similar to Fig. 8, springs of considerable length but which do not show a point of inflection, breakages generally occur within the first three loops measured from the arbor.

The inner end of the spring is tangent to the arbor, the outer end approaches asymptotically to a circle of radius $R = tE/2S$.

In terms of the values assumed for the design illustrated by Fig. 12, the limiting radius of the circle which a spring of infinite length would approach as asymptote is:

$$R = \frac{0.025 \times 30{,}000{,}000}{2 \times 375{,}000} = 1 \text{ in.}$$

SPIRAL SPRINGS OF ANY THICKNESS

The radius of curvature of the completely released spring in terms of the thickness of the spring t, the working stress S, and the modulus of elasticity E, is given by the expression:

$$R = \frac{r}{1 - \frac{2Sr}{tE}} = \frac{r_1 + nt}{1 - \frac{2S}{tE}(r_1 + nt)}$$

Some other springs with an arbor radius $r_1' = wr_1$ and thickness $t' = wt$ would have a radius of curvature in the released state of

$$R' = \frac{r_1' + nt'}{1 - \frac{2S(r_1' + nt')}{t'E}} = \frac{w(r_1 + nt)}{1 - \frac{2S}{tE}(r_1 + nt)} = wR$$

As long as r_1 and t are maintained in a fixed ratio (in the design of Fig. 12, $r_1/t = 0.225/0.025 = 9$), therefore, Fig. 12 represents to some scale the outline of any spring designed to satisfy the condition of a working stress of 375,000 lb. per sq. in. and a modulus of elasticity of 30,000,000 lb. per sq. in. When the curve represented by Fig. 12 was plotted full size to represent a spring of thickness 0.025 in., its overall dimension was 53 in. In reducing the original for reproduction, the overall dimension proves to be $8^1/_2$ in. Any portion of the figure shown in Fig. 12 in this paper, measured from the arbor at the left, thus represents to full size the ideal shape of a spiral spring with a thickness $8^1/_2/53 \times 0.025 = 0.004$ in., designed for a working stress of 375,000 lb. per sq. in.

Fig. 12 may be photographically enlarged or reduced to represent to size the ideal outline (for the purpose of maximum storage of energy), for any spring with a ratio of arbor radius to thickness of spring equal to 9, a working stress of 375,000 lb. per sq. in., and a modulus of elasticity of 30,000,000 lb. per sq. in. In fact, nearly all of Fig. 12 represents the ideal outline of any spiral spring with a view to storing a maximum elastic energy, regardless of arbor dimension. For a spring with an arbor dimension larger than nine times the thickness of the spring, the point of beginning of the spring may be located on Fig. 12(*b*) and its corresponding point on Fig. 12(*a*), or may be obtained from values corresponding to these points listed in the table. For a spring with an arbor dimension smaller than nine times the thickness of the spring the curve should be plotted for smaller values than the initial values in the table.

Thus, Fig. 12, except possibly for the point of beginning, represents to some scale the ideal shape of any spiral spring of rectangular cross-section, designed for a stress of 375,000 lb. per sq. in. and a modulus of elasticity of 30,000,000 lb. per sq. in.

SPRINGS PARTIALLY RELEASED IN BARREL

Fig. 12 shows the outline which a spring must have in the unstressed state in order that it may be uniformly stressed throughout its length, and that it may store a maximum of elastic energy when completely wound. It is not likely that the total potential elastic energy in a spring can be utilized. A common practice is to restrain a spring against complete expansion. This practice finds its justification in the fact that the elastic energy stored is a function of the square of the stresses. For example, if the initial stresses in a partially released spring be $^1/_4$ of the maximum stresses throughout its entire length, and if, in the ultimate tightly wound condition [Fig. 12(*B*)], maximum stresses prevail throughout the entire length of the spring, then the spring will have stored in its partially released state $(^1/_4)^2$, or $^1/_{16}$ of the total potential energy which the spring is capable of storing. This would then leave $^{15}/_{16}$ of the spring's potential energy available for utilization.

The elastic energy in a spiral spring in any intermediate state is dependent upon the initial shape of the spring in the unstressed state. No convenient short-cut formula can be offered to express the energy of a spring in any state. It has been seen earlier in the section on design that commercial spiral springs at present available fail to satisfy the outline which our theory would dictate. Rather than make an analysis on the basis of an arbitrary shape of spring, it is proposed to evaluate the elastic energy stored in the spring, discussed in the section on design. For such analysis we have definite limiting conditions, when the spring is partially released in a barrel. A twofold purpose underlies this analysis: First, to illustrate how the energy of a spring in any shape may be evaluated, second, to obtain a numerical estimate of the statement previously made to the effect that partial restraint of a spring is not objectionable as long as opportunity remains of utilizing the highest increments of stress.

The spring represented by Fig. 12 is 267 in. long, 1.000 in. wide, and 0.025 in. thick. When completely wound, on an arbor of radius $r_1 = 0.225$ in. [Fig. 12(*B*)], it assumes approximately the shape of a cylinder consisting of 50 coils and having a final radius $r_2 = 1.475$ in. In this latter state it is uniformly stressed throughout its entire length to a stress of 375,000 lb. per sq. in., and stores a total elastic energy equal to 5215 in-lb. It is proposed to discuss the energy conditions of this same spring when released in a barrel having an inside radius twice as large as the radius of the spring in the tightly wound state [Fig. 12(*C*)]. The inside radius of the barrel then is $r_b = 2.95$ in.

Fig. 12(*C*) represents the spring as released in a barrel. Furthermore, all diagrams in Fig. 12 are drawn to scale, except that in (*B*) and (*C*), the closely wound portions of the spring, because of the reduction necessary, are represented as black rings instead of Archimedean spirals.

When the spring of Fig. 12(*B*) is released in a barrel of 2.95 in. radius, the outer end of the spring presses against the wall of the barrel in the shape of an Archimedean spiral. The inner end of the spring, however, is in the unstressed state as represented by Fig. 12(*A*). The point at which this unstressed portion of the spring [Fig. 12(*C*)] begins, is located in the following manner:

Suppose the entire length of the spring were crowded as closely as possible against the wall of the barrel. The entire spring then would be in the shape of an Archimedean spiral with a minimum radius of 2.565 in.

It may be seen from Table 1 that when the 20th coil [Fig. 12(*B*)] is released, it assumes a radius of 2.61 in., and at the release of the 21st coil the radius of the latter is increased to 3.00 in. The distance out to the end of the 20th coil [Fig. 12(*B*)] is 61.26 in.

As the spring represented by Fig. 12(*B*) is permitted to expand against the walls of a barrel having a radius of 2.95 in. [Fig. 12(*C*)] the last thirty coils [Fig. 12(*B*)] press against the barrel and against each other in the shape of an Archimedean spiral, while the first 20 coils assume the unstressed shape as represented in Fig. 12(*A*).

In the final shape [Fig. 12(*C*)] the inner 61.26 in. of the spring are unstressed, and therefore this portion has no elastic energy stored within it. The outer portion of the spring is in the shape of an Archimedean spiral. It is 267 — 61.26 = 205.74 in. long. Let r_4 represent the distance from the center to the point marking the end of the unstressed portion of the spring, which is the beginning of the Archimedean spiral of Fig. 12(*C*). The value of r_4 may then be found from the following equations:

$$r_4 = r_5 - n_4 t = 2.95 - n_4 t$$

$$L = \pi n_4(2r_5 - n_4 t) = 205.74 = \pi n_4(5.90 - n_4 \times 0.025)$$

Therefore $n_4 = 11.8$, and $r_4 = 2.95 - 11.8 \times 0.025 = 2.655$.

Our problem, then, is to find the elastic energy stored in the Archimedean spiral, consisting of 11.8 coils, having an outer radius $r_5 = 2.95$ in. and an inner radius $r_4 = 2.655$ in. In the coiled state this same spring is uniformly stressed from end to end to a maximum bending stress of 375,000 lb. per sq. in. [Fig. 12(*B*)] and consists of 50 coils having an outer radius $r_3 = 1.475$ in. and an inner radius $r_2 = 0.725$ in.

In changing from the closely coiled state to the expanded state any point on the spiral undergoes a change in curvature,

$$\frac{1}{r} - \frac{1}{R} = \frac{M_1}{EI} - \frac{M_2}{EI}$$

The radial distance to any point on the closely coiled spiral is, $r = r_2 + n_2 t$.

The radial distance to the same point on the expanded spiral is $R = r_4 + n_4 t$.

M_1 is the moment in the closely coiled spring [Fig. 12(*B*)]. We may express M_1/EI as K, and in this particular example $M_1/EI = K = 1$. M_2 is the moment in the expanded spiral.

The energy in the spiral closely pressed against the wall of the barrel is:

$$W = \int_0^L \frac{M^2_2 dL}{2EI}$$

$$\frac{M_2}{EI} = \frac{M_1}{EI} + \frac{1}{R} - \frac{1}{r} = K + \frac{1}{r_4 + n_4 t} - \frac{1}{r_2 + n_2 t}$$

From the equation $L = \pi n_4(2r_4 + n_4 t)$ we obtain:

$$r_4 + n_4 t = \sqrt{r_4^2 + \frac{Lt}{\pi}}$$

Similarly we may write:

$$r_2 + n_2 t = \sqrt{r_2^2 + \frac{Lt}{\pi}}$$

Thus:

$$\frac{M_2}{EI} = K + \frac{1}{\sqrt{r_4^2 + \frac{Lt}{\pi}}} - \frac{1}{\sqrt{r_2^2 + \frac{Lt}{\pi}}}$$

Hence, energy is expressed by

$$W = \frac{EI}{2}\int_0^L \left(\frac{M_2}{EI}\right)^2 dL$$

$$= \frac{EI}{2}\int_0^L \left(K + \frac{1}{\sqrt{r_4^2 + \frac{Lt}{\pi}}} - \frac{1}{\sqrt{r_2^2 + \frac{Lt}{\pi}}}\right)^2 dL$$

Integrating and substituting limits, the elastic energy stored in the spring represented by Fig. 12(*C*) is:

$$W = \frac{EI}{2}\left\{ K^2L + \frac{4\pi K}{t}\left(\sqrt{r_4^2 + \frac{Lt}{\pi}} - r_4\right) - \frac{4\pi K}{t}\left(\sqrt{r_2^2 + \frac{Lt}{\pi}} - r_2\right) + \frac{2\pi}{t}\log_e \frac{\sqrt{\left(r_2^2 + \frac{Lt}{\pi}\right)\left(r_4^2 + \frac{Lt}{\pi}\right)} \times \left(r_2r_4 + \frac{r_2^2 + r_4^2}{2}\right)}{r_2r_4\left(\sqrt{\left(r_2^2 + \frac{Lt}{\pi}\right)\left(r_4^2 + \frac{Lt}{\pi}\right)} + \frac{Lt}{\pi} + \frac{r_2^2 + r_4^2}{2}\right)}\right\}$$

In the example, $K = 1$, $r_2 = 0.725$, $r_4 = 2.655$, $L = 205.74$, and $t = 0.025$. Substituting these values in the foregoing formula we obtain for the elastic energy stored in the partially expanded spring [Fig. 12(*C*)]:

$$W = 925 \text{ in-lb.}$$

This is 17.7 per cent of the energy stored in the same spring when completely wound [Fig. 12(*B*)]. The spring, partially expanded in a barrel, may therefore be utilized to 83.3 per cent of its maximum potential energy.

EFFICIENCY OF SPIRAL SPRINGS

The only experimental evidence the author has to offer is of a qualitative nature. It consists of the photographs represented by Figs. 7, 8, and 11, which demonstrate the desirability of mounting springs in agreement with the theory expounded in case I and as represented by the loading and restraints shown in Fig. 1.

Since writing the foregoing, a valuable contribution to the spiral-spring theory has come to the author's notice, namely, "Spiral Springs for Spring-Driven Motors," by E. C. Wadlow, in *The Engineer*, October 31, 1930.

Mr. Wadlow comments on the inadequacy of the current theory of spiral springs. Although he offers no contribution toward improving this theory (such theory as he gives is practically identical with that found in Morley's "Strength of Materials"), he offers the results of some very interesting tests. In tests on four phonograph springs, with the inner end wound on an arbor and the outer end attached to a barrel, the springs being greased with a mixture of castor oil and graphite, he found the difference between the work supplied to the spring and the work given up amounted to a maximum of 35 per cent and to a minimum of 13 per cent. Furthermore, he states that the lubricating mixture between the leaves has a thickness of 0.003 in.

Aside from the undesirability of having to use a lubricating compound, which in time may lose its properties, its presence demands space and thus results in a loss of efficiency. In a spring of 0.025 in. thickness, assuming it otherwise to be most favorably stressed, this loss in efficiency amounts to 12 per cent.

On the basis of Mr. Wadlow's experiments, therefore, it would seem that the highest efficiency of a spring, having its outer end attached to a barrel and the leaves greased with a lubricating compound, is only 75 per cent that of a spring mounted in the manner shown in Figs. 8, 9, or 11.

To attain the highest possible efficiency in a spiral spring, one more point needs consideration, namely, the attachment of the spring to the arbor.

In the development of the theory the author has used the expression $r = r_1 + nt$, which is correct for an Archimedean spiral. He has also used the expression, $L = \pi n(2r_1 + nt)$, which expresses the length of a tightly wound spring, considered as equivalent to a number of concentric circles. The latter expression, although never strictly true, does not introduce any appreciable errors. The advantage of designing a spring in the manner shown in Fig. 12 and of mounting it in agreement with Figs. 8, 9, or 11, lies in the fact that under these conditions the spring is uniformly stressed from end to end with no localized points being subjected to overstress. If a spiral spring is wound on a cylindrical arbor, a bump is created when the second leaf adjusts itself over the first leaf at the point of attachment. For a very short distance the spring will be understressed and for a short distance, adjacent to the understressed portion, the leaf will be overstressed. This condition will make itself felt in a lesser degree throughout the coils at points approximately on a radius passing through the point of attachment of the spring to the arbor. The spring must be designed so that at this point of overstress the stress shall be within the safe working stress. This would be highly inefficient, as the condition in a fraction of 1 per cent of the spring would be the limiting condition for the entire spring. The other alternative is so to construct the arbor that its circumference will describe an Archimedean spiral. It may be difficult to realize the latter suggestion. On the other hand, the efficiency gained thereby is very considerable.

ACKNOWLEDGMENTS

The author is indebted to John Wiley & Sons, Inc., for permission to quote from his book, "The Elastic Energy Theory;" to Mr. Olaf Ohlson, of the Waltham Watch Co., for the use of Fig. 7; to Mr. Zimmerli, of Barnes, Raymond, Gibson & Co., for material supplied for testing purposes; to Messrs. Edw. A. Clark, watch repairer, and W. M. Simmons, phonograph repairer, both of Ann Arbor, for practical information; and to his colleagues, Professors H. R. Lloyd and T. H. Hildebrandt, of the University of Michigan, for valuable suggestions and criticisms.

Discussion

M. F. Sayre.[3] Certain criticisms in matters of detail might well be made in connection with this paper.

As dealt with by the author, case III (*b*) is identical with case III (*a*), and it in turn is identical with case I. In case III (*c*) there is an inconsistency in the statement that point *B* is free to move on the line *BE*, while at the same time assuming a reaction at *B* in the direction *BE*. As this case has been actually handled, the reaction has been ignored, so making it identical with case II.

In case II, the statement is made that "in case point *A* is restrained in a horizontal direction as well as in a vertical direction, the horizontal component of the reaction at either *A* or *E* is zero, provided the spring may be considered as composed of a large number of concentric rings." The derivation is then continued on the basis of zero horizontal restraint. This would appear to be a case of placing the cart before the horse. As shown by the author himself later on, even minute horizontal restraint acts to change radically the shape of the spring. This whole derivation hinges, therefore, not on the absence of a horizontal reaction at *A*, but on the limitation of angular distortions to extremely small amounts. It would seem better, therefore, to start with a different initial assumption.

From a practical standpoint, the effect of frictional resistance within the coils is extremely important, and usually well safeguarded against, in a hairspring. In the usual power spring it is of very much less importance, since in the wound-up position of the spring, in which friction is largest, the spring will usually be developing considerably more power than is needed. Any losses of torque in the run-down position of the spring are undesirable, as they act to decrease the number of working turns; but at this stage, friction is more likely to result from rubbing between the spring and the case than between successive coils of the spring.

[3] Associate Professor of Applied Mechanics, Union College, Schenectady, N. Y. Mem. A.S.M.E.

Attention might well be directed to recent work of the A.S.M.E. Spring Committee, which has shown that stress distribution in fibers in a cold coiled power spring is likely to be very far from directly proportional to distance from the neutral axis. The differences are great enough to call for attention in any attempts at exact analysis.

J. S. A. JOHNSON.[4] The writer should like to have information regarding the behavior of a closely wound spiral spring when the end *A*, Fig. 1, is fixed and a load whose line of action is perpendicular to the plane of the coil (or parallel to its axis) is applied at the inner end *E*.

E. C. WADLOW.[5] The first part of the paper demonstrates the importance of a clear statement and understanding of the problem under discussion, and the discrepancies between the results obtained in the paper and those of other writers appear to have arisen out of the incomplete treatment previously given to the problem.

The use of spiral springs instead of helical springs subject to axial twist is no doubt due to practical advantages which the spiral spring possesses, quite apart from any question of efficiency as the medium for storing elastic energy. The length of the path traversed by the free end of a spiral spring is very considerable, and owing to the ease with which this type of spring is able to drive mechanisms through gearing, it is possible to utilize this great deflection while still retaining the spring within the confines of a barrel a few inches in diameter. The best way to appreciate the merits and conveniences of the spiral spring is to attempt to substitute for it a spring of another form.

No matter what system of anchoring and loading is employed, so far as gramophone motors are concerned, the final condition is a spring wound tight on the arbor. This is the form in which the stress in the material is highest, and for the most efficient use of the material the stress should be uniform throughout and the highest allowable. Since the shape of the spring when fully wound is determined almost entirely by geometrical considerations and not by considerations of stress due to end fixing, and since this is the time when maximum energy is stored in the spring, it follows that for gramophone springs which are wound tightly, the end connections do not play such an important part as in other types of spring which do not undergo such considerable changes in shape.

Since S, r, t, and E are known in the equation $\frac{1}{r} - \frac{1}{R} = \frac{2S}{Et}$ (which was incorrectly quoted in the article in *The Engineer* referred to by the author), this equation enables us to determine the radius of curvature of every point of the spring in the unstressed state in the manner shown in the paper.

In the example chosen to illustrate the use of the formula, the author arrives at double involute curves shown in Fig. 12. These curves are calculated on the assumption that the elastic limit for the material is 375,000 lb. per sq. in., but judged by the material used in this country for springs of the dimensions given, this stress is much too high. The material used for mainsprings of gramophone motors has an ultimate stress of about 240,000 to 300,000 lb. per sq. in. and an elastic limit of about 180,000 to 240,000 lb. per sq. in. The spring also is exceptionally long. Springs employed in this country for gramophone motors usually are not longer than 200 in.

To avoid unnecessarily high stresses where the spring is bent round the arbor, the ratio of arbor radius to spring thickness is also much greater than the value of 9 assumed.

[4] Professor of Applied Mechanics and Experimental Engineering, Virginia Polytechnic Institute, Blacksburg, Va. Mem. A.S.M.E.

[5] Hayes End, Middlesex, England.

When these values are employed, the double involute form shown in Fig. 12 of the paper is never necessary—and fortunately so, for the coiling of a spring to this form would be much more difficult and costly than the simple coiling at present used.

In practice, the involute form is never accurately obtained by the coiling, as indeed is to be expected.

As a result of these departures from the ideal form when free, the stress when fully wound is rarely the same all along the length

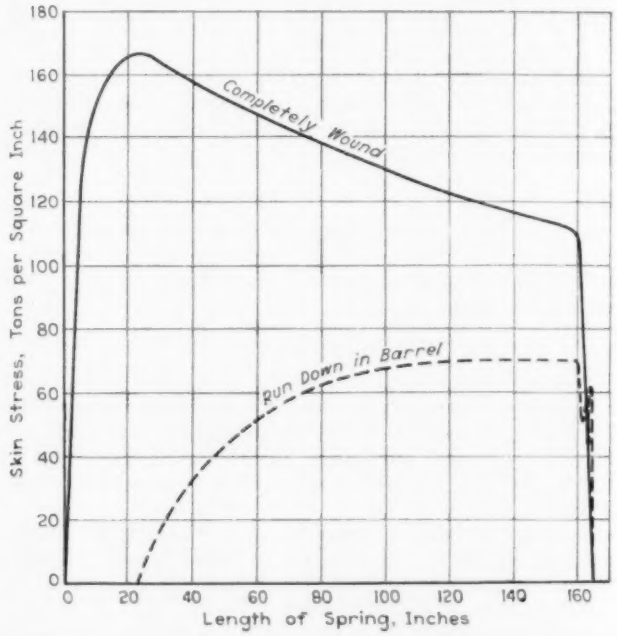

FIG. 13 CALCULATED SKIN STRESSES IN A GRAMOPHONE MOTOR SPRING

of the spring. Fig. 13 shows the calculated skin stress in a spring used in a portable gramophone motor, many thousands of which are giving a satisfactory performance. The stress when fully wound is very far from uniform, due to incorrect shape when free. It may also be observed that these calculated stresses are higher than the known breaking strength of the material, this resulting mainly through assuming that the material is perfectly elastic over the whole working range of stress shown. A certain amount of plastic deformation takes place in the most highly stressed layers every time the spring is wound up. This leads in time either to actual breakage of the spring or to sufficient permanent set to render the spring useless. Which of these happens, and the time elapsing before the failure, depend upon the properties of the material being used.

The initial deformation which takes place when a new spring is put into use is often considerable. Fig. 14 shows the results of measurements on two similar springs. The one was new, while the other had been in use for over a year. The change, however, usually takes place fairly quickly, and after a dozen winds is fairly stable. The condition that the spring must be able to withstand a number of winds without the number of coils, when free, increasing beyond a certain percentage, is sometimes included in a specification for spring material.

With regard to the lubrication of mainsprings the following figures may be of interest. They were obtained with a spring 176 in. long in a barrel $3^{11}/_{32}$ in. internal diameter with a sleeve $^{5}/_{8}$ in. in diameter. The spring was 0.022 in. thick and 1 in. wide.

The limiting conditions are shown in Fig. 15. The continuous line gives the torque when the spring was lubricated with a mix-

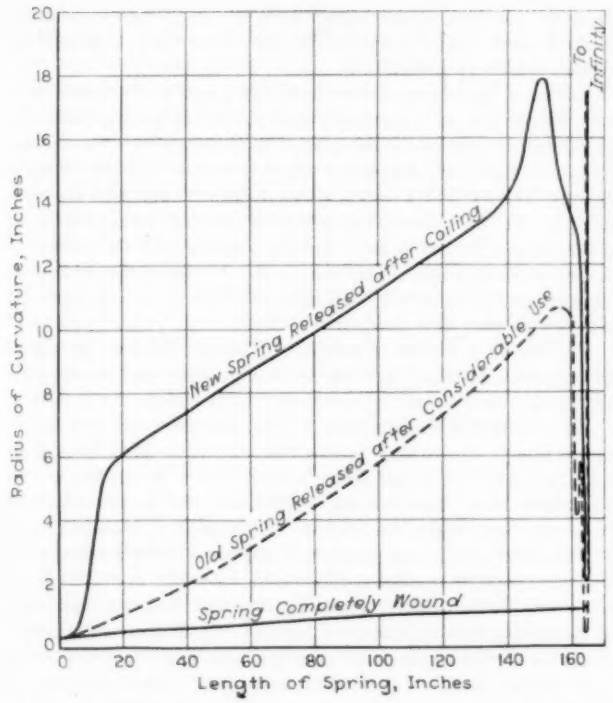

FIG. 14 RADII OF CURVATURE OF GRAMOPHONE MOTOR SPRINGS

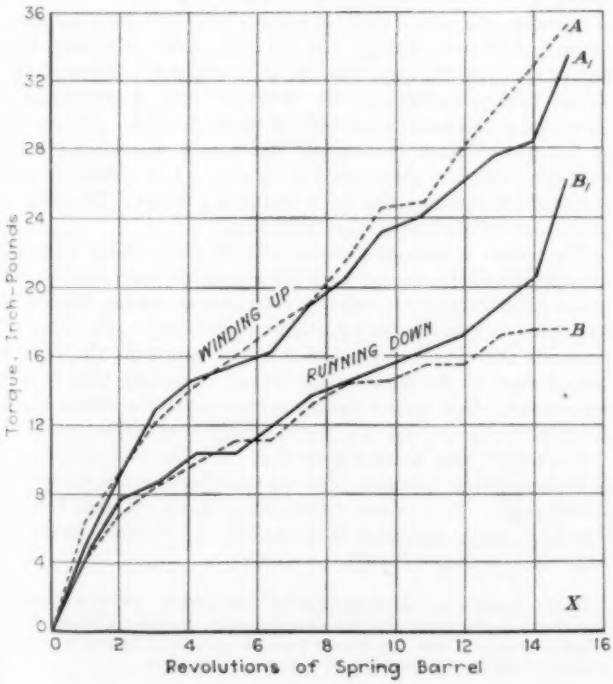

FIG. 15 TORQUE-ANGULAR DISPLACEMENT CURVES FOR SPIRAL SPRING

(Broken line, unlubricated; solid line, lubricated with castor oil and graphite.)

ture of castor oil and mineral graphite in approximately equal weights. The broken line shows the torque without any lubricant being present. The efficiencies on a number of cases were as follows, the efficiency being the ratio:

$$\frac{\text{Work recoverable while unwinding}}{\text{Work to wind}} = \frac{\text{Area } OBX}{\text{Area } OAX} = \frac{\text{Area } OB,X}{\text{Area } OA,X}$$

Lubricant	Efficiency, per cent
Castor oil and mineral graphite	70.4
Colloidal graphited castor oil	69.5
Mobiloil BB	68.6
Pure castor oil	66.1
No lubricant	61.2

These values are for single tests on the same spring carried out as nearly as possible under identical conditions.

With this design of spring and mounting, therefore, the increase in efficiency due to the lubricant more than outweighs the loss due to the space it occupies.

The conditions under which spiral springs have to perform in motors are particularly arduous. Few instances can be found where both the range of stress and the maximum stress are so great. This is possible, no doubt, because the allowable number of cycles of stress to cause failure is fairly small, being in the region of 30,000 to 50,000 cycles.

A. NÁDAI.[6] With reference to the principle of superposition employed in the paper and frequently in textbooks on strength of materials as one of the independent principles or assumptions on which the ordinary stress calculations are based, it seems to the writer that this principle could in many cases be considered merely as a consequence of *other* experimental and mathematical premises or fundamental assumptions also used in these computations, and on which certain parts of the theory of elasticity are ordinarily based: namely, that the three components of the displacement of a point in an elastic body are small (compared with the smallest dimension of the stressed body), and that stress and strain are connected by linear relations. As a consequence of these assumptions, differential equations are obtained which are linear, and therefore one solution or stress system can be added to another and the principle of superposition holds.

The superposition of particular integrals might sometimes even be applied when one of the displacement components starts to become greater; for example, when the plane elastic deflections of a slender straight steel strip clamped at one end and loaded by forces in one of its principal planes of inertia are considered at deflections which are *finite* and moderately large (for example, $^1/_{20}$ or $^1/_{10}$ of the span). The errors introduced by using the expressions $\epsilon_x = \frac{\partial u}{\partial x}, \ldots, \gamma_{xy} = \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}, \ldots$ where ϵ or γ are the unit strains, u, v, w the components of displacement and which are only valid for small values of u, v, w, might in such cases not be too serious, if one or the other of the components u, v, w becomes moderately larger. In other cases, however, of large deformation of beams (as in the case of the "Problem of Euler's Elastica"[7] or in the case of a beam with both ends rigidly clamped under moderately large deformations) these expressions cannot be used, or only in an infinitesimal region within the deflected beam; also in the case of the bending of flat, thin plates with moderately large deflections certain additional precautions have to be carefully considered, even if the deflections are still very small compared to the lateral dimensions of the plate.

One further important point might also be mentioned here, which has been clearly brought out by H. M. Westergaard.[8] There are cases in which, although stress and strain are still connected by linear equations and although the displacement components remain small, the deflections will not be linear func-

[6] Research Laboratories, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Mem. A.S.M.E.

[7] Cf. A. E. H. Love, "A Treatise on the Mathematical Theory of Elasticity," 4th edition, p. 401, Cambridge University Press.

[8] "Buckling of Elastic Structures," Proc. Am. Soc. C.E., vol. 47, no. 9, Nov. 1921, p. 455 (cf. especially p. 456.)

tions of the resultant forces under which they were produced. A well-known example is that of a beam bent by two equal axial loads acting eccentrically. In this case the greatest deflection of the beam is by no means proportional to the load, although the differential equation for the deflection is still a linear one. Further references to these and other similar points must be omitted here, as they are discussed clearly in detail in Westergaard's paper.[9] The writer thinks, therefore, that the statement: "The current theory of spiral springs appears to be one more case in which practice and theory disagree—with practice carrying off the honors," made by the author, may be a slightly exaggerated expression of the true conditions. The usual assumptions made in this special theory and in other parts of the mathematical theory of elasticity have often been verified for elastically isotropic materials such as steel by test. What is here important is that they have their definite limits of application as do all theories in physics. If this is borne in mind, if some errors apparently made in the boundary conditions in certain former computations on spiral springs as quoted by Professor Van den Broek are corrected, and if the conditions which define the limits for each assumption of the theory are carefully taken into consideration, no serious disagreement between "theory" and "practice" should remain.

In the second equation on page 2 of the paper and in the text below it, it would seem desirable to use for a displacement component not a capital letter and especially not the letter E_y, as E should be reserved for Young's modulus, which appears in the same equation.

It was instructive for the writer to see from one of the experimental demonstrations of Professor Van den Broek that the first winding of the spiral was mainly distorted, but the other windings remained practically circular. It would seem that this fact might be utilized for a more exact theory of the deformations of the spiral, including also large displacements in certain parts of the spring. How far Castigliano's theorem will still be valid in such a case of bending of a flat steel strip with parts of it having large lateral displacements seems to be a question which apparently has not yet been answered.

Author's Closure

The conclusions of the paper are to the effect that, except for friction between the coils, the principle of superposition holds and that the same theory and its resulting formulas are applicable throughout the entire loading range of spiral springs regardless of their condition of mounting.

Professor Sayre appears to argue that since the various cases in the last analysis are identical, they need not have been discussed. In the application of the theory of strength of materials we very often find that the principle of superposition is assumed without first verifying its applicability. Further, the analysis of structures involving material changes in dimensions while being loaded very rarely comes under discussion. In view of this the author considered it a necessary part of a rigorous proof to trace such changes of dimensions and loadings in detail.

In the preprint of the paper, in the middle of the fifth page left column, there appeared a typographical error; "case III (*a*)" was incorrectly printed as "case III (*b*)." Professor Sayre is correct in his claim that except for the shifting of the x-y coordinate system as the spring is loaded, case III (*b*) is the same as case III (*a*).

However, the author cannot agree with Professor Sayre when he charges that an inconsistency obtains in case III (*c*), (Fig. 4). True, Fig. 4 shows an upward force Q at B. Another downward force Q, however, is also shown at point A. Thus there is no vertical reaction at E, and point E is free to move in a vertical direction relatively to point B.

Professor Sayre's quotation from the paper with reference to his criticism of case II is correct, but entirely misleading when the paragraph in question is not quoted in its entirety. The author makes reference to a discussion which occurs in his book, "Elastic Energy Theory," of a spiral spring with its outer-end pin connected. In the present argument he omitted consideration of this case and instead chose to discuss a spring with the outer end A unrestrained in the direction A-E. If the outer end A is unrestrained in direction A-E, how can there be any component reaction in that direction?

The author is unable to enlighten Professor Johnson in regard to spiral springs fixed at their outer extremity and loaded concentrically with a force perpendicular to the plane of the spring.

Mr. Wadlow's contribution to the discussion is very much appreciated. He evidently has had extensive experience with spiral springs. It is not clear, however, how he arrives at the conclusion that, "the increase in efficiency due to the lubricant more than outweighs the loss due to the space it occupies."

The difference in percentages of efficiency between the best-lubricated spring and the unlubricated one taken from Mr. Wadlow's table is the difference between 70.4 and 61.2, or 9.2 per cent. If (according to Mr. Wadlow's paper in *The Engineer*) the space provided for the oil, amounting to 0.003 in., were filled with steel, there would be 3/22 more steel used, and thus an increase in power of $^3/_{22}$ of 61.2 or 8.35 per cent would be obtained. Even considering that there would be no deterioration of the lubricant with the passing of time, the lubricating of springs, though mounted in the old way, appears to have little to recommend it.

However, the author does not want to appear to be contending for more friction in springs. In the light of Mr. Wadlow's own curves (Fig. 15) showing the loss of energy due to friction, the author fails to understand Mr. Wadlow's lack of interest in a mounting which would practically eliminate friction. The spring in the motor-driven phonograph has a way of releasing itself suddenly while the phonograph is playing. This sudden release is invariably accompanied by a disturbing sound. This objection is met by the elimination of friction.

The author is inclined to agree with Professor Sayre when he asserts that in the wound state the spring has such an excess of power that, except for resulting intermittent action, friction is less objectionable than in a partially wound state. Mr. Wadlow contends that the energy stored in the spring in the tightly wound state is the determining factor. Granting this, it still remains true that in this tightly wound state, the spring being mounted in the old way, the stored energy is not all available.

The author very much regrets that Prof. Dr. Ing. Otto Föppl of Braunschweig, Germany, did not contribute to the discussion of this paper. In a review of the author's book, "Elastic Energy Theory," which appeared in *Zeitschrift des Vereines deutscher Ingenieure*, of July 11, 1931, he wrote:

> In the chapter on spiral springs he (the author) raises legitimate objections to the corresponding discussions in the older editions of A. Föppl's book. These objections have in part been taken into consideration in the last edition of Vol. 3 of this book.

By his reference, "the last edition," Föppl has in mind the book entitled, "Festigkeits Lehre von August und Otto Föppl," 1927. This is that celebrated book by the late August Föppl, the father, revised by Otto Föppl, the son.

In discussing the "principle of superposition," Dr. Nádai appears to interpret this principle as implying that the deformations are of a small order of magnitude relative to the smallest cross-section dimension of the structure. Has Dr. Nádai failed to

[9] With regard to these questions, compare also the corresponding chapters in Love's "Elasticity" quoted above, and S. Timoshenko's "Strength of Materials," 1930.

observe, what appears to the author one of the points of interest in his paper, that relatively very large deformations are taken into account without violating the principle of superposition? The case of the spiral spring is the only one within the author's experience in which this condition prevails. It may be true that relatively small deformations are generally a sufficient test for the applicability of the principle of superposition except in case of columns or examples supplied by Mr. Westergaard and referred to by Dr. Nádai. The author considers it as one of the points of interest of his analysis of spiral springs that it provides a clear illustration of an example in which the principle of superposition holds in spite of very large deformations. It thus provides an argument against a too ready conclusion that small deformations are a necessary and sufficient test of the applicability of the principle of superposition. It is not clear how, in the face of this evidence, Dr. Nádai still advances the requirement of small deformation as a necessary test of the linear relationship between stress and strain.

Dr. Nádai says that "the statement, 'the current theory of spiral springs appears to be one more case in which practice and theory disagree—with practice carrying off the honors,' made by the author of the paper, may be a slightly exaggerated expression of the true conditions." The author called attention to a disagreement between his own and August Föppl's conclusions, the difference amounting to several hundred per cent, and pointed out that his conclusions differed from those of Timoshenko by 100 per cent. As mentioned earlier in this closure, Otto Föppl, son of the late August Föppl, acknowledges the correctness of the author's conclusions. It is very much regretted that Dr. Timoshenko did not express his views on the merits of the author's contentions. If Dr. Nádai is of the opinion that the formulas quoted in the paper from other books correctly represent the elastic behavior of spiral springs, then why does he not defend them? If he believes they are incorrect and the author's conclusions correct, how then can he speak of an "exaggerated expression?"

As to Dr. Nádai's question relative to the applicability of Castigliano's theorem, it would appear that the answer is quite simple. Certainly, in cases involving friction between the leaves, no theorem based on the assumption of perfect elastic behavior can be considered as valid. In case 1, page 2, column 1, the energy due to bending is given as $W = \frac{M^2}{2}\frac{L}{EI}$. Thus $\frac{dW}{dM} = \frac{ML}{EI}$, which, by formula [3], page 2, column 2, is equal to θ. Thus the derivative of the energy due to bending with respect to M gives the angular displacement θ of the spring at the point of application of M. This is in perfect agreement with Castigliano's theorem, and independent of the degree of the deformation involved—provided the assumption of the existence of a relatively large number of concentric coils is satisfied.

Dr. Nádai further says, "If some errors apparently made in the boundary conditions in certain former computations on spiral springs as quoted by Professor Van den Broek are corrected, and if the conditions which define the limits for each assumption of the theory are carefully taken into consideration, no serious disagreement between 'theory' and 'practice' should remain." The author was naive enough to think he had done exactly that.

FSP-53-1

Stokers and Furnaces for New England Fuels

By R. A. FORESMAN[1] and DONALD J. MOSSHART,[2] PHILADELPHIA, PA.

In this paper the authors describe and analyze some of the troubles encountered in stoker installations and discuss the principal factors to be considered in making a successful stoker installation. The discussion is limited to those problems found in New England, where the fuel used creates problems peculiarly local. The principal fuel of New England is a semi-bituminous coal, known to the trade as Pocahontas and New River coal. Among the points discussed are, selection of type and size of stoker, preheated air, furnace volume, furnace walls, ash-disposal apparatus, waste fuel, operating methods, banking, boiler operation, and recent stoker installations. Many of the points discussed receive recognition in the majority of plants, but relatively few plants recognize them all. The authors bring these practical matters together in one group.

EVERY new boiler room is a potential trouble job. The various installations differ only in a degree governed by the design of the equipment, the fuel to be burned, and the manner in which the equipment is applied.

These statements concern both stoker and pulverized-fuel installations. The authors will make no attempt to compare stokers with pulverized-fuel equipment. Such comparison is better made by those who operate comparable installations of both classes of equipment. That such comparisons are being made is indicated by the continuously increasing sale of stokers and their repeated encroachment into the plants of users who have been, until recently, stanch supporters of pulverized fuel. The reason for the increasing favor accorded to stokers is that their troubles and advantages combine and react to produce steam more cheaply than the combined and reacting troubles and advantages of pulverized-fuel installations.

In this paper the authors will attempt to describe and analyze some of the troubles encountered in stoker installations and to discuss the principal factors to be considered in making a successful stoker installation. The discussion will be limited to those problems found in New England, where the fuel supply, which differs from that of other sections of the country, creates problems peculiarly local.

The principal fuel of New England is semi-bituminous coal, known to the trade as Pocahontas and New River coal. This fuel is used almost exclusively, for several reasons:

(*a*) It has a very high heat value
(*b*) The freight charges on coal delivered to New England are quite high, necessitating the purchase of coal of a high heat value, to keep the freight charges per B.t.u. as low as possible
(*c*) This coal can be safely stored in large quantities and for long periods of time, with a minimum of danger from spontaneous combustion
(*d*) Its low ash content reduces the charges for ash handling
(*e*) It is nearly smokeless, a quality desirable in those plants using hand firing or the less highly developed stokers.

In many respects Pocahontas and New River coal are highly prized for stoker use. They are more difficult to handle than the so-called "low grade" coals, when such factors as stoker maintenance, capacity, and flexibility are considered.

Some small quantities of waste fuels are available. The use of these fuels will be mentioned, but only in reference to burning them simultaneously with semi-bituminous coal.

It is a generally accepted fact that the multiple-retort underfeed stoker is the best stoker for semi-bituminous coal. This type of stoker has enjoyed wide popularity for many years, and has produced operating results of the highest order. The discussion will be confined to this type of stoker.

Selection of Stoker Size

The load requirements should be carefully estimated so that the proper size of stoker can be selected. Overloaded stokers are poor investments because of poor performance. Underloaded stokers are poor investments because money is unnecessarily tied up in them. The size of stoker to be selected is governed by:

(*a*) The amount and character of the load on the boiler unit
(*b*) The cost of coal and the evaluation of efficiency
(*c*) The capabilities of the stoker.

The limit of the capacity of the stoker is reached when the fuel bed is blown off the grates. This is a function of the velocity of air through the fuel bed, which, with a given percentage of excess air, is directly proportional to the combustion rate.

It is known from physical law that the force of impact of a current of fluid against a stationary object is proportional to the square of its velocity. Therefore, as the combustion rate increases, it might be expected that the lifting effect of the air current on the fuel bed would increase as the square of the combustion rate, with a consequent sudden and complete blowing of the fire from the stoker. However, certain changes take place in the character of the fuel bed, so that the actual area of air passage through the fuel is larger at the higher rates. A compensating reduction in actual velocity through the air passages somewhat modifies the expected action.

Stokers are rated with their 24-hour and 4-hour or 2-hour capacity. The 24-hour capacity is that combustion rate just short of where the ash-discharge section is smothered with fine coke blown from the fire or where the blowing is so severe that the fuel bed cannot be maintained in proper condition over a long period of time. The limits of capacity for the shorter periods are of the same nature, the more severe blowing at the maximum rates simply putting the fire out of condition more quickly and limiting the length of time that a given load can be carried.

In the past, stoker capacity has been measured in pounds of coal burned per square foot of grate surface.

The amount of air required to burn a pound of coal is a function of the combustible content of the coal, and therefore of the heat content of the coal. In other words, the factor which limits

[1] Chief Engineer, Stoker Department, Westinghouse Elec. & Mfg. Co. Mem. A.S.M.E.
[2] Assistant Chief Engineer, Westinghouse Elec. & Mfg. Co. Assoc-Mem. A.S.M.E.

Presented at a meeting May 15, 1929, under the auspices of the Boston Local Section of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

the capacity (the velocity of air through the fuel bed) is a function of the amount of heat being released per unit area and time, rather than of the weight of coal being burned per unit area and time.

This is an important consideration when comparing performance with different coals. The stoker which burns Illinois coal of 10,000 B.t.u. at a maximum rate of 80 lb. per sq. ft. could be expected to fail to burn New River coal of 14,000 B.t.u. at rates above 57 lb. per sq. ft. This comparison is based on equal heat-liberating rates.

New River or Pocahontas coal is relatively hard to ignite. Therefore, more of the grate area is inactive with these coals. Equally proficient stokers will be capable of a slightly lower heat-liberating rate when burning such coals than when burning high-volatile coals.

The conclusion is therefore that stoker tests should be compared on a basis of heat-liberating rate with similar coals.

Fig. 1 shows the characteristic performance of underfeed

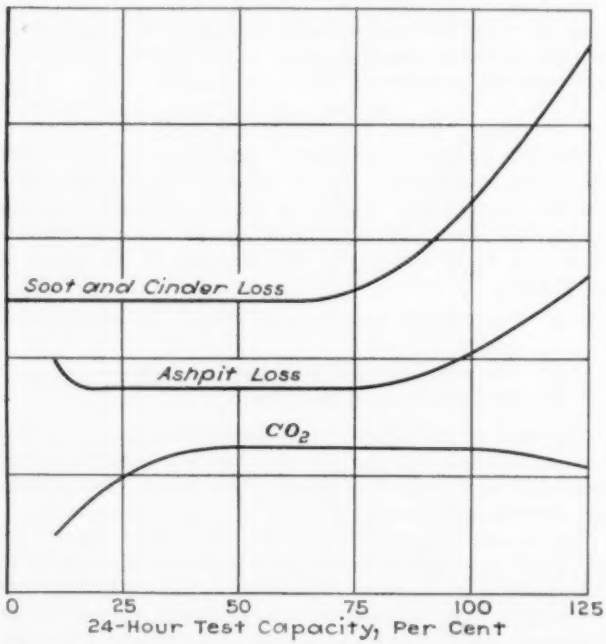

Fig. 1 Characteristic Performance of Underfeed Stokers

stokers. The abscissas represent percentages of the load that can be carried for 24 hours under test conditions. The ordinates are the three factors in the efficiency of the unit over which the stoker exercises control. Definite values are not assigned, but the different ordinates are of a similar scale of value in per cent overall efficiency of the unit.

Fig. 2 shows the typical load curves of three classes of industries. On these graphs the blocked figures show the load on the stoker (expressed in per cent of the 24-hour test capacity) for greatest dollar economy, considering investment cost, maintenance, and thermal efficiency, under average conditions. Analysis of local conditions, with particular regard to coal cost, may slightly modify these figures.

Knowing the capabilities of the stoker, the efficiency of the boiler unit, and the load conditions, the selection of the size of the stoker becomes a matter of arithmetic.

Selection of Type of Stoker

In this section there is covered the choice between clinker grinders and dump grates.

Where the plant carries a fairly heavy load 24 hours per day, a clinker-grinder stoker will ordinarily produce about 2 per cent more in efficiency than a dump-grate stoker.

For the load shown at *A*, Fig. 2, dump grates are the most economical, if the stoker is less than about 14 ft. long. Above

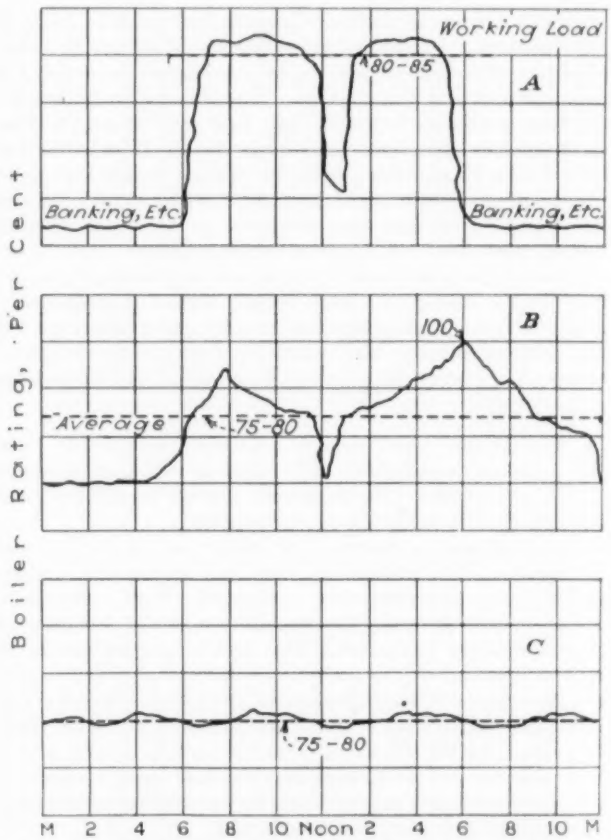

Fig. 2 Typical Load Curves of Three Classes of Industry (*A*, daily boiler-load curve, usual industrial plant; *B*, daily boiler-load curve, typical central station; *C*, daily boiler-load curve, base central station or industrial plant, as paper mill, using process steam continuously.)

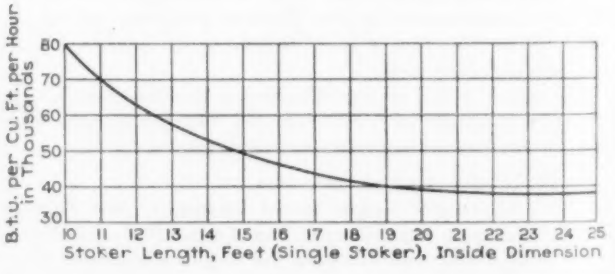

Fig. 3 Values of Heat Release With Different Lengths of Stokers

that length, clinker grinders should be used because of the large amount of ash to be handled per unit of stoker width. When using stokers of short or moderate length for such loads, the refuse is dumped during light loads or banked periods, and the performance closely approximates that obtained from clinker grinders under similar conditions.

For the loads shown at *B* and *C*, Fig. 2, clinker grinders should be used for all lengths of stoker, wherever space permits. If space limitations, particularly headroom prohibit the installation of clinker grinders, dump grates may be installed with the assur-

ance that they will give good results on any length of stoker yet developed.

Preheated Air

Preheated air has been in general commercial use for about four years. Extensive study during this time, of the problems created and of the results obtained by the use of preheated air, has permitted the following general conclusions to be drawn:

(1) Improvement in combustion, expected by the sponsors

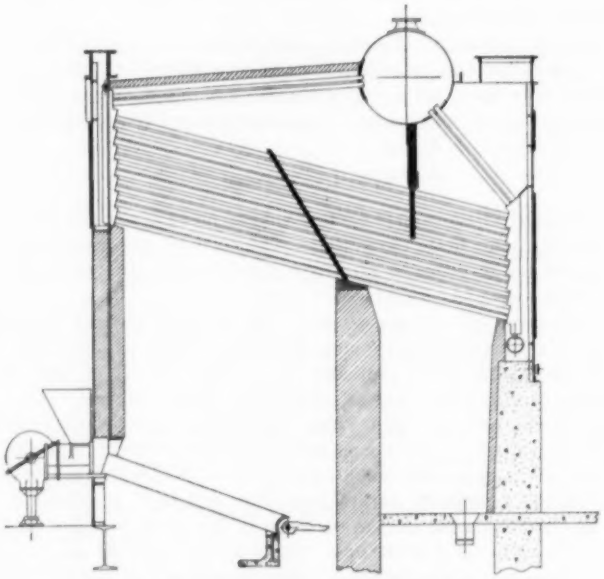

Fig. 4 Dead Areas in the Furnace Space

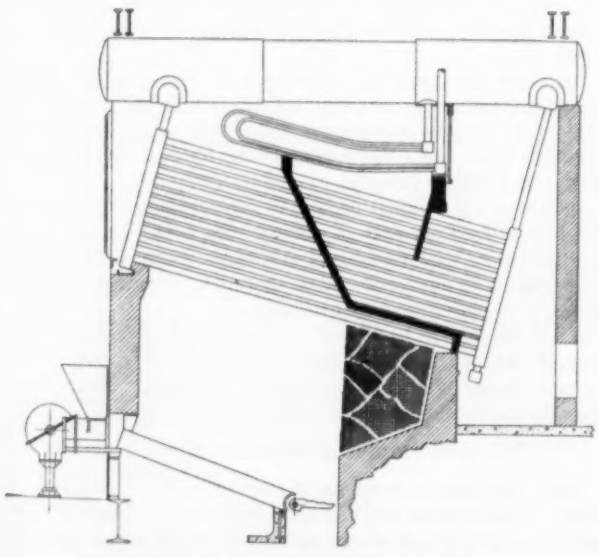

Fig. 5 Dead Areas in the Furnace Space

of preheated air and reported as being obtained by some users, has not materialized. Some changes do take place, but the beneficial effects, if any, can be duplicated with cold air by proper adjustment of the stoker.

(2) Preheated air does not measurably increase the capacity of the unit. The increased velocity of air through the fuel bed, caused by the greater specific volume of the heated air, increases the blowing of fuel and slightly reduces the coal-burning capacity of the stoker. A good rule for commercial practice is to figure a unit of grate area as having a fixed capacity in B.t.u. per hour, the amount of heat admitted to the furnace being

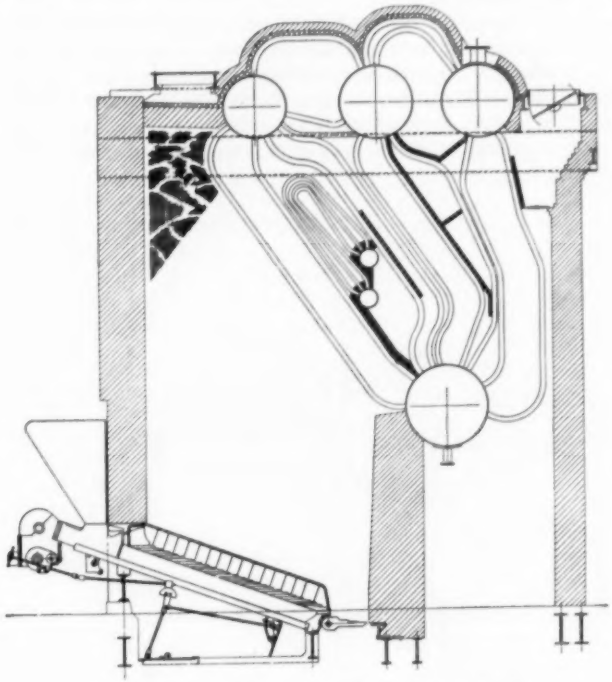

Fig. 6 Dead Areas in the Furnace Space

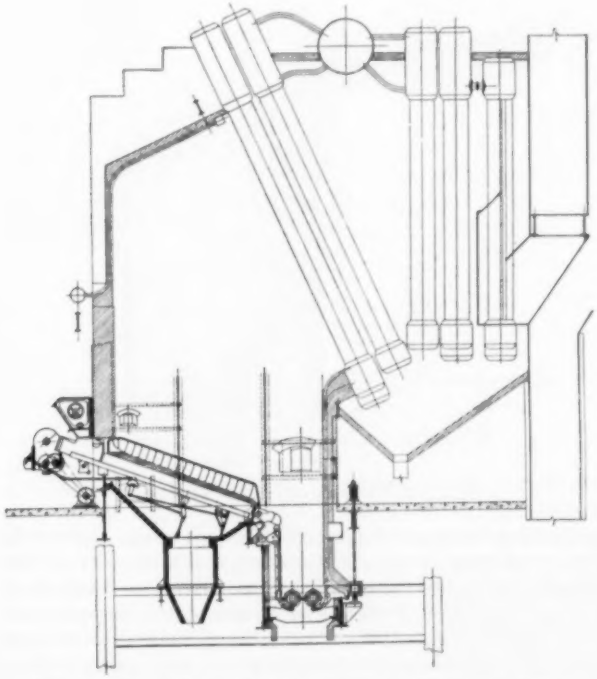

Fig. 7 Water-Wall Arrangement to Decrease Slag

the same whether or not the air is preheated. In the case of cold air, the heat released by combustion is the capacity. In the case of preheated air, the heat released by combustion plus the heat returned by the air is the capacity. In either case the total heat admitted to the furnace would be the same, but

with preheated air the amount of coal burned would be less by the coal equivalent of the heat in the air. This rule is not intended as a statement based on tests; it is for the commercial selection of stoker size.

(3) Preheated air does not measurably increase the efficiency of combustion. It may slightly decrease the ashpit loss, but this is offset by the increased loss in soot or fine carbon carried up the stack. The only value of preheated air lies in the amount of heat recovered and returned to the boiler.

(4) It is more difficult to operate an underfeed stoker with

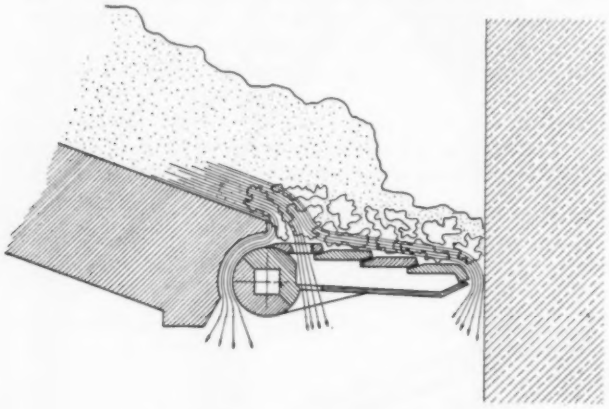

FIG. 8 DOWNWARD FLOW OF AIR

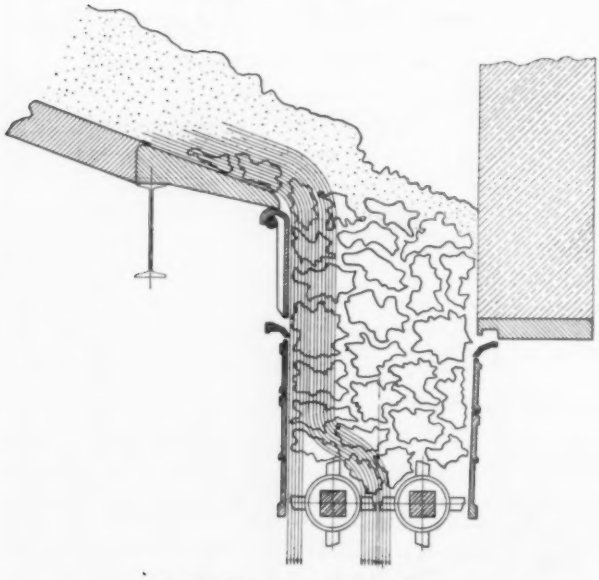

FIG. 9 DOWNWARD FLOW OF AIR

preheated air than with cold air. If the fuel in the retort swells slightly and tends to stick in the retort, as it may easily do with preheated air, any of the various designs of retort mechanisms yet produced lose part of their effectiveness in moving the coal. Readjustment of the motion of secondary pushers or other retort mechanism must be made to compensate for such conditions, and when the conditions disappear, further readjustment becomes necessary. Therefore the amount of operating attention required is considerably increased, particularly where a long retort is used. The longer the retort, the greater becomes the problem of handling fuel mechanically. Some manufacturers have limited the length of the retort and are applying a different type of grate surface to complete the stoker to the desired length.

(5) Present-day knowledge limits air temperatures to 350 deg. fahr. for satisfactory operation of a stoker of average length—that is, a stoker with retorts 9 or 10 ft. long, with semi-bituminous coal. It probably will be necessary to make rather radical changes in the basic method of handling fuel if this limit is to be raised.

(6) There is bound to be some increase of stoker-maintenance costs when preheated air is used. Present-day knowledge indicates that this increase is small and of lesser magnitude than the variation in costs between different plants operating under very similar conditions.

The economics of the local plant layout, the load factor of the plant, and the price of fuel must be evaluated to determine if the heat recovered by the preheater will pay adequate return on the required investment. Such matters are beyond the scope of this paper.

FURNACE VOLUME

The part that adequate furnace volume plays in efficient operation has long been recognized. The authors are mentioning the subject in order to present a more specific analysis of the problems than usually is made.

A number of variant values of the permissible heat release per cubic foot of furnace volume have been advanced. The authors recently assembled for analysis a large number of tests of stoker-fired boilers. It was found that, while the short stokers produced excellent results with surprisingly high heat release per unit of volume, the longer stokers suffered losses from incomplete combustion when operated with the same high heat releases.

This is a perfectly natural condition and is to be expected. The operator is less able to see flaws in the fire of a long stoker than in that of a short one. Areas of fuel bed of too great thickness may go undetected. The control of fuel distribution over a long stoker is less readily obtained than on a short stoker. All these factors render it necessary to increase the furnace volume in order to balance and compensate for imperfections in the fire.

Fig. 3 shows a graph of values of heat release per cubic foot of furnace volume for maximum efficiency with different lengths of stokers. Greater heat-release values may be employed where available space limits the volume of the furnace, but a lowered efficiency should be expected.

In comparing different designs of furnaces and in calculating the heat release per unit of volume, due consideration should be given to the relative value of different sections of the furnace. It is possible to put much useless space into a furnace and show a deceptively low rate of heat release.

If a boiler furnace be laid out with enough of the boiler surface to show the first baffle, one can readily detect dead areas in the furnace space. Figs. 4, 5, and 6 are examples. Heat-release rates should be compared on a basis of useful volume.

FURNACE WALLS

Much has been claimed for the use of water-cooled furnace walls. These claims have included reduction of furnace maintenance, reduction of stoker maintenance, increased heat absorption with consequent lower flue-gas temperatures, reduction of clinker trouble, reduction of radiation losses, and increase of stoker capacity. The authors have not seen conclusive and authoritative figures which place definite values on these various claims. Observation of various water-wall applications prompts the following statements:

(1) Water walls are a valuable aid to the stoker when they provide a clinker-proof wall at the edges of the fuel bed. Aside from this, they are of no value to the stoker burning semi-bituminous coal.

(2) The rear wall of the furnace should receive first consideration in the application of water walls. Insurance against freezing-over of the ash-discharge section is the most valuable function that a water wall can perform. Should more extended use of walls be justified, they should be installed so as to clinker-proof the sides of the stokers. The authors see no justification for the use of a water-cooled front wall.

(3) Semi-bituminous coal burns best if the furnace temperature is high. Low furnace temperatures tend to increase losses from incomplete combustion of gases and unburned solid particles of fuel carried up the stack. A true measure of this effect has not yet been made available, but there is ample evidence that the tendency exists. Naturally, such effects can be offset by increasing the furnace volume. The authors do not believe that there is any justification for the statement that water-cooled furnace walls permit an increase of the rate of heat liberation per unit of furnace volume; rather that the reverse is true.

(4) For present-day practice, therefore, in the opinion of the authors, water walls should be designed and applied in a manner that will not unduly lower the temperature of the furnace.

(5) Some users have found that the use of water walls, particularly in applications where the furnace temperature was materially lowered, resulted in decreasing the amount of slag deposited on the lower tubes of the boiler. The authors believe that it is quite possible to do this without seriously affecting combustion, particularly by arranging the water walls so that they exert a maximum cooling effect on the space just below the boiler and a minimum effect on the space just above the fire. Fig. 7 shows such an application at the plant of the New Haven Pulp and Board Company.

Ash-Disposal Apparatus

The authors will not attempt to compare the advantages of the various methods of disposing of the refuse, such as car haulage, sluicing, the use of chain or belt conveyors, or steam jets. Any method can be satisfactory so far as the stoker is concerned. There is only one requirement, and that is that the ashpit below the stoker must be effectively sealed to hold internal pressure at all times, except for the brief interval necessary for removal of the refuse.

If the ashpit is not sealed, there frequently may be a downward flow of air from the lower end of the stoker through the dump grates or clinker grinder, as shown by Figs. 8 and 9. In its passage the air may burn enough fuel to raise itself to a temperature high enough to destroy the parts of the ash-discharge section. Many cases of high maintenance of dump grates or clinker grinders have been traced to this cause.

Proper sealing of the ashpit, confining the air and gas until a slight pressure builds up in the ashpit, stops this action.

Practically all manufacturers of ashpit gates, sluicing systems, etc., are now building such apparatus in a manner that provides satisfactory sealing.

Waste Fuel

Many plants find themselves in possession of quantities of waste fuels, such as pulpwood bark, sawdust, scrap wood, domestic-size coke, coke breeze, anthracite waste, etc. Generally the available amount of such fuel is not sufficient to pay a good return on the investment in a separate boiler and furnace designed especially for its utilization. Such fuels can be burned quite efficiently and economically with an underfeed stoker.

If the fuel is of a fibrous nature, liable to clog the rams, it can be burned by dropping it on top of the fuel bed, through chutes in the front wall. Such a scheme will work well with hogged wood refuse or similar material.

Fig. 10 shows such an installation at a new plant in the South. In making such an application the following should be observed:

(1) The chutes in the front wall should center on equal portions of the stoker width. They should be located from 7 to 10 ft. above the grate surface and should be spaced not more than 7 ft. apart. Such precautions are necessary to assure fairly even distribution of waste fuel over the stoker fire.

(2) Provision should be made to admit the waste fuel into the furnace as nearly continuously as possible, so that uniform combustion conditions can be maintained. Blowing the fuel into the furnace with a current of air is unsatisfactory, unless

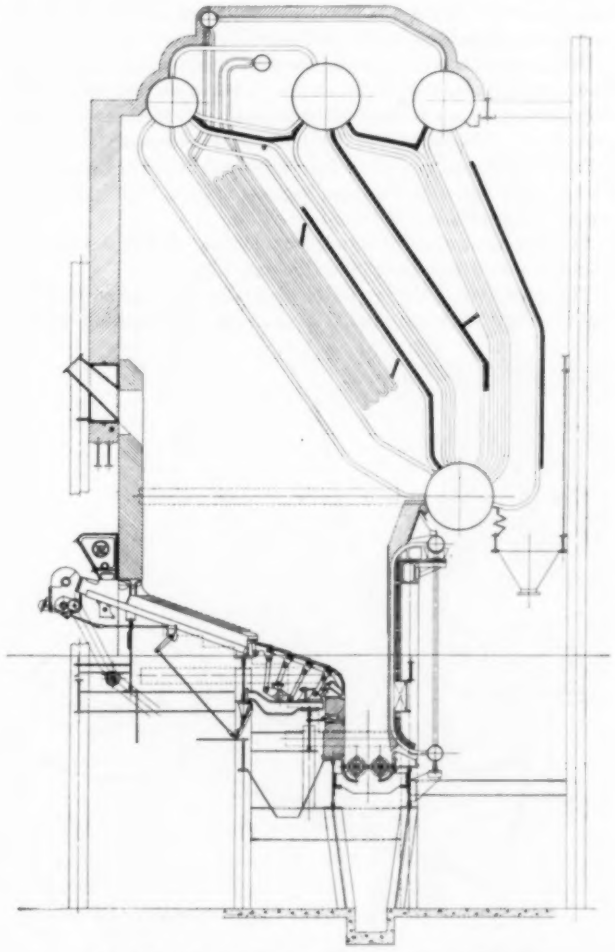

Fig. 10 Design for Burning Waste Fuels

the fuel is actually pulverized. Even very small chips of wood will drop to the bottom of the furnace, leaving the conveying air current to pass upward from the chutes as useless excess air. The better method of supplying the fuel is to have some sort of feeder, such as a paddlewheel, which drops the fuel into the chute at a controllable rate, relying on gravity to feed the fuel through the chute. By maintaining proper draft conditions in the furnace, the amount of air infiltration through the open chute can be made negligible.

(3) The chute should be divergent; it should increase in area as it approaches the furnace, in order to prevent clogging. It is preferable to water-cool the edges of the chutes next to the furnace. The amount of heat thus absorbed can be made so small that the cooling water can be discharged to waste without undue loss.

(4) Generally speaking, provision should be made for the injection of considerable quantities of free air over the fuel bed, under the control of the operator. This is particularly necessary if the waste fuel contains resin, oil, or similar substances.

If the waste fuel is granular or brittle in character, as coke breeze, anthracite waste, etc., it is burned to best advantage when mixed with the coal.

Such mixtures are hard to make and maintain in the bunkers. Coke, particularly, has a pronounced tendency to separate from the coal, so that the stoker receives alternate batches of coal and coke from a bunker mixture.

Figure 11 shows a mixing device which has been quite successfully used. In this device, the stoker ram feeds, with each charge, definite amounts each of coal and other fuel.

The hopper is divided, above the ram, into two compartments. The compartments are separated by a movable partition. The front compartment is supplied with coal, and the rear one with other fuel. The position of the partition determines the relative proportions of coal and other fuel which will be fed in by the ram. By the time the retort mechanism has fed the fuel up into the fire, the two fuels are well mixed.

The ram is always surrounded by coal, so that it is protected from the abrasive action of such fuels as coke.

The capacity of the unit will generally be reduced if waste fuel is mixed with the coal. By making the partition quickly

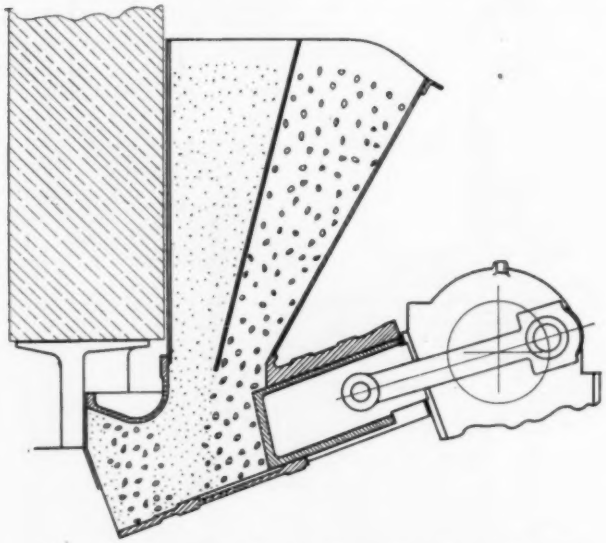

FIG. 11 DEVICE FOR MIXING COAL WITH OTHER FUEL

adjustable, the peak capacity of the stoker can be retained. The waste fuel can be cut off and the stoker operated on coal alone during the periods of heavy load.

OPERATING METHODS

STOKER REGULATION. A few simple rules for the best operation of underfeed stokers should be used as a basis for organizing and training the boiler-room personnel. They are:

(1) The rate of coal feed should be proportional to the rate of burning, so that uniform combustion conditions are maintained. The operator should be provided with some sort of fuel meter which he can compare and correlate with the steam-flow meter. This may be a table of speeds for different stoker motor controller points, an indicating device operated by the stoker engine or stoker turbine governor, or some form of tachometer. Any automatic controls of stoker speed should be frequently and carefully checked to assure that they maintain this relation.

(2) The stoker should be protected from the heat of the fuel bed by a layer of ash. This condition is sometimes hard to maintain with New England fuels, because of their low ash content, so that stoker maintenance is sometimes higher in New England plants than elsewhere. The operators should be trained

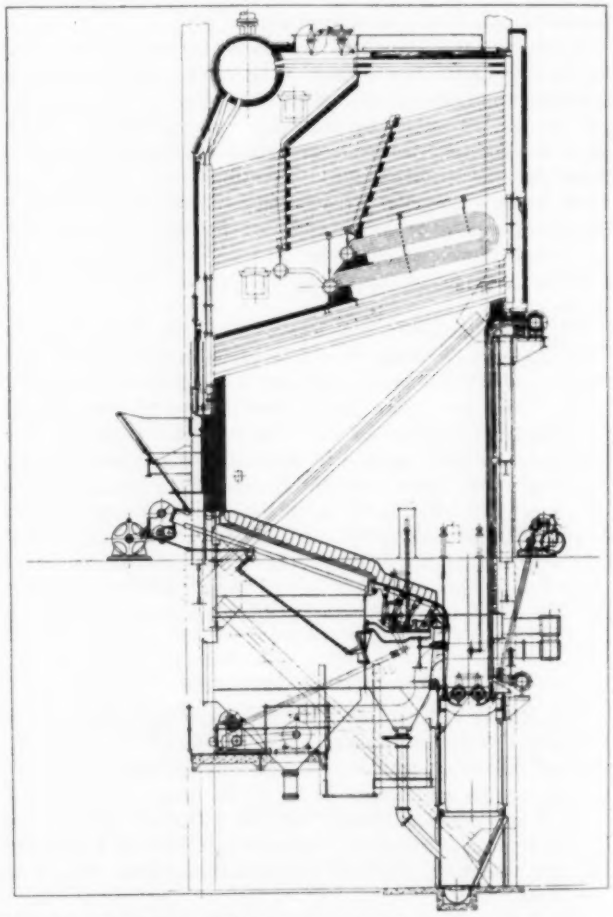

FIG. 12 STOKERS IN HUDSON AVENUE STATION OF BROOKLYN EDISON COMPANY

to watch this factor, and it is not improbable that the majority of supervisors could well give the matter study.

The principal things to watch are:

(*a*) With clinker grinder stokers, keep the level of the refuse in the pit at a sufficient height to hold an adequate layer of ash on the lower end of the stoker

(*b*) With dump-grate stokers, care should be exercised that the fire be moved back not too rapidly after dumping the refuse. If the refuse on the lower end of the stoker is suddenly shoved over to the dump grate, the lower end of the stoker and the dump grates themselves may be unduly exposed to the hot fuel, with resultant burning of parts.

(3) The underfeed stoker is essentially a machine for producing complete combustion of the fuel in all parts of the furnace. In other words, there should not be a stratum of gas over one section of the stoker containing an excessively high percentage of CO_2 and some CO, and another stratum over another section containing an excessively high percentage of oxygen. Losses from both incomplete combustion and excess air occur under this condition. Also the section of stoker having too little excess

air may be overheated. The distribution of fuel over the grate area should be such that combustion conditions are substantially the same in all parts of the furnace, except over the ash-discharge section.

Banking

It has long been a custom, accepted as being best practice, to bank boilers when the load drops below a certain point, say 100 per cent of rating, leaving other boilers to operate at higher loads.

Some years ago this was probably the best thing to do, because there were no instruments in the boiler room to guide the fireman. The only way to make him fire properly was to throw a heavy

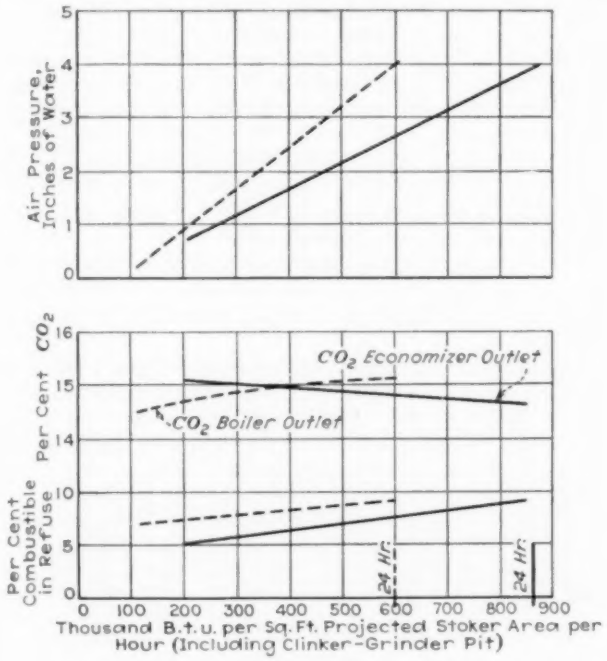

Fig. 13 Comparison of 1928 and 1923 Designs
(Broken line, 1923 design; solid line, 1928 design.)

load on his boiler so that he had to have a good fire to hold the steam pressure.

Basically and practically, this system is wrong. Modern stokers are capable of operation over a range in load of 6 or 7 to 1, with substantially the same combustion efficiency at all loads. Instead of banking some boilers and operating others at fairly heavy loads, all boilers should be operated at the same load. The operators should be provided with proper instruments and be held responsible for maintaining efficient combustion at all loads. Such practice will result in material economies, for several reasons:

(1) Due to highly efficient heat absorption by the boiler at light loads, the boiler-room efficiency is higher at such loads than at heavy loads.

(2) Banking losses are eliminated.

(3) The stoker parts are cooled by air at all times, instead of being exposed to the heat of a banked fire without a supply of cooling air.

(4) All fires are instantly ready to take a sudden increase of load.

The authors know of several plants burning Pocahontas coal which operate at 50 per cent of boiler rating, 24 hours per day, for weeks at a time with an efficiency of boiler, superheater, and stoker of 83 per cent. At other times these plants carry 250 per cent of rating on the same equipment at an efficiency of 78 per cent.

Boiler Operation

The authors believe that this paper would be incomplete unless mention were made of the difficulties experienced from the formation of slag masses on the lower tubes of the boiler.

Much theorizing about the causes and reasons for this slag formation has been indulged in by engineers. The various boiler manufacturers have produced slag screens which, in most cases have effected marked improvements. Nevertheless, the problem remains, even though it be in a modified form. Slagging of tubes is of course due to the air current lifting ash particles out of the fuel bed and subsequently depositing these particles on the tubes of the boiler. Remembering again the laws of physics, it would be expected that the slag formation would vary approximately as the square of the velocity of air through the fuel bed,

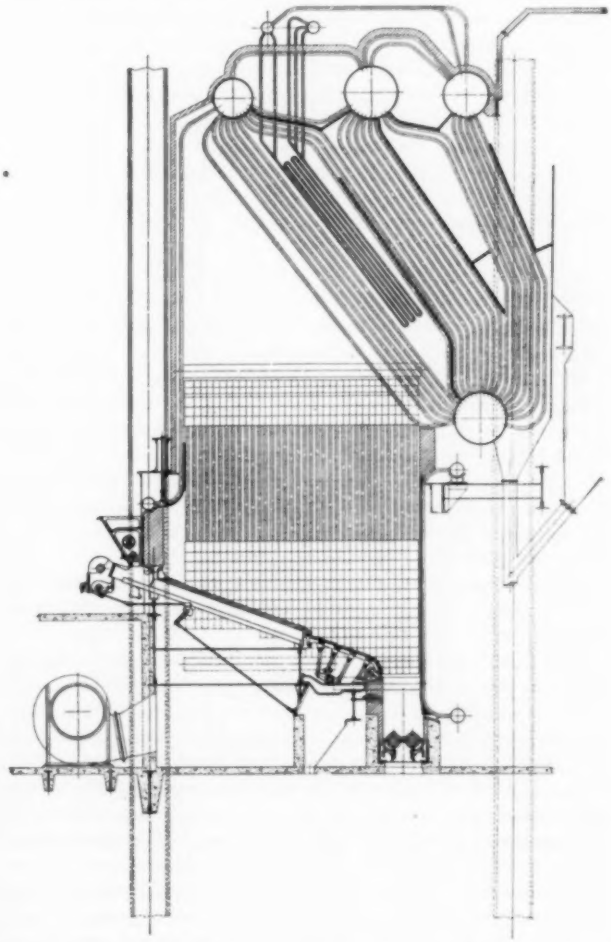

Fig. 14 Stoker Installation of Duquesne Light Company

or, in other words, as the square of the combustion rate. Therefore the only control that the stoker can exercise over slagging of the tubes is to operate with a maximum activity of fuel bed so that the air velocities through the fuel bed are as low as possible.

Semi-bituminous coals are bad tube slaggers for two reasons:

(1) The slowness of these coals to ignite reduces the active burning area of the stoker and therefore increases air velocities through the fuel bed.

(2) The ash in the majority of these coals is relatively light and easily carried away by the air current.

Therefore it is the authors' opinion that all boilers should be equipped with means for removing the slag from the lower tubes while the boiler is in operation at light loads or is banked. By far the most effective means of slag removal is to lance the tubes through doors located at the top of the furnace just below the boiler tubes. Such doors are readily installed with either brick walls or water walls.

A walkway should be provided so that the men can easily reach all parts of the lower tubes with a lance. Convenient connections for the lancing medium should be provided at both sides of the boiler so that two or more men can work simultaneously and keep the lancing period as short as possible.

Eastern operators favor compressed air or steam for lancing the tubes. Either of these mediums is rather slow in action. Western operators use a water lance with a remarkable degree of effectiveness. This water lance consists of a pipe turned up at the end and supplied with water so regulated that a tiny stream issues from the end of the lance. The stream of water need not be over 6 in. long for maximum effectiveness. The only precaution necessary is to regulate the water so that it is not sprayed against the joints of the tubes in the headers.

By such means the lower tubes of the boiler can be kept relatively clean at all times, so that the draft loss of the boiler will remain reasonable and there will be a minimum of slag formation on the upper tubes of the first pass of the boiler.

Recent Stoker Installations

Fig. 12 shows an installation in 1928 of stokers in the Hudson Avenue Station of the Brooklyn Edison Company. These stokers are 15 retorts wide and have an inside length of 19 ft. 9 in. They burn semi-bituminous coal with cold air in a furnace having refractory-covered water walls for side and rear walls and a solid refractory front wall. These stokers have developed in excess of 300,000 lb. of steam for 24 hours and in excess of 360,000 lb. of steam for 2 hours, on official tests. The heat-liberating rate for the 24-hour period is in excess of 825,000 B.t.u. per sq. ft. of grate area and is approximately 53,000 B.t.u. per cu. ft. of useful furnace volume.

Fig. 13 shows the results of official tests of one of these 1928 units compared with the results of similar tests on stokers designed in 1923.

Both equipments were tested (in different plants) by the ascending-descending series method. That is, individual tests were run at different loads, but were run as a continuous series, without gaps between tests, starting with a test at light load and running succeeding tests at successively increasing loads until the maximum load was reached, then reversing the process and running tests at successively decreasing loads until the last test is run at the same load as the first. This method eliminates the errors due to storage of coal on the stoker. It also eliminates the inaccuracies and deceptive results which occur under the common practice of burning down and cleaning the fire between tests.

The heat-absorbing equipment used with the two different stoker equipments is not comparable, so the comparison is made on a basis of combustion efficiency.

The soot and cinder loss was not measured on the 1923 design, but the heat balances indicate that it was about the same at the 24-hour capacity of that stoker as it was at the 24-hour capacity of the 1928 design—that is, about 3.5 per cent.

Air pressure is not necessarily a measure of air velocity through the fuel bed, but it is interesting to note that the same air pressure is used at the 24-hour capacity of both equipments.

However, it is interesting to note the progress of the art in increased capacity per unit of stoker area. The 24-hour capacity of the 1928 design is 1.4 times that of the 1923 design, and approximately the same combustion efficiency is obtained at the increased capacity.

Fig. 10 shows a stoker installation now being made at the Mobile Steam Plant of the Alabama Power Company. This installation is being equipped to burn wood refuse with high-volatile bituminous coal and preheated air.

Fig. 14 shows a stoker installation soon to be made at the new Reed Station of the Duquesne Light Company, Pittsburgh. These stokers are 18 retorts wide and have an inside length of 19 ft. 9 in.

These three recent installations are equipped with a new type of stoker which is an underfeed stoker with an undulating link-grate overfeed section. This design permits the construction of extremely long stokers, and at the same time eliminates the problems of handling fuel through extremely long retorts.

Fig. 7 shows an installation recently placed in service by the New Haven Pulp and Board Company, New Haven, Conn. This is an eight-retort stoker of the straight underfeed type with an inside length of 14 ft. 8 in. New River coal is burned with preheated air. One unit now carries the entire load that formerly was carried on several smaller stoker-fired boilers.

Conclusion

The authors have endeavored to present and to discuss the factors that are important in making a successful stoker installation. Many of the points discussed receive recognition in the majority of plants, but it has been their observation that relatively few plants adequately recognize all of them. It was with the idea of bringing all of these practical matters together in one group that this paper was written.

While the paper has been presented by individuals, it does not represent the individual thought or effort of one person; rather it is the accumulation of the experience of the authors and their associates.

Soot Particles in New York City Air

By E. E. FREE,[1] NEW YORK, N. Y.

In this paper the author tells of the methods used and the results obtained in a series of counts of soot and dust particles in the air of New York City. The counts were made by an impact dust counter. Two variables affect the results. One is the wind and the second the degree of clumping or flocculation of the soot particles in the air. The number of soot particles counted showed a high degree of correlation with wind direction. Nothing was discovered to show the causes for clumping of the soot particles.

IN APRIL of this year there was started a series of approximately daily counts of soot and dust particles in the air of New York City. During April and May counts were made at a number of different stations on the Island of Manhattan, to get some idea of the geographical distribution of air particles. Subsequently, most of the counts have been made from the seventeenth floor of an office building at Twenty-Third Street and Fifth Avenue. The earlier counts at other localities show that this station is not unrepresentative of average air in the central part of Manhattan.

All the counts have been made by an impact dust counter, slightly modified from the instrument devised by Dr. J. S. Owens, of England. In these instruments a definite volume of air is first moistened by being allowed to remain for a few moments inside a tube lined with wet blotting paper. A definite volume of this air is then drawn by a suction syringe through a small orifice. The expansion of the air thus produced cools it, and condenses moisture on any particles which are present. These moistened particles impinge on the surface of a glass microscope slide, a short distance beyond the orifice. Being moist the particles stick to this glass surface. The slide is then removed and examined under the microscope, the numbers of particles being counted in the usual manner.

The modification of the instrument used in these counts, as compared with the standard Owens counter consists in the use of a circular orifice instead of a narrow slit. This is in order to obtain, it is believed, a better estimate of the aggregates of soot particles. The slit instrument breaks up these aggregates more generally than the instrument with a round hole. Counts of particle numbers obtained with the slit instrument are larger than those obtained with the round-hole instrument for the reason that the latter instrument counts aggregates as one particle each, while the slit instrument counts each individual particle into which the aggregates are divided.

It is believed that for practical purposes it is desirable to count the aggregates as one particle each rather than dividing them into their constituents.

In the instrument used in these counts the volume of air tested was in some instances 5.9 cu. in., in others 2.95 cu. in., depending upon the amount of dust in the air. In either case, a proper factor is applied to convert the measured counts into numbers of particles per cubic foot of air.

One hundred and forty-two counts have been made, many in duplicate. In general, these have been taken approximately at midday, although the hour is of little importance as the 24-hour variation is entirely obscured by other and greater variations.

Data obtained are chiefly characterized by very high variability, it being not unusual for the numbers of particles in the air to change by a factor of as much as ten, either way, within twenty-four hours. Instances have been observed of such extreme changes within two or three hours, usually correlated with changes in wind direction or velocity.

The maximum count obtained was on July 30, 1928, equaling 880,000 particles per cu. ft. of air. The minimum count was on July 2, 1928, and was 35,000 particles per cu. ft. The average of all counts during the period specified was 470,000 particles per cu. ft. of air. No great numerical accuracy is attachable to these figures, even to the averages. It is possible to say, however, that approximately a half-million dust and soot particles are to be found, on the average, in each cubic foot of New York City air.

The character of the particles observed, as judged by qualitative tests under the microscope, is remarkably uniform. Counted slides have shown never less than 96 per cent of particles which are clearly ordinary soot, that is, unburned carbon. This is for the level of the seventeenth floor. A slightly higher percentage of other particles is usually found at the street level. It is believed, however, that at least 90 per cent of all solid particles ordinarily encountered in New York City air are soot.

Other materials observed in individual instances include particles of rubber from automobile tires, of asphalt, of brick, of rock from excavations, of horse excrement and other organic materials, and slivers of glass at first believed to be distant volcanic dust, but later found to be too numerous for this. These are now considered to be minute flakes scaled off from glazed tile used on buildings. A few particles of leather have been found, a few cotton fibers, an occasional hair or skin scale apparently from a human being, and the usual relatively small number of what seem to be spores of living molds.

No identifiable soil particles have been found, no diatoms, and none of the so-called Tissandier spheres which are apparently tiny globules of metallic iron. The apparent absence of these usual constituents of air dusts from New York counts may be explained, however, as due to the coating of these objects with the omnipresent soot particles.

The sizes of these soot particles vary from approximately one ten-thousandth of an inch to approximately one fifty-thousandth of an inch. As stated, a relatively large percentage of these soot particles is observed to be gathered together in clumps or aggregates, like grains of popcorn stuck together to make a popcorn ball. These aggregates measure between one fifteen-hundredth of an inch and one five-thousandth of an inch. The percentage of the soot particles present in the air as aggregates has been found to be exceedingly variable. This variability is not believed to be due to any variation in method of collection or counting but to represent a real variability in the clumping together, or flocculation of soot particles in the air. This observation is believed to be new, and may have some importance in practical problems of city soot and city fog.

The effect of elevation above the street level is to decrease the number of soot particles in the air. The percentage of decrease is extremely variable but approximately 100 ft. of rise above the street level means between 25 per cent and 50 per cent reduction in the number of soot particles. The above figures for the particle counts should be multiplied, therefore, by between 1.5 and 2.0 to give the average number of particles at the street level. This conclusion applies to the Fifth Avenue and Twenty-Third Street

[1] School of Commerce, Accounts, and Finance, New York University.

Contributed by the Fuels Division and presented at the Annual Meeting, New York, N. Y., Dec. 2 to 6, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

district only; no high-level counts having been made at other points. As might be expected, there is some evidence that days on which the ultimate soot particles show much aggregation into clumps are also days of greater difference between the dust counts at the street level and at higher levels, indicating the relative rapidity with which the soot aggregates settle out of the air as compared with the settling rate of the ultimate particles.

Rain appears to have less effect on the particle counts than would be expected. Also, the effect is erratic. Some rains apparently produce virtually no decrease in air soot. Other rains produce relatively large decreases. It has not been possible to correlate these variations with rain intensity or with any other characteristic of the rainy days.

All of the data are consistent with the idea of two chief variables; the wind and the degree of clumping of the particles. The wind is undoubtedly the more important. Geographical counts make this evident. When the wind is blowing, for example, across Manhattan Island from west to east, the air of the west shore of the Island is relatively low in soot particles. At the same time the air of the east shore is relatively high. Similarly, the number of soot particles counted at Twenty-Third Street and Fifth Avenue shows a high degree of correlation with wind direction and wind velocity. Winds from smoky areas mean high soot counts. Winds from directions in which little smoke is being discharged usually mean low soot counts.

Nothing has been discovered, as yet, concerning the causes of the variation in the clumping or flocculation of the soot particles in the air. Nor is it possible to say, as yet, how important this factor is in removing soot particles from the air, as compared with the velocity and direction of wind. There is some suggestive evidence that the city experiences more haze and fog when the degree of flocculation of the soot particles is low. If true, this would be highly important in aiding the prediction of fog, now possible only with considerable inaccuracy on the basis of wind direction. However, until more has been learned of the reasons for the variation in soot flocculation it will be impossible to make use of these ideas with much assurance. Several theories have suggested themselves concerning the cause of these flocculation variations such as differences in humidity, differences in sunlight reaching the particles, differences in air ionization, etc. None is supported, as yet, by direct evidence. Obviously, the problem deserves further investigation.

Little practical importance attaches to the calculation of the total amount of suspended soot in city air. It may be said, however, that the average over New York City, on the basis of these counts appears to be approximately one ounce, Avoirdupois, for each 10,000,000 cu. ft. of air. For the air over the entire city the amount is from four to five short tons. Ninety per cent or more of this is soot. The total probably varies, with the wind and other conditions, from about one-tenth of this value to about three times the value. Discrepancy with previous much larger estimates which have been published is believed to be due to the fact that these previous estimates, made on the basis of solid materials caught by air-washing plants, include a considerable fraction of roof-fall of cinders and similar particles which remain only a brief time in air suspension. These are not really a part of the normal air dust of the city.

As to the ultimate sources of city soot, the relative absence of ash confirms, so far as it goes, the opinion easily formed from direct observation; namely, that most of the city's soot and air dust comes from many small fires in apartment houses, office buildings and homes, not from the smoke stacks of the large power houses or other industrial plants. This conclusion is supported, as is well known, by much other evidence. The present investigation while agreeing with this, provides few additional facts.

This is a preliminary report. The soot counts will be continued during the winter and probably for a considerable portion of the coming year. It is planned, also, to compare these counts more definitely than hitherto with weather conditions, with the receipt of ultraviolet radiation at the building level in the city, and with other similar factors. It is a pleasure to acknowledge the assistance of C. A. Johnson and Bernard Stoll of my laboratory. Mr. Stoll has made the majority of the counts.

Discussion

DAVID R. MORRIS.[2] The Weather Bureau has been making dust counts at 12 noon daily for nearly a year at 13 of its stations with the Hill dust counter. It is thought that this is the first concerted count using identical technique to be taken in this country. The instrument used is similar to the one used by Dr. Free, but under the Hill method the count is made with a magnification of 80 instead of 1000. The work is in cooperation with the American Society of Heating and Ventilating Engineers, which is also receiving health statistics from the cities where the counts are made.

In New York City the count is made at the Central Park Weather Bureau, and the results are published in the Monthly Bulletin of the observatory. Numerous weather data are printed alongside the dust observation at the time of the count and for some hours previous to the count.

The importance of dust in producing various weather conditions has been mentioned in meteorological textbooks for a long time. This was mostly the dust from wide country areas or volcanic erruptions. The generic name "dust" still holds today, but the character of the particles and their source are now quite different, especially in our large cities. It is in the latter regard that the most interest exists today and which may be expected in time to yield improved apparatus and the adoption of methods which will put the entire work on a more comparable basis.

HENRY KREISINGER.[3] It is stated that 96 per cent of the dust particles in the New York City air are soot coming from small fires in apartment houses, office buildings, and homes, and not from the smokestacks of large power plants and other industrial plants. It would be interesting to know to what extent the automobile vehicles contribute toward loading the New York air with soot. There are thousands of these vehicles running over the streets of the city under conditions very adverse to good combustion. The automobiles have to run slowly and they also frequently stop and start up again, conditions which make it necessary to operate the engines with excess fuel. Even under the best operating condition the combustion in an automobile engine is far from complete. Numerous tests made by the Bureau of Mines and other laboratories show that normally one half of the carbon of the fuel supplied to the automobile engines burns to CO. It is to be expected that when CO is formed there is also a large amount of soot formed and exhausted into the air. Let it be assumed that about a hundred thousand automobiles are running over the streets of New York during the busy hours. Under the unfavorable condition of operation, each automobile consumes about two gallons of gas per hour. This would make the gasoline consumption about two hundred thousand gallons, or approximately one and a half million pounds. This amount of gasoline is equivalent to about two million pounds of coal, or about one thousand tons of coal per hour. It takes a good-sized power plant to consume one thousand tons of coal

[2] New York Meterological Observatory, Department of Parks, Central Park, New York, N. Y.

[3] Research Engineer, Combustion Engineering Corporation, New York, N. Y. Mem. A.S.M.E.

per day. These figures may not be correct, but they indicate the extent of soot contribution by the running automobiles toward the sooty atmosphere of New York City. Moreover, the soot made by automobiles is discharged into the atmosphere at the street level and is more apt to find its way into the offices and dwellings. Soot from chimneys is discharged at higher elevations and is more likely to be carried away by the wind.

The paper states that there is no appreciable soot reduction in the atmosphere after rain and that the main factor tending to clear the atmosphere is wind. It is a common experience that soot and all very small particles floating in gases are difficult to wet and wash out. If such washing is to be successful, the dust particles must be wetted by the condensation of water vapor. If the gases containing the dust particles are first saturated with water vapor and then cooled below the condensation point, the water vapor will condense on the surfaces of the dust particles and wet them, thus increasing their agglomerating property and their weight. When in such state they can be more easily washed out or separated from the gases. The principle of condensation of water vapor on the dust or soot particles is used by the author of the paper for collecting the dust in the air samples.

PHILIP DRINKER.[6] The author discusses the presence of aggregates or clumps of soot particles in the air sampled and mentions the high correlation between counts and wind velocity. We have found in laboratory studies[8] that the settlement of fine particles, of the order of 0.5 to 5 microns, especially particles of carbon, is accomplished mainly by aggregation and that turbulent air motion or ionization will accelerate this aggregation. Whether or not this fact, well known in chemical warfare,[9] has a direct bearing on Dr. Free's problem, is not known.

In our experimental work, we have had abundant experience in the use of Owens' standard slit instrument, but have not used the modified Owens counter that the author describes. Our observations[7] indicate a rather low partial correlation coefficient between dust counts and wind velocity. In calculating these coefficients, we used routine counts taken twice daily for 16 months. Kimball and Hand[8] and Owens,[9] using data of a more selected nature, showed that a distinct inverse, but non-linear, relationship existed between counts and wind velocity. Their data would seem to agree with those in this paper.

It is hoped that, in his final paper, Dr. Free will work out and publish the partial correlation coefficients between counts, wind velocity, visible and ultra-violet solar radiation, and per cent relative humidity, and that he will be able to publish his final results in c.g.s. (and microscopist's) units.

C. HAROLD BERRY.[10] To the engineer it may seem that the presentation of data on a quantity that varies from 5 to 100 in no very systematic fashion is of little value, but it should be borne in mind that we are on the threshold of an important and difficult study. Its importance to the public is evident. No less is its importance to industry. Information is needed to refute false charges and to serve as a basis for the removal of grounds for well-founded charges. Air pollution is too great a price for the public to pay for the carelessness or indifference of industry, if these are the causes. On the other hand, if air pollution is largely caused by small furnaces of which the domestic heating plant is typical, the fact should be proved beyond doubt. In either case, it is the task of the engineer to remedy the situation.

The wide variability of results doubtless reflects the fact that we are dealing with a quantity that actually does vary widely in place and in time. This, combined with the difficulty of securing a small representative sample, makes precise measurements exceptionally difficult.

It is to be hoped that much more work will be done along this line in the near future.

LOWELL ANDREW.[11] The paper adds valuable information to the very limited knowledge of the amount and character of the microscopic particles present in the air in large cities. In some respects, however, the paper might have contributed more tangible information had it described in greater detail the means used of identifying under the microscope the particles observed and had presented further information on the size of the orifice used and its effect on the number of particles counted as compared with the Owens machine using the slit. Observation and experience with this type of instrument and the Hill instrument has been that the degree of magnification used in counting must be specified before the figures presented for dust counts can assume any relative value.

Extreme variability from day to day seems to characterize observations with jet dust counters, but as yet we have been unable to observe any great seasonal variations such as one might expect—for instance, between summer and winter.

We have not been able to get satisfactory comparisons between counts with the Owens type counters using high magnification of 1000 diameters and the Hill type using a magnification of only 80 diameters. This is no doubt due to some extent to the variable characteristic of aggregation in large particles.

One particle per cubic centimeter is equivalent to approximately 28,000 particles per cubic foot, so that the minimum count of 35,000 particles, as mentioned in the paper, represents only about $1^1/_4$ particles per cubic centimeter. The widely quoted figure for a certain city is 17,600 particles per cubic foot or $^2/_3$ particle per cubic centimeter. However, with an Owens counter and a magnification of 1000 diameters, counts as high as 152,000,000 particles per cubic foot have been obtained.

Dust counts are being made this winter with the Owens type of instrument using a slit and the particles counted under a magnification of 1000 diameters. It is to be hoped that further, better, and more reliable methods of determining the amount and character of the particles in the air will soon be developed.

LAURA A. CAUBLE.[12] The National Conference Board on Sanitation is made up of men and women, scientists, physicists, department of health officials, physicians, organized bodies of womens' clubs, and home makers. We are making a determined inquiry into the question of the increasing pollution of the air of cities with the consequent loss of sunlight and the vital ultra-violet.

This body is very much interested in the study of dust that the author has been making. It has been measuring visible light for the last three years. We have used the Case photo-electric cell with a Leeds & Northrup potentiometer. Our records show that there is a constant average loss of 30 per cent of light in the city caused by the smoke pollution as compared with the light recorded in the country at a point not subjected to the same waste by smoke.

On the longest sunny day in June, in which there was 15.1 hours of sunshine, the records showed a loss of 42 per cent of visible light. The following day was continuously sunny, with a loss of 36 per cent of light. The difference between the available sunlight in the country and in the city is the measure of pollution by smoke which is being endured in the city. It is an intolerable burden for which relief must be found, and no body in the country is so capable of solving this problem as the mechanical engineers.

Our measurement of light is a continuous record from daybreak until sunset. There has been no such continuous measurement of dust made at any point so far as can be learned. These measurements are made momentarily over short periods of time, and they do not give any accurate measure of air pollution.

Boiler Settings for Burning Refuse Wood

By C. S. GLADDEN,[1] DETROIT, MICH.

This paper includes a discussion of: (1) Some recent developments in the design of boiler furnaces for burning green or wet refuse wood; (2) the experiences influencing the development of furnaces for burning dry refuse wood; and (3) factors influencing the design of wood-burning furnaces.

THE economic utilization of wood refuse from lumbering and woodworking operations has become a problem of increasing interest. Formerly, when fuels were comparatively cheap and lumber-cutting operations produced more waste wood than could be consumed, there was little concern given to efficient methods of burning it in steam-boiler furnaces. In lumber-sawing operations, the sawdust produced has in most cases been sufficient to generate all the steam required for operating the mill, and the slabs have been disposed of either by burning in large incinerators or working up into lath, kindling wood, or other commercial products. Later, as lumber and fuel became more expensive and woodworking plants producing finished parts from kiln-dried lumber became more numerous, improvement in the utilization of the wood refuse for the generation of steam became more imperative. Certain modern mills for the production of finished kiln-dried lumber from the log have arranged their plants so that the steam requirements for power and kiln-drying operations will quite nearly consume all of the mill refuse in its generation. By-product processes, such as the evaporation of salt, and the production of power to the extent that all of the refuse may be utilized in the generation of steam have been given increasing consideration.

The refuse resulting from the milling of air-dried or kiln-dried lumber produces a fuel which is especially well adapted for burning under steam boilers in properly designed furnaces, and there are now many installations which indicate the increasing efficiency that is being attained in the burning of this material.

In the plants of furniture and automobile manufacturers the demand for power and steam is such that the problem of properly burning the kiln-dried wood refuse is one that is worthy of serious consideration of the most efficient methods.

The wood refuse available for fuel may be considered under three general classifications:

1 The sawdust and slabs from sawmills containing from 30 to 50 per cent of moisture, where logs are transported to the mill dry, to perhaps 70 per cent moisture if the logs are of softwood and have been floated to the mill through rivers and streams or have been held in storage in mill ponds. The bark and shavings from pulpwood held in water storage are also very wet and contain over 70 per cent of moisture. Such refuse will be classified as wet refuse

2 The refuse of planing mills and finished-lumber operations resulting from the working of air-dried lumber containing from 15 to 25 per cent moisture

3 The wood refuse of furniture factories and automobile-body plants resulting from cutting and finishing of parts from kiln-dried lumber, in which case the refuse usually contains from 5 to 7 per cent moisture.

Combustion Temperatures and Calorific Values of Wood

We shall now consider the heating values and theoretical combustion temperatures of this material. It is apparent that in burning wet wood the fuel must first be raised to the temperature required for the evaporation of the moisture, then the latent heat for the evaporation must be supplied, and the resulting steam must be superheated to the final temperature of the products of combustion. A study of the combustion temperatures has been made of wood under different conditions of moisture content and of excess air for combustion. The results are shown in Fig. 1. The combustion temperatures are the temperatures which would be produced if there were no absorption of heat from the flame as the processes of combustion take place,

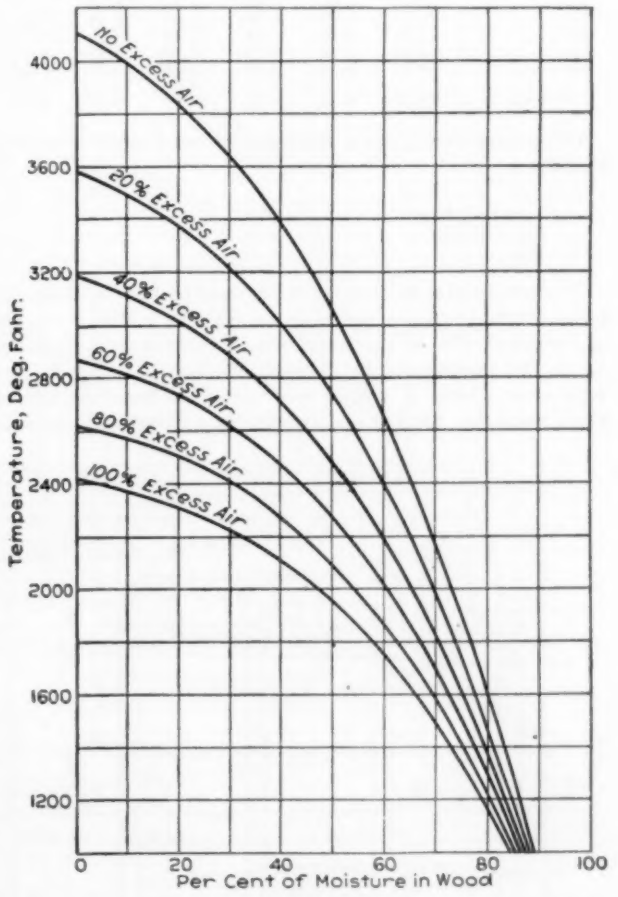

Fig. 1 Combustion Temperatures of Wood With Varying Moisture Content

[1] Director, Power and Maintenance Section, General Motors Corporation. Mr. Gladden was formerly associated with E. I. du Pont de Nemours & Co. at Wilmington Del., and with the J. G. White & Co., at New York, in steam power-plant design and construction work. Mem. A.S.M.E.

Contributed by the Power Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

and the curves indicate the relative heat produced by the different classes of wood fuel with respect to moisture content.

The method used in determining the combustion temperatures is that outlined by Arthur D. Pratt in his "Principles of Combustion in the Steam-Boiler Furnace" in which the mean specific heats of the different constituents of the products of combustion vary, depending on the final temperatures attained. This method gives somewhat higher results with increasing moisture content than the formula frequently used in which the specific heat of the products of combustion is assumed to be constant regardless of the amount of excess air, moisture content, or of the final temperature.

The percentage chemical composition and calorific value of moisture-free wood have been taken as the averages of the data (by Gottlieb) given in Table 1.

TABLE 1 ULTIMATE ANALYSIS AND CALORIFIC VALUE OF DRY WOOD

Kind of wood	C	H	N	O	Ash	B.t.u. per lb.
Oak	50.16	6.02	0.09	43.36	0.37	8316
Ash	49.18	6.27	0.07	43.91	0.57	8480
Elm	48.99	6.20	0.06	44.25	0.50	8510
Beech	49.06	6.11	0.09	44.17	0.57	8591
Birch	48.88	6.06	0.10	44.67	0.29	8586
Fir	50.36	5.92	0.05	43.39	0.28	9063
Pine	50.31	6.20	0.04	43.08	0.37	9153
Average	49.56	6.11	0.07	43.83	0.42	8671

The proximate analysis of moisture-free wood refuse is roughly as follows:

	Per cent
Volatile matter	81.5
Fixed carbon	18.0
Ash	0.5

The calculated calorific value of dry wood by Dulong's formula, based on the above average ultimate analysis, is 7626 B.t.u. per lb. compared with an average of the calorimeter determinations for all the woods given by Gottlieb of 8671 B.t.u. per lb. and with several tests of hogged wood from an automobile-body plant averaging 8413 B.t.u. per lb. on a moisture-free basis. It has been demonstrated by various investigators that Dulong's formula does not apply accurately to wood, due to the presence of large percentages of hydrocarbons. In the case cited above the actual calorific value as determined by bomb calorimeter is 13.7 per cent higher than the calorific value calculated by the Dulong formula. Accordingly in computing the combustion temperatures of wood under different conditions of moisture content as given in the curves, the heating values obtained by the Dulong method have been increased by 13.7 per cent.

The actual combustion temperature in a boiler-furnace setting is lower than that indicated by these curves since the absorption of radiant heat by the boiler and the dissipation of heat by

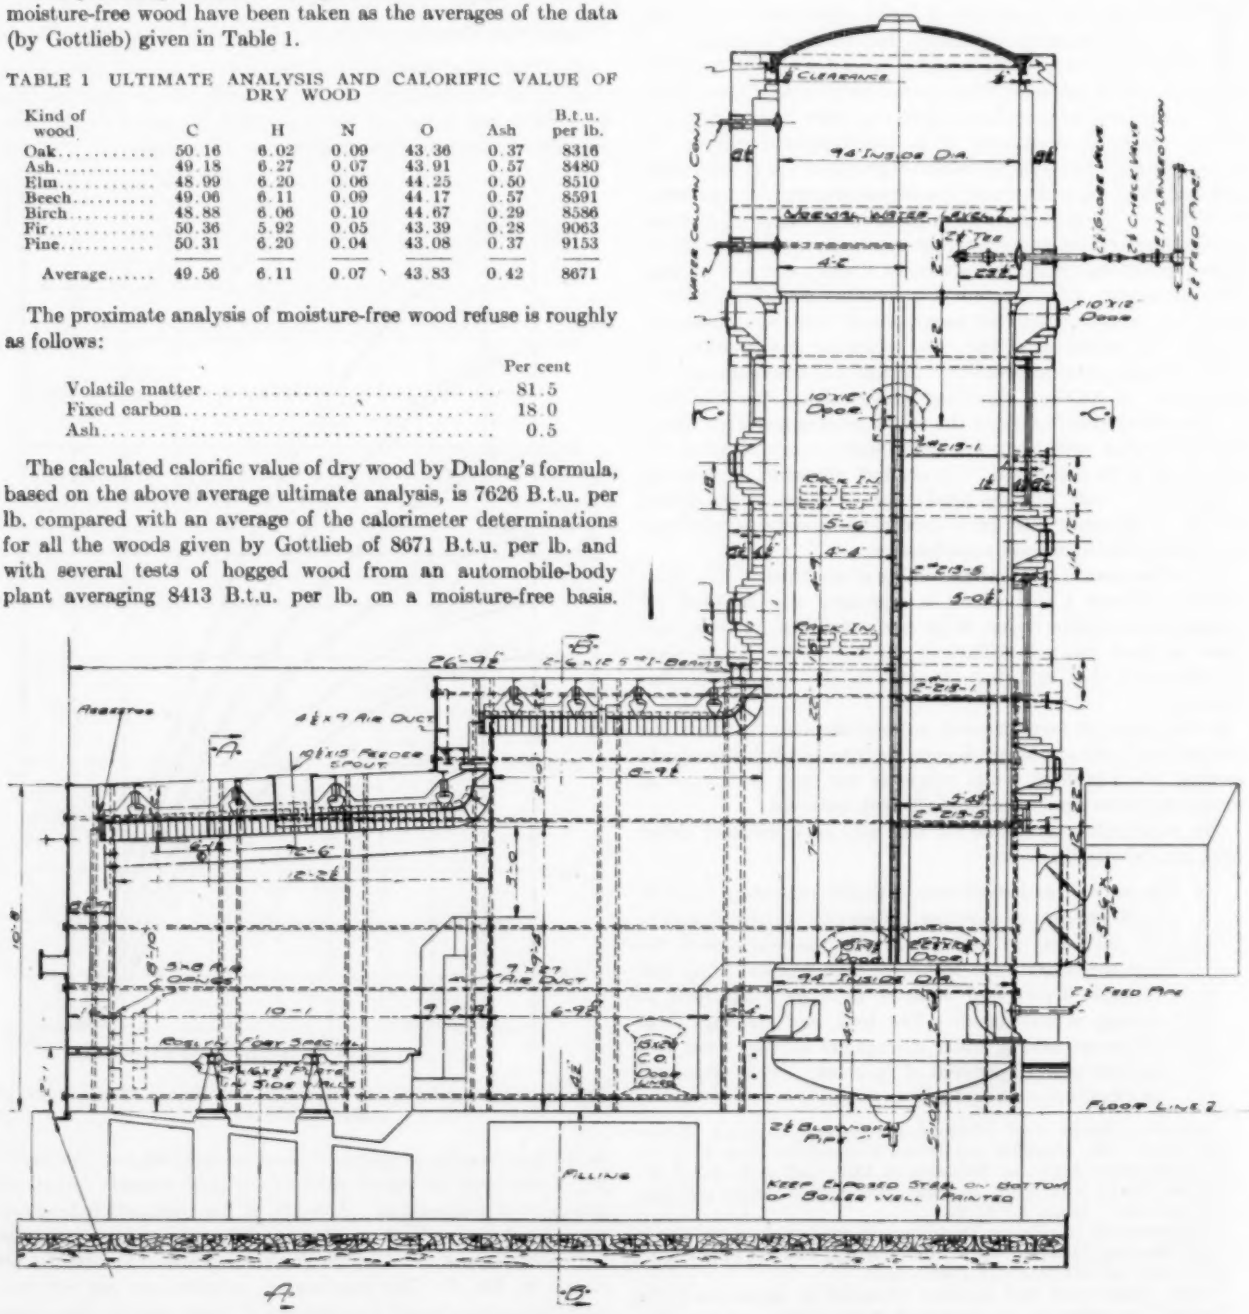

FIG. 2 FURNACE FOR SAWMILL REFUSE WITH VERTICAL WICKES BOILER

radiation and conduction through the furnace walls will prevent the maximum temperature of combustion from being attained.

On account of the high flame temperature of burning dry wood with little excess air, the problem of suitable refractories for wood-burning furnaces is of great importance. Although the ash of the wood is not of serious consequence, due to its small quantity, its silica and alkaline constituents combine to form a low-temperature-fusion slag which readily fluxes with the silica of ordinary firebrick. Some improvement has been obtained in the maintenance of wood-burning furnaces operating at high temperatures by the use of brick containing high percentages of alumina; but the most satisfactory results have been obtained both by the use of air-cooled refractory walls in which the temperatures of the refractories were maintained below the point of heat liberation. The air-cooled wall has greatly improved the life of the refractories in wood-burning furnaces, and the water-cooled wall has also been used with success. The temperature of the furnace should be maintained as high as possible to produce smokeless combustion, but not so high that the refractories suffer from fusion. It appears at the present time that a certain amount of water cooling together with air cooling provides the best type of furnace for air-dried and kiln-dried refuse wood.

The burning of wet refuse does not involve the question of life of refractories and the dissipation of heat from the furnace so much as the conservation of the heat of combustion and utilization of its radiant heat by means of reflecting arches and side walls to heat the refuse wood and evaporate the moisture in the fuel as it is delivered to the furnace.

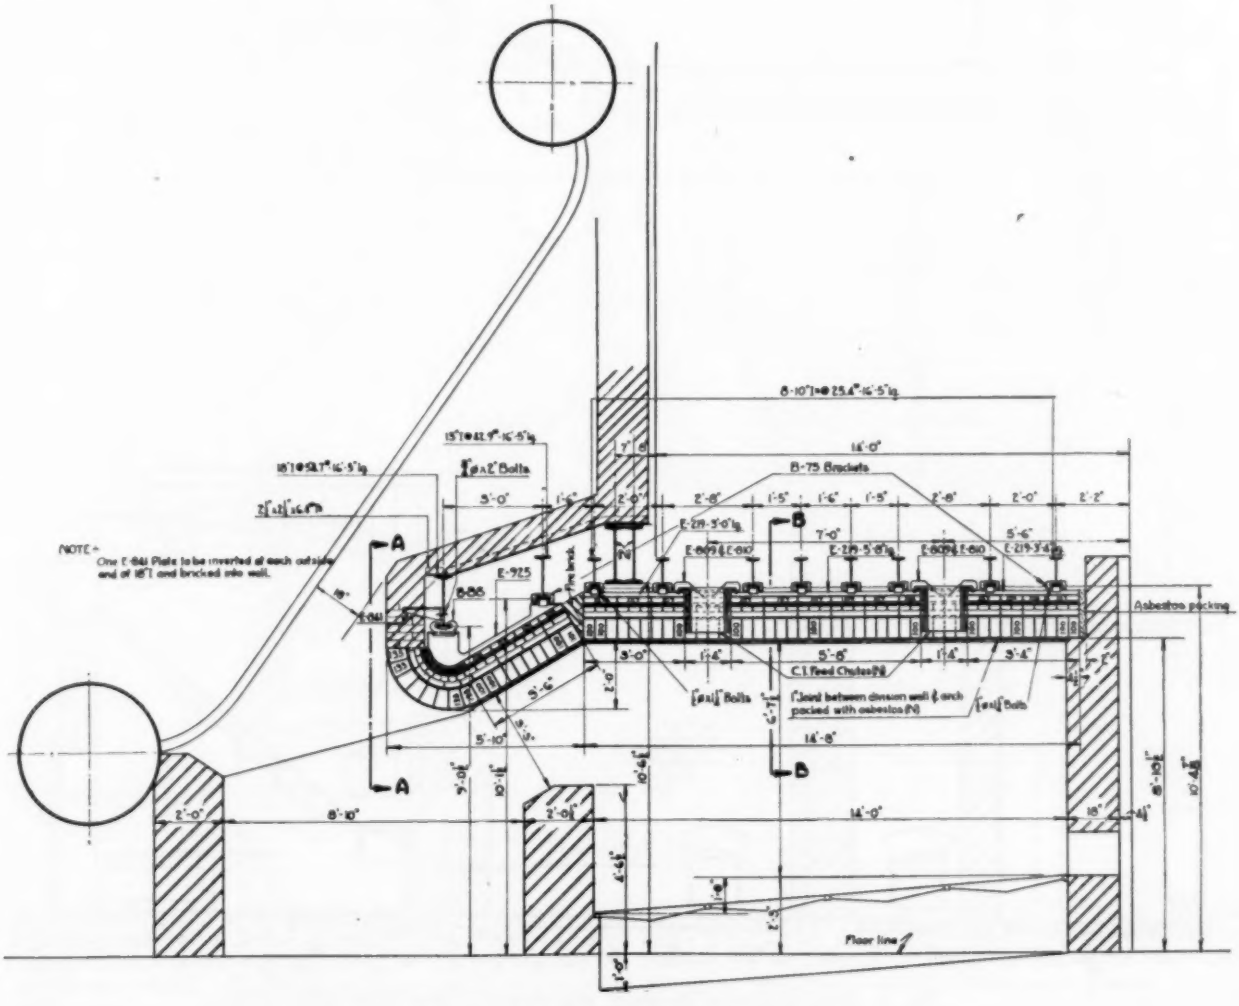

FIG. 3 FURNACE FOR SAWMILL REFUSE
(Louisiana Central Lumber Co., Clarksburg, La.)

at which the silica of the firebrick will fuse with the ash and cause erosion and by the introduction of water-cooling surface in the side walls of the furnace. Substantially the same development has taken place in the design of the side walls of dry-wood-burning furnaces as has occurred in recent years in the design of furnaces for burning pulverized coal. That is, the solid refractory walls were found to require high maintenance and frequent reconstruction, especially when the excess air is reduced to a minimum or the wood is burned in a dry state and at high rates

The early designs of boiler furnace for burning wood gave no consideration to efficiency of combustion or to the smoke nuisance. However, the present smoke-elimination ordinances of municipalities in which furniture, automobile-body, and other woodworking plants are located require the most careful consideration of the smoke problem.

The question of setting singly or in battery is also one worthy of serious consideration, depending on the extent of the operation, the single setting being considerably more flexible and easier

to maintain and repair than the battery setting with its troublesome common center wall.

Designs for Wet Wood Refuse

For refuse wood consisting of sawdust, shavings, and hogged wood, and slabs direct from the log or green lumber extended furnaces having reverberatory arches over the top should be provided. In the burning of wood as contrasted with the burning of coal, the combustion takes place from the surface of the pile of fuel in the furnace, while with coal the combustion is maintained throughout the fuel bed. This means that for burning green refuse wood the furnace should be provided with side walls and arches arranged to reflect the radiant heat back to the burning wood and thus promote the evaporation of moisture before combustion takes place.

A typical example of a green-wood-burning furnace installation is shown in Fig. 2. This furnace consists essentially of two combustion chambers. The fore oven is arranged with a suspended arch above the grates, on which the green fuel falls through the feeder spout. This pile of fuel is burned by air admitted above the grates by air openings near the front of the furnace side walls and through the portions of the grate around the pile of wood which is not covered too deeply. The products of combustion passing through the 3-ft. space above the bridgewall are mixed with additional air through the rear of the bridgewall, and further combustion of the gases and cinders takes place in the secondary rear oven. The wood is dried and combustion takes place from the surface of the pile, assisted by the heat reflected from the arch above and from the side walls. This typical setting for burning green wood is shown in conjunction with a vertical water-tube boiler. There are many of these boilers throughout the lumber-producing areas of the South and Northwest, primarily because this particular type of boiler was first introduced in these regions for steam production, and, secondly, it is a self-contained unit which can be shipped and erected intact and is therefore a cheaper installation than the modern type of bent-tube or horizontal straight-tube boiler which requires additional assembly and erection cost on the job.

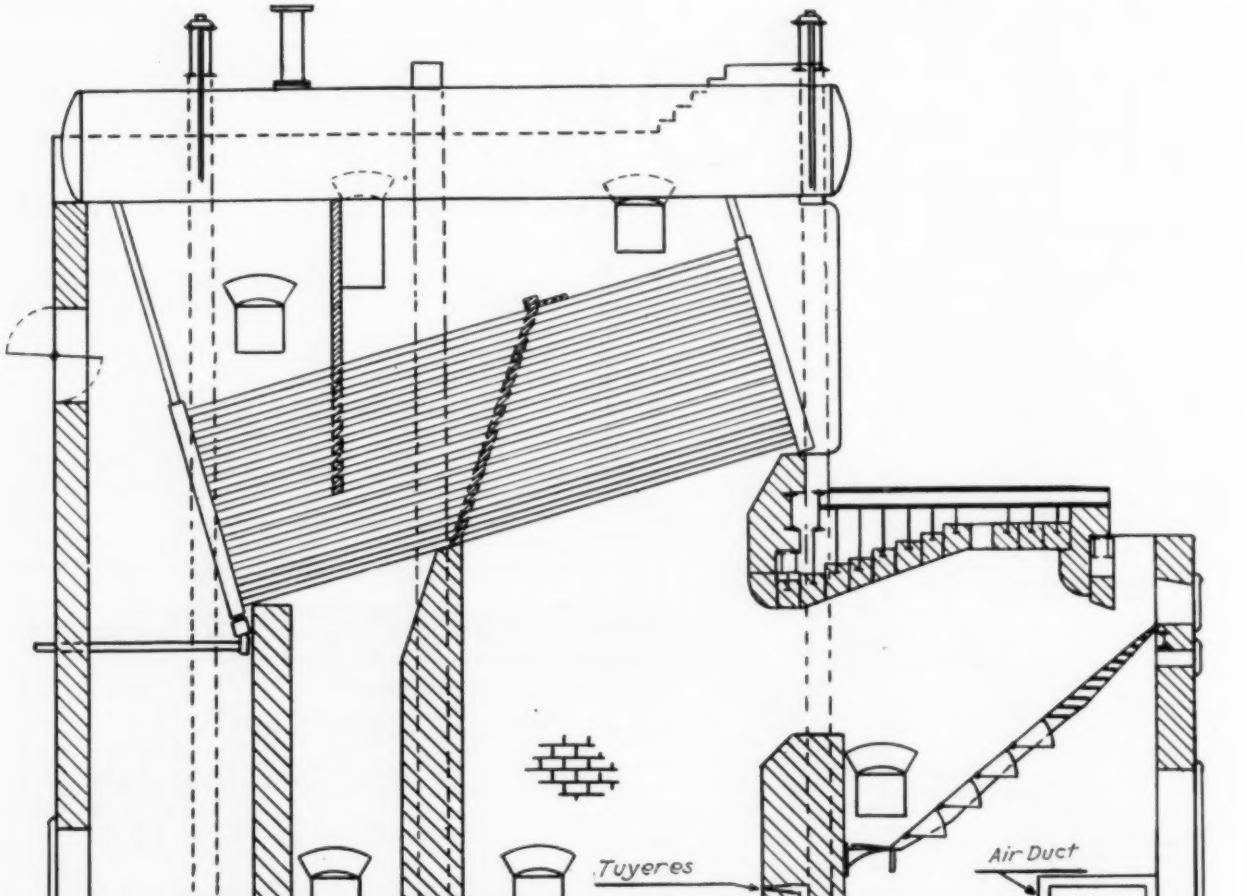

Fig. 4 Inclined-Grate Furnace for Burning Wet Refuse
(600-hp. Babcock & Wilcox boiler, Chicago Mill & Lumber Corporation, Tallulah, La.)

Fig. 3 shows a furnace in conjunction with a Stirling-type boiler designed for burning green wood in which the fuel is admitted through two feed chutes to horizontal grates. In this case the secondary chamber for the combustion of cinders and gases for the wood-burning chamber is located beneath the boiler. This is a typical installation of units of this type which are now being used in the Southern lumber regions. If

space in the boiler room permitted, however, the combustion chamber should be brought forward so that the entire space underneath the boiler could be used as a secondary combustion chamber.

The furnace shown in Fig. 4 for the burning of green or wet wood refuse is arranged with sloping grates so that as the wood is admitted through the feed chute at the top and front of the furnace, the upper surface of the pile of refuse in the furnace is approximately the same distance from the grate line from top to bottom.

The upper portion of the sloping grates which run longitudinally is fitted with horizontal steps. The lower portion is also of longitudinal grates alternating with sector fuel pushers between the grates which control the movement of the fuel toward the dumping grate at the rear. In this furnace the fuel burns progressively from the top to the lower end of the grate, and the slope of the grates is such that the fuel slides readily without avalanching. The thickness of the fuel bed is controlled by the width of the throat at the upper end of the grate. Doors in the front are also provided for hand manipulation as may be necessary.

The suspended arch over the combustion chamber is arranged to reflect the radiant heat back to the surface of the fuel bed and promote the drying and volatilization processes. The back end of the arch is dropped to further reflect the radiation to the pile of fuel and to mix the gases. The thinner and hotter gases at the lower end of the grates being forced to mix with the gasified volatile matter from the upper portion of the drying fuel, thus assist in promoting complete combustion. At the rear of the bridgewall there is also a line of tuyères to supply additional air for burning the gases in the rear combustion chamber beneath the boiler.

In Fig. 5 is shown the installation of a large wet-wood-burning furnace for a 1100-hp. boiler. This installation was made in California for burning water-soaked redwood refuse, which is about the poorest fuel imaginable, the moisture content being very high. In this furnace it will be noted that there are six chutes for supplying wood refuse to the furnace, which automatically form six conical piles of fuel on the horizontal grates. Air is admitted to the combustion chamber through the uncovered grates beneath the fuel and through a series of $4^1/_2$-in. by $4^1/_2$-in. openings on 9-in. centers in the side walls, center wall, and front wall of the furnace. The air ports are all arranged horizontally to admit air near the base of the cones of fuel. The air enters through an air intake in the back of the bridgewall, and through inlets at the top of the furnace in the front wall and in the forward portion of the side walls. The furnace is laid up with hollow-wall-tile construction providing free passage of air through ducts in all portions of the side walls, and thus the air admitted from the outside is first preheated by the air-cooled side-wall refractories before being admitted into the combustion chamber through the series of horizontal openings. Air is also admitted through ports in the bridgewall to the large combustion chamber beneath the boiler. The suspended arch is arranged to reflect the radiant heat back to the fuel cones and assist in the drying and volatilization processes.

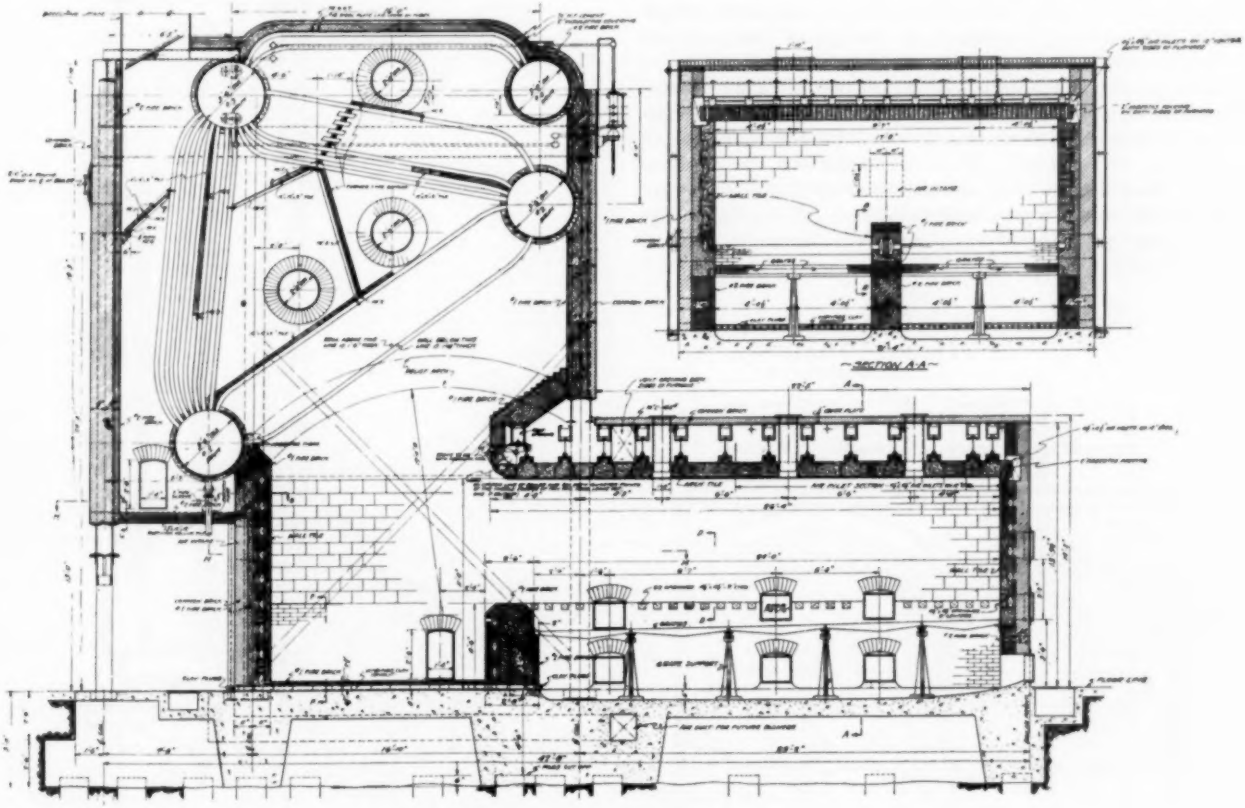

FIG. 5 FURNACE FOR WET REDWOOD REFUSE
(1100-hp. Badenhausen boiler, Hammond Lumber Co., Samoa, Calif.)

It is stated that with this design of furnace it has been possible to obtain outputs of 200 per cent of boiler rating, which is undoubtedly accounted for by the liberal provision in the combustion chamber for the utilization of the radiant heat in drying

the wood, promoting the volatilization of the combustible constituents of the fuel, and by the access of preheated air to all sides of the fuel cones.

In the lumber operations of Oregon and Washington there are some very interesting and well-designed boiler furnaces for burning green or wet wood refuse. These installations include boilers of over 2500 rated hp. in capacity, and the details of the furnace construction are of decided engineering interest.

Designs for Air-Dried and Kiln-Dried Wood

In industries where the maximum use of refuse wood for fuel is required and is commercially economical, the boiler settings should receive very careful engineering consideration. Many of the earlier types of boilers in such plants—and these are still used in most of the present-day furniture operations—employ vertical water-tube boilers with Dutch ovens, receiving the refuse directly from cyclone collectors. An example of this is shown in Fig. 6.

This type of installation is still in common use among furniture manufacturers and is representative of the earlier design for the burning of refuse wood at automobile-body plants dating back about 10 years ago. In such installations the sawdust, shavings, and hogged wood are delivered through the furnace front through chutes from a collector above. The collector also delivers large quantities of excess air to the furnace, and therefore the efficiency of such an installation is considerably reduced.

Certain plants have been arranged to burn dry hogged wood, sawdust, and shavings in furnaces which are also burning coal on underfeed stokers. The wood enters the furnace through chutes and is deposited on top of the coal fire and burns in an atmosphere of carbon dioxide and carbon monoxide without sufficient air. The volatile combustible matter is driven off, and these gases may or may not burn when they mix with the excess air admitted through the wood chutes above the fuel bed. This method of operation, however, usually proves to be a smoke nuisance. A certain amount of coal firing by the stokers is required to protect the stokers from the heat of the burning wood.

The bent-tube Stirling type of boiler with extended front walls is now extensively used in modern industrial plants, and

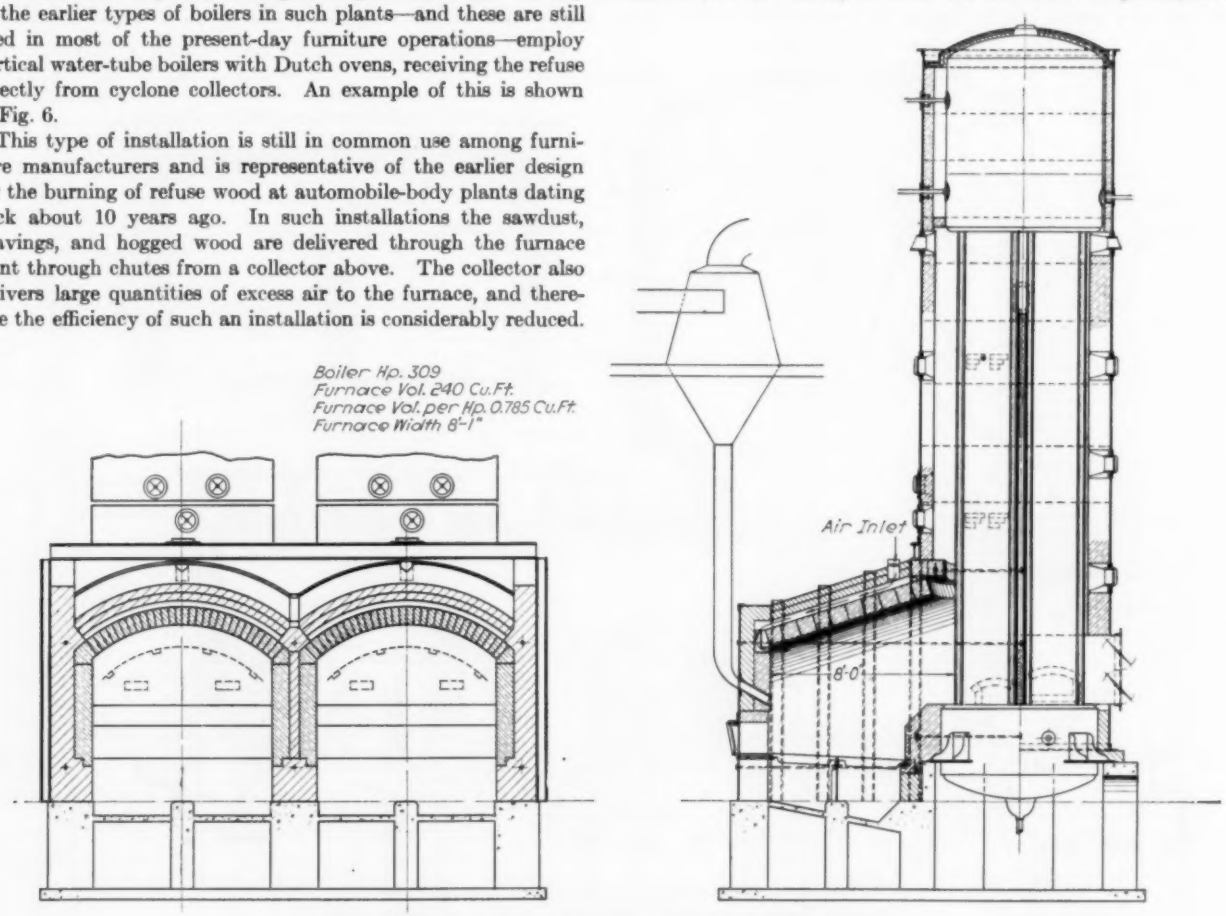

Fig. 6 Dry-Refuse Dutch Oven and 303-Hp. Wickes Boiler
(Original installation of Fisher Body Corporation, Detroit, Mich.)

The combustion space of this furnace is about one-tenth of the combustion space now considered most efficient for the burning of air-dried and kiln-dried refuse wood in suspension. At practically all rates of combustion this boiler and furnace setting would produce dense, black smoke, due primarily to the incomplete combustion of the high-volatile content of the wood and to the flame impingement on the boiler tubes, which produces smoke and soot. Also, certain kinds of refuse wood such as the pines have a large percentage of resinous volatile content which, without complete combustion, is sure to produce dense smoke. An additional air inlet to the furnace is also provided through the air inlet at the upper end of the arch, which serves also to cool the inner sprung arch and at the same time mix with the products of combustion in the upper portions of the furnace.

this type of setting lends itself to the auxiliary firing of the boiler with pulverized fuel as it has been found that the combustion space for burning either wood in suspension or pulverized coal is approximately the same.

Another type of boiler setting which is also largely used is the horizontal straight-tube type of boiler set over the top of the furnace. This arrangement has given very satisfactory operation. However, the Stirling type and the horizontal straight-tube boiler have their respective advantages, depending on the arrangement in the boiler plant and the floor-space and headroom requirements.

St. Louis Wood-Burning Boilers

Immediately after the World War, when one of the body-

manufacturing plants of the General Motors Corporation was being designed for St. Louis, a study of existing plants was made and the boiler setting shown in Fig. 7 was finally decided upon. In this setting it will be noted that the wood is fed through the arches of a double Dutch oven located in the basement below the main firing aisle of the boilers. This plant contained three stoker-fired coal-burning boilers set at the same elevation as shown in Fig. 7, with underfeed stokers operated from the main floor, and four wood-burning boilers set in batteries of two each with the Dutch-oven wood-burning furnaces in the basement in the relative position occupied by the ash bunker

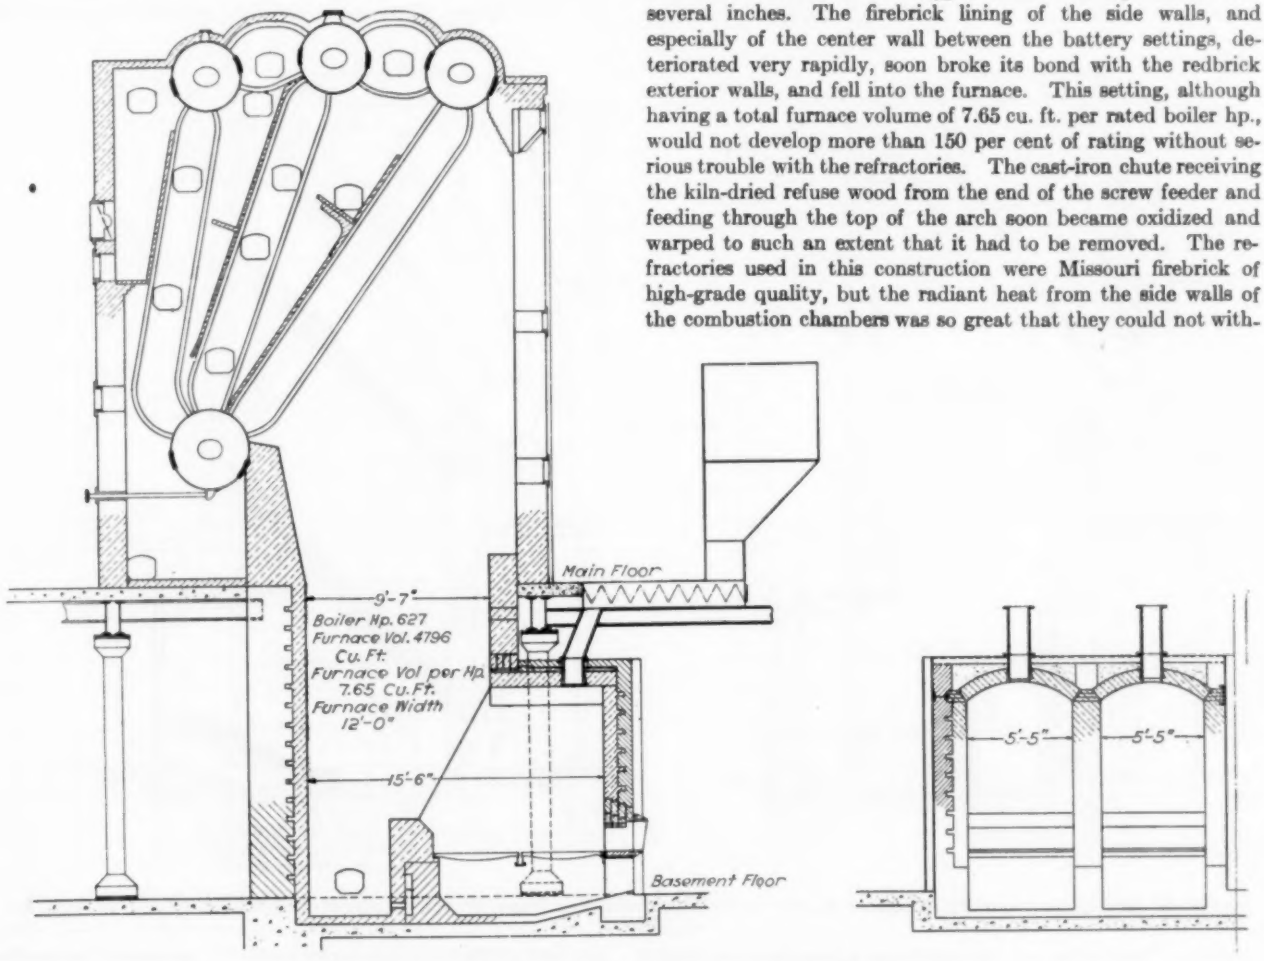

FIG. 7 ORIGINAL SETTING FOR BURNING DRY WOOD REFUSE
(627-hp. Stirling boiler, Chevrolet Motor Co., St. Louis, Mo.)

and the forced-draft duct of the stoker-fired boilers. The Dutch-oven combustion chamber consisted of two compartments separated by a center wall. Above the sprung arches of the two small combustion chambers, a sprung arch supported the curtain wall, sealing the boiler setting inside of the main front wall above the main floor line. This wood-burning setting was considered to be the most up-to-date of its kind at the time. However, at the time this installation was made the effect of reflected radiant heat on refractories and the most advantageous exposure of boiler tubes to the source of heat in the furnace were not fully understood. In this setting, it will be noted that provision is made for removing ashes from beneath the grates and that a cinder chamber at the rear of the bridgewalls is provided to which air is admitted through the bridgewalls. It is of interest to note that no ashes were ever accumulated in the ash-pit, as the draft through the grates would not permit the light ash to fall through. Also very little cinder collected in the back of the boiler setting. Ash removal in wood-burning settings is not a problem, for there is practically no ash.

After these furnaces had been in operation for a time the brickwork in the combustion chambers was found to suffer from overheating, and the sprung arches over the top as well as the curtain wall above the arches began to sag. The center wall between the combustion chambers melted to a considerable degree, and the entire center wall sagged so that the top was lowered several inches. The firebrick lining of the side walls, and especially of the center wall between the battery settings, deteriorated very rapidly, soon broke its bond with the redbrick exterior walls, and fell into the furnace. This setting, although having a total furnace volume of 7.65 cu. ft. per rated boiler hp., would not develop more than 150 per cent of rating without serious trouble with the refractories. The cast-iron chute receiving the kiln-dried refuse wood from the end of the screw feeder and feeding through the top of the arch soon became oxidized and warped to such an extent that it had to be removed. The refractories used in this construction were Missouri firebrick of high-grade quality, but the radiant heat from the side walls of the combustion chambers was so great that they could not withstand the temperature. Another point of interest in the design of this setting is that the sprung arches are covered with concrete slabs for insulation, thus retarding the radiation of heat and causing the arches to fail all the more rapidly.

The correction of these difficulties was made as shown at the left in Fig. 8. It will be noted in this sketch that the center wall of the Dutch oven was removed and the two sprung arches of the combustion chamber were replaced with one suspended arch. No attempt was made to admit air through the bridgewall. The curtain wall was reconstructed on supporting I-beams and a small, thin secondary curtain wall was constructed inside the other and supported on the nose of the suspended arch. The firebrick lining of the rear wall and side wall was increased in

thickness from 9 in. to 13½ in. This setting is much more successful in operation and in refractory maintenance than the preceding installation. It was still found, however, that 150 per cent of rated capacity was the maximum that could be obtained, even with this setting. The side-wall linings constructed of first-quality Missouri firebrick would erode at the rate of 1 in. to 1¼ in. per month, and would require relining every 90 days.

The next step in the development of this installation occurred when it became desirable to increase the capacity of the station for the generation of steam with coal as a fuel when there was insufficient supply of wood. At this time it was decided to install water-cooling protection for the side walls and the upper portion of the bridgewall, and introduce a powdered-coal burner above the main floor as shown at the right in Fig. 8. This construction was carried out in three of the four wood-burning boilers. The protection of the refractory side walls was taken care of by the installation of inclined fin-tube water-cooled construction with vertical headers beneath the mud drum and above the main floor as indicated. There are four 4-in. water-supply connections from the mud drum to each lower vertical header and four 4-in. connections from the upper horizontal extension of the upper vertical header into the front steam drum. The upper part of the bridgewall is protected by fin-tube construction from a water header at the rear and extending to the upper steam drum in front of the main bank of boiler tubes. A burner for pulverized coal was placed in the front wall of the setting. The other alteration consisted in removing the flat grates and installing a Drake patented step grate with refractory facings as shown. Air under fan pressure passes through small nozzles in the steps and horizontally through slots under damper control in the risers of each step. Thus the larger chips (hogged wood) which do not burn in suspension fall to the step grate and are burned by the impinging air. The wood-burning alterations were undoubtedly an improvement over the old. It is interesting to note that it has been possible by the addition of the pulverized-coal-burning equipment to operate the boiler at higher continuous ratings than before. In normal operation about 150 per cent of rating is obtained with wood; pulverized-coal fuel is then added at such a rate that the steam output is increased to 250 per cent of rating, and this seems to be about the maximum continuous steam generation that can be reasonably expected of this installation. These units are used for producing about 88 per cent of the total steam generated, the remainder being generated by the stoker-fired boilers.

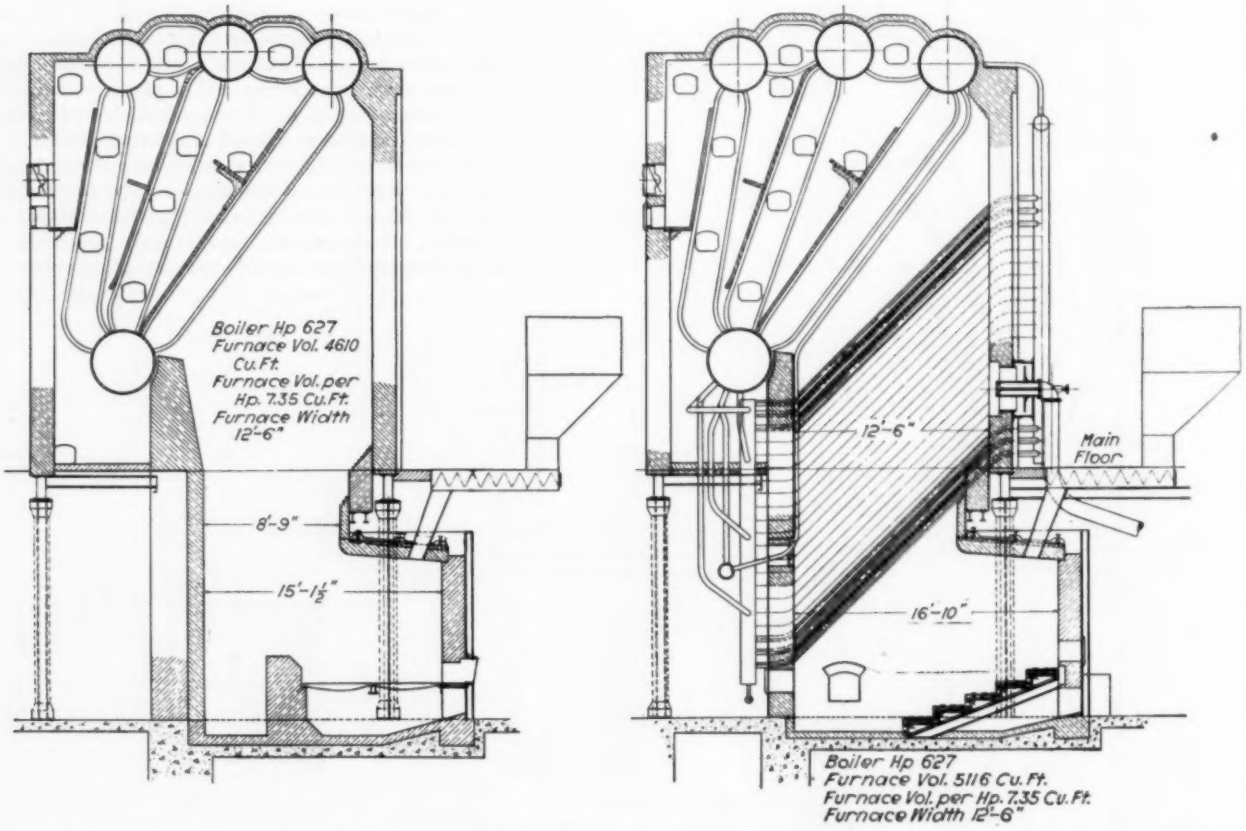

FIG. 8 ALTERATION AND FINAL ARRANGEMENT OF FURNACE AND SIDE-WALL WATER COOLING OF FURNACE SHOWN IN FIG. 7

DETROIT WOOD-BURNING BOILERS

Fig. 9 shows a cross-drum Heine boiler which was the first attempt of one of the large automobile-body manufacturers to employ the principle of air cooling to the side walls. On account of structural conditions in the building, it was impossible to extend the air cooling below the main floor. Consequently the lower half of the combustion chamber is restricted in width and is of solid-refractory construction. This setting is also provided with herringbone grates covering the entire bottom of the furnace. It will be noted in this layout that the air may be supplied either to the space below the grates or above them. This setting is a natural-draft setting in which the air is drawn through the horizontal passages in the side and rear walls, to a collecting duct at the rear wall, passing through ducts into the

air ports on either side of the setting as indicated. The operation of this unit was quite satisfactory, although there was still considerable maintenance required in the lower portion of the combustion chamber where solid walls were still used. It was found that the hogged wood which was not burned in suspension would accumulate on the grates to a depth of three or four feet except at the side-wall ports where the incoming air would cause rapid combustion, and the wood would burn as fast as it fell in these regions. It may also be observed that whenever the front doors of the setting were opened the wood would burn rapidly owing to the admission of air through the doors. In observing the burning of this fuel from air introduced beneath the grates, it was found that the combustion took place at the depth of three or four feet in the center because of insufficient contact with air, until the wood falls into the streams of air through the side ports and is consumed as fast as it falls. This type of setting has proved quite satisfactory in operation. The furnace linings are held to the outside wall by means of refractory blocks and hook irons as shown, with a 9-in. firebrick wall between each row of blocks. Air is admitted at the front of the boiler, passes around the side walls, and is collected at the rear with a fan, which is also provided with a bypass for natural-draft operation when desired, and enters through the side ports near the furnace bottom.

The life of the refractories in the side wall of this setting averages approximately 18 months, during which time the surface

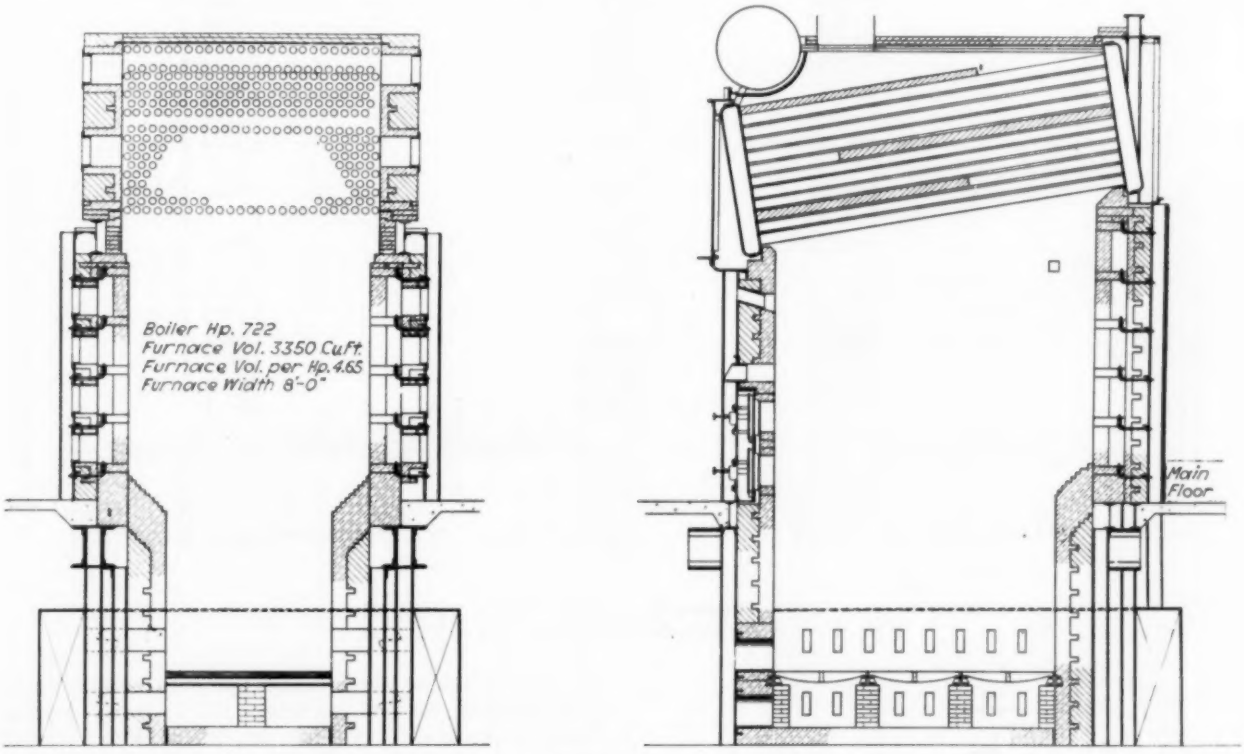

FIG. 9 FIRST DESIGN OF AIR-COOLED FURNACE FOR 722-HP. HEINE BOILER
(Fisher Body Company, Detroit, Mich.)

surface of the pile in small craters of a miniature volcanic nature. From observations taken here it was noted that dry hogged-wood refuse burns from the surface of a pile of fuel and not throughout the entire mass, as would be expected in the case of burning slabs, edgings, or pieces of considerable size.

As the next step in the development of wood-burning-boiler settings for this body manufacturer it was decided to eliminate the grates altogether and burn the wood from the floor of the furnace. The longitudinal cross-section of Fig. 10 shows the method of collecting the air from the horizontal ducts with a fan, which also forces the air into the furnace through the ducts and ports shown in the transverse cross-section. The central duct was provided to supply air to a pulverized-fuel burner for auxiliary firing in case it should be desired to add this feature to the unit at some future time. There is also shown a small port connecting with the outside of the top of the lateral ports which permits the use of steam or air lances for the purpose of stirring up the wood which accumulates in the center of this setting. Here again the hogged wood will pile up to a maximum erodes back from the original surface to the extent of approximately $4^1/_2$ in.

OTHER RECENT DESIGNS

The setting shown in Fig. 11 was a development designed after the one shown in Fig. 10 had been placed in operation. This furnace was designed to burn all the wood as it fell to the bottom of the furnace by introducing the air for combustion through the side walls of the boiler setting through comparatively small ports and at high velocity. The illustration shows the air being taken from the side walls, where it is admitted at both the top and the bottom of vertical ducts in the side walls, to a central collecting duct and after passing through the fan is delivered either to the wood-burning ports or through a riser to the pulverized-coal burner in the front of the boiler setting for auxiliary firing. The wood is admitted through four supply chutes in the upper portion of the front wall about 16 ft. above the furnace floor.

A test was run on this setting to determine the amount of air

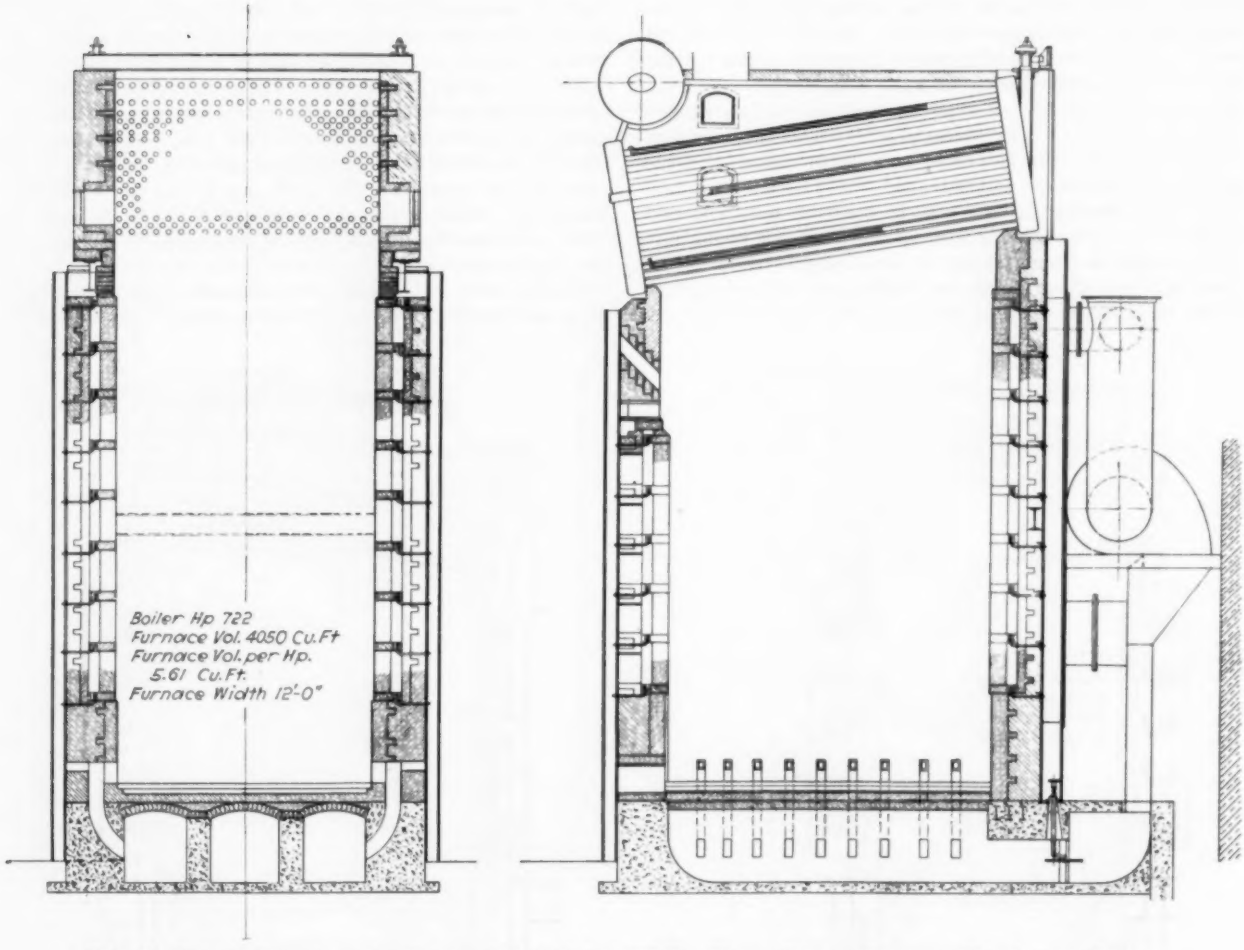

FIG. 10 SECOND DESIGN OF AIR-COOLED FURNACE FOR 722-HP. HEINE BOILER BURNING KILN-DRIED REFUSE
(Fisher Body Company, Detroit, Mich.)

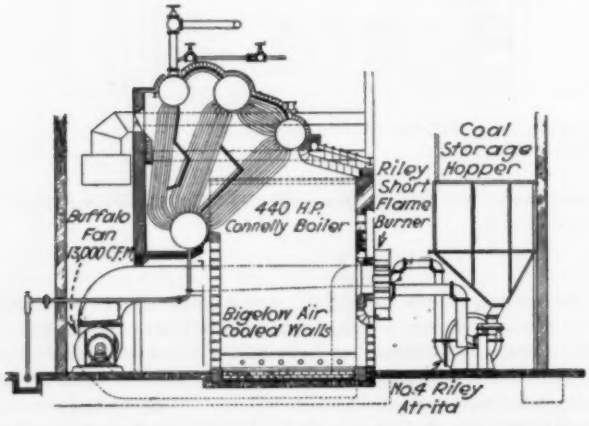

FIG. 11 DRY-REFUSE FURNACE WITH HIGH-VELOCITY AIR PORTS
(440-hp. Connelly boiler, General Motors of Canada, Ltd., Oshawa, Ont.)

required through the lower ports. This test was run at an average load of 836 hp. on the 440-hp. boiler, which is 190 per cent of rating, and it was found that the air required through the lower ports for combustion with CO_2 at 17 per cent, which corresponds with 18 per cent excess air, was 32 per cent of the total air required for combustion. The remainder of the oxygen required for combustion was contained inherently in the wood itself, and was also admitted through the wood chutes from the stoker supplying wood to the furnace and by leakage through the side walls and arch. The ports are designed with a tapering nozzle to provide a velocity of air under this condition of operation of about 4500 ft. per min. The shavings and sawdust burn in suspension before falling to the floor and before coming in contact with the front bank of boiler tubes. In this setting the hogged wood which dropped to the bottom was consumed as rapidly as it fell, and there was no accumulation whatever of wood or cinders on the furnace floor.

The design for the furnace shown in Fig. 12 provides for the collection of the air at the top of the vertical air-ducts in the walls of a boiler setting; this is the natural course for heated air to take, due to the chimney effect or draft produced by the heated air. The air is collected from the top of each of the vertical ducts by a horizontal collecting duct connecting to the suction of a fan. The delivery of the air from the fan is through the steel ducts at the side of the boiler setting at the bottom, and through small tapered ports as shown for delivering the air impinging on the floor of the furnace at high velocity. The operation of this boiler has been entirely satisfactory from the start. No wood accumulates on the bottom of the setting. The furnace is also arranged for auxiliary firing with pulverized coal, the burner being placed in the front wall of the boiler setting. This furnace, however, is rather narrow, and the reflected heat from one side wall to the other may result in overheating of the re-

fractories, and flames from the coal burner may impinge on the side walls to an extent which would not be the case if the furnace were of wider design.

Fig. 13 illustrates an air-cooled wood-burning furnace in which the wood is introduced through four ports in the front wall of the furnace setting and air is admitted through tapered side ports inclined toward the bottom after it has passed through cooling ducts beneath the furnace floor and through the vertical ducts of the side-wall cooling system. This unit has recently been reconstructed as shown with a furnace width of 14 ft. to replace two furnaces each 7 ft. 2 in. in width with an air-cooled center wall between them. On account of the narrow width of the old furnaces and the absence of cooling in the side walls, the refractory maintenance was excessive and it was necessary to of a fan, the fan delivering it to the two outside ducts under the bottom of the furnace, which in turn supply the air for combustion through the side ports at an average velocity of 1700 ft. per min. when operating at about 160 per cent of rating. In this installation the wood accumulates to a depth of about three feet at the bottom of the furnace as in cases previously mentioned (Figs. 9 and 10), but since no ash is deposited by the burning of gas in the auxiliary burners, this piling up of fuel is not objectionable. The operation of this setting has been most satisfactory. The control of the boiler is easily handled, and short-run tests made on the boiler indicate that it is a decidedly efficient installation.

The Stratton furnace which is designed for burning finely crushed coal in suspension has been tried with kiln-dried wood refuse as a fuel. This furnace has a hopper bottom with steep

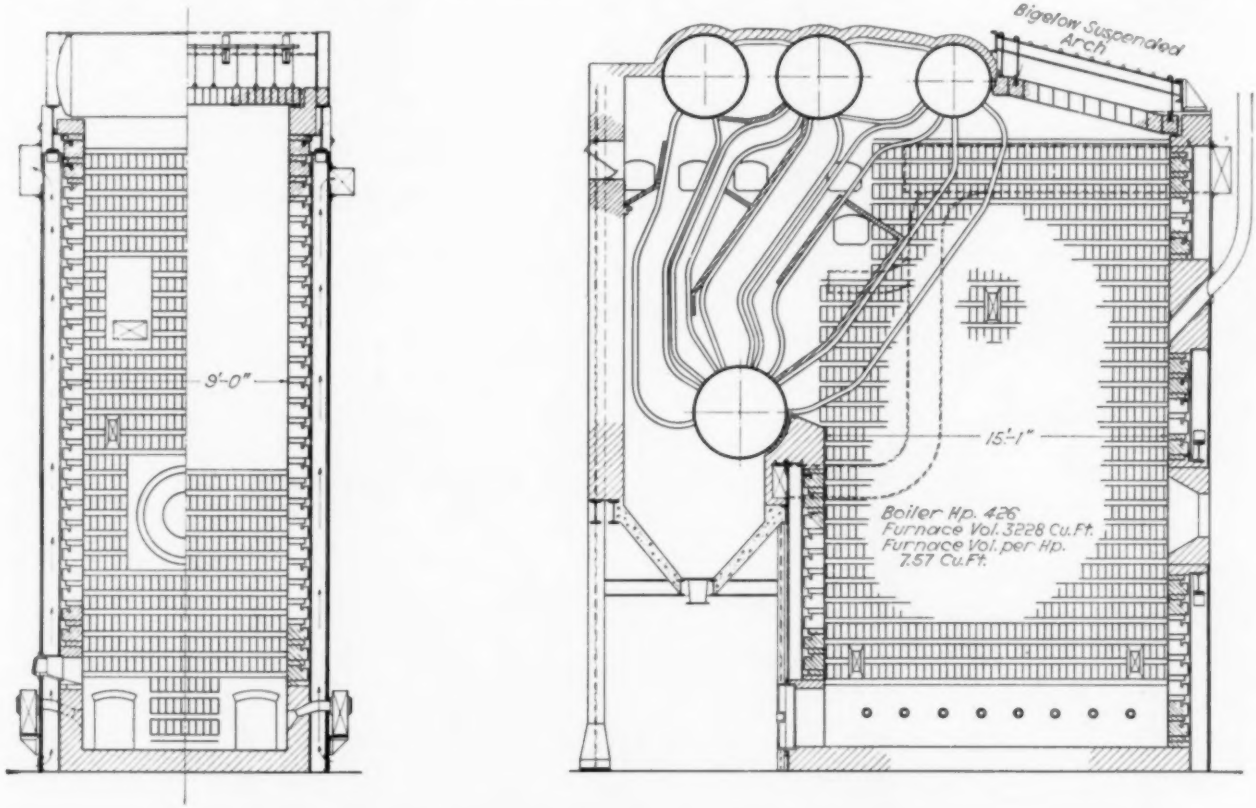

FIG. 12 DRY-REFUSE FURNACE AND 426-HP. STIRLING BOILER
(Rudolph Wurlitzer Company, North Tonawanda, N. Y.)

entirely rebuild the setting. Accordingly, the two 250-hp. cross-drum B. & W. boilers, formerly in battery setting, were combined into one by eliminating the center wall, moving the two banks of tubes together and installing a new cross-drum.

The installation shown in Fig. 14 is one of the most recent installations of an automobile-body plant. This boiler is fired with refuse wood from kiln-dried lumber used in the construction of automobile bodies, and natural gas is used for auxiliary firing, when wood is not available at night or during week ends. The boiler has 8870 sq. ft. of heating surface, and the water-cooling surface of the side walls is 540 sq. ft. Allowing 4 sq. ft. of surface per horsepower in the side-wall tubes, the combined rated capacity of boilers and walls is 1022 hp. In this setting the two side walls are water cooled with fin-tube construction; the front portion of the side walls and the rear walls are cooled with vertical air ducts through which air is drawn to the suction sides and a comparatively small grate so designed that the required amount of air will have sufficient velocity to keep the burning fuel in suspension until it is completely consumed. The trial, however, was not of sufficient duration, and the rates of steam generation were too low to prove much concerning the adaptability of the furnace for burning wood in continuous operation. However, the idea appears to be a good one, and if an installation were made with proper methods of controlling the wood entering the furnace it is quite probable that a satisfactory dry-wood-burning furnace would result.

An interesting design of dry-wood-refuse furnace was installed at Pekin, Arkansas, last year. Two 506-hp. boilers were set with the Drake patented wood-burning system consisting of air-cooled walls lined with interlocking refractory blocks 4 in. in thickness and refractory-faced step grates. The air was supplied by a fan, passing first through the side walls where it was pre-

heated, then entering the furnace through jets located in the front wall below the wood chutes and through the vertical and horizontal ports in the step grates. This setting has not been subjected to severe service, but the operating results thus far have been entirely satisfactory, and it presents features of unusual interest.

Conclusions

For burning green or wet wood refuse, considerations in the design of the furnace include the average moisture content of the fuel and the relative proportions of sawdust, shavings, hogged wood, and larger pieces.

The ignition arches should be designed to promote the maximum evaporation of moisture and volatilization of the wood. If possible, preheated air should be provided to further promote combustion in the furnace. Because of the low combustion temperatures of wet or green wood refuse, standard brands of firebrick may be used. The furnace volume should be liberally designed and be arranged with a primary combustion chamber for drying, volatilization, and ignition, and a secondary combustion chamber for further and complete burning of the volatile gases. In the case of the setting shown in Fig. 5, which is typical of recent practice, the primary ignition chamber has a volume of 3.3 cu. ft. per rated boiler hp. and the secondary combustion chamber 3.2 cu. ft. per hp., or a total combustion space of 6.5 cu. ft. per hp.

For burning dry wood refuse, the furnace should be arranged to satisfactorily meet the following conditions:

1 General arrangement of the setting as a whole with respect to the boiler to be used;
2 If supplementary firing with other fuel than wood is required, the furnace must also be designed to suit the auxiliary firing equipment decided upon;
3 The maximum rate of steam generation desired; and
4 The walls should be designed to insure minimum refractory maintenance for the rate of heat liberation per cubic foot of furnace volume decided upon.

The first two of these conditions are entirely dependent upon the requirements of any particular case, and upon decisions which do not affect the volumetric proportions of the furnace.

The maximum rate of steam generation, however, requires for any boiler a quite definite furnace volume for satisfactory smokeless combustion. To produce rated capacity of a boiler (i.e., 34.5 lb. evaporation per hour from and at 212 deg. fahr. per 10 sq. ft. of heating surface) would require a heat liberation in the furnace of 47,890 B.t.u. per hour per boiler hp. if we assume an efficiency of the boiler and furnace of 70 per cent. If it is desired to operate the boiler at higher rates of evaporation per 10 sq. ft. of heating surface, the heat liberation in the furnace will increase accordingly.

Table 2 is offered as representing good practice for rates of heat liberation for different wall constructions and the corresponding furnace volumes of varying rates of steam generation, assuming 70 per cent efficiency at all ratings.

The trend of increasing furnace volume per rated boiler horsepower for burning dry wood is indicated by some of the recent designs described in this discussion which average 7.4 cu. ft. of furnace volume per rated boiler hp. as compared with 0.8 cu. ft. per hp. in the Dutch-oven construction of the vertical water-tube boilers which were formerly so extensively used.

TABLE 2 CUBIC FEET OF FURNACE VOLUME SUGGESTED PER 10 SQ. FT. OF BOILER HEATING SURFACE

Type of furnace wall	Maximum rate of heat liberation, B.t.u. per cu. ft. per hr.	Maximum desired rate of steam generation: Normal rating, cu. ft.	200 per cent of rating, cu. ft.	300 per cent of rating, cu. ft.
Solid standard firebrick walls	11,000	4.35	8.70	.....
Special 60 per cent alumina firebrick walls	14,000	3.42	6.84	10.26
Air-cooled wall construction	17,000	2.82	5.64	8.46
Air-cooled walls with water-cooling protection	20,000	....	4.79	7.15

Although refractories are procurable containing up to 80 per cent of alumina in the form of mullite which will withstand extremely high temperatures and no doubt give good service in a furnace burning kiln-dried wood refuse, the cost of furnaces constructed with these brick would be greater than for air-cooled wall construction with standard 40 per cent alumina content refractories, and the additional cost is not economically justifiable.

The furnace construction which will require the least expenditure in maintenance is without doubt the air-cooled wall laid up with standard first-quality firebrick with a certain amount of water-cooling protection. The extent and distribution of the water tubes along the side walls must be carefully determined and not overdone to the extent of lowering the temperature in the combustion space so that smokeless combustion of the wood refuse becomes impossible.

Discussion

R. L. Beers.[2] For burning wet wood refuse, there are many plants in operation that use mechanical stokers. The underfeed stoker has been very successful for this application. It is customary to set the stoker in an extension furnace, coal is fed into the furnace with the underfeed stoker, and the wood is spouted into the furnace through an opening in the roof. With this arrangement, wood of high moisture content can be burned at high rates of combustion, due to the hot coal fire underneath and the reflected heat from the brickwork above.

Due to the rapidity at which wood is burned, if the supply is stopped, the wood in the furnace is quickly exhausted, and then it is important to have an auxiliary means for carrying the load. When this occurs, the load can be quickly picked up and carried entirely with a straight coal fire. In some plants, with wood under 50 per cent moisture content and ample supply, the load is carried on straight wood, and the stoker is held in reserve for emergency use or for periods when there is insufficient supply to carry the load.

The underfeed stoker, with most Eastern coals, does not depend upon reflected heat for ignition, and a coal fire can be carried with a deep pile of wood over it. With an overfeed type of stoker, wet wood cannot be so successfully handled, as the fire seems to be smothered.

There are many small plants that use wood for generating part of the steam. In most of these plants, kiln-dried wood is used. With this fuel, ignition arches are not necessary. In these small plants, reserve boiler capacity is not always available, and it is quite essential that auxiliary fuel-burning equipment be used. Stokers have been widely applied for burning coal in conjunction with sawdust, shavings, and kiln-dried wood.

The furnace setting with a stoker is practically the same as for burning straight coal. An extension furnace is usually not necessary. The wood is spouted into the furnace through the front wall, and most of the wood is burned in suspension. Care should be exercised, however, to get ample furnace volume, depending upon the load and the percentage of wood being burned, and provision should be made to admit a large volume of air over the coal fire. It is also important that the wood supply be controlled with the air supply and vary with the load. With dry wood, used in conjunction with underfeed stokers, straight wood can be burned over long periods, but it is advisable to

[2] Vice-President in Charge of Engineering, Detroit Stoker Company, Detroit, Mich. Assoc-Mem. A.S.M.E.

fill these retorts with ashes and to admit some air through the tuyères to protect the ironwork.

With dry wood, high furnace temperatures, with resultant short life of brickwork, are frequently experienced, particularly with high boiler settings, but this is caused to a great extent by the large amount of brickwork in proportion to the heating surface of the boiler exposed to the radiant heat of the furnace. With wood free from foreign material, and providing furnace water-tube area equal or greater in proportion to what is commonly used with straight coal-burning furnaces, the brickwork maintenance should not be excessive.

L. S. Cockburn.[3] For the past ten years, the writer has been directly connected with the problem of burning kiln-dried wood waste.

In the early days it was looked upon as merely a method of disposal of this waste product with the generation of such steam as could be had from it. In most cases there was more than enough fuel available to produce all the steam required, and efficient operation meant nothing. The question of smoke emission had not arisen, and furnace maintenance was more or less taken for granted.

New processes came into use requiring steam, and more efficient manufacturing methods reduced proportionately the quantity of wood waste available as fuel. It became necessary to purchase fuel for steam generation.

Then, the efficiency of operation meant something, and steps were taken to find out just what was going on, and development took place leading up to what we now have, going through the stages as outlined by Mr. Gladden.

As Mr. Gladden stated, furnace volumes ten years ago were small. The 400-hp. boilers then in use had only 288 cu. ft. of furnace volume. Our latest installation of about 1000 hp. has 4700 cu. ft. of furnace volume. In other words, the rated horsepower of the unit has only increased two and one-half times, while the furnace volume has increased sixteen times.

The writer wishes to point out that the proper furnace design is not the end of the problem. The method of feeding the fuel is important. The feed must be uniform, without belching, and it must be directed to feed into the furnace at the proper points and at the proper angle.

There is one installation we made several years ago that has proved very satisfactory. In this installation, we are using a chain-grate stoker designed for wood-burning. When this installation was first made, considerable trouble was encountered. We attempted to carry the fuel so as to burn out at the end of the grates. This resulted in the grates becoming red hot, warping, and breaking. After some time, it was found that the fire should be burned out a little over half the length of the grates and the air allowed to pass through the grates at the rear end, cooling the grates.

The maintenance on both furnace and stoker has been very reasonable, but the main objection has been that, when wood fuel is not available, the boiler is down, as coal cannot be burned on that type of chain grate satisfactorily.

Mr. Gladden mentioned our latest installation at Memphis, Tenn., and shows a section of this boiler in Fig. 14. We have some figures on the operation of this boiler that might be of interest.

In the first place, this boiler is equipped with a Pratt & Daniels Thermix stack, the fan being driven by a steam turbine, as is the forced-draft fan, and is provided with automatic control. This combination has given us very flexible operation and when set for any desired operating condition, this condition is maintained within a very close range.

When the unit was first placed in operation last November, tests were made to determine the most efficient operating conditions for different ratings. While we were unable to measure the quantity of fuel burned, we were, however, able to make some comparisons as to quantity from the speed of the screws on the fuel feeders.

(25)	B.t.u. release per cu. ft. furnace volume per hour	17,300

[1] In connection with the tests on natural gas, it is pointed out that the efficiency as shown does not check with that found in calculating a heat balance using the fuel analysis given. The heat balance shows an efficiency of 79 per cent. The discrepancy probably is due to the gas having a higher heat content than the figure used, which would reduce the test results, and also to the gas having a lower methane content and a higher ethane content, which would reduce the hydrogen content, and therefore the losses due to combustion of hydrogen, which would increase the efficiency as found from the heat balance, bringing both results in closer agreement. The heat value and analysis were taken from data furnished by the utility furnishing the gas.

Runs were also made carrying high percentages of CO_2 in the flue gas to determine the effect on the refractories. We found that up to 16 per cent CO_2 and over 80,000 lb. steam per hour generated for a period of several hours, there was no effect on the brick. In our air-cooled jobs, with CO_2 as high as this and at comparable ratings, the refractories would show signs of distress in less than two hours.

The test results given in Tables 3 and 4 were obtained during the trial period in November.

As there was no method of weighing the wood fuel, it was necessary to compute the heat balance, assuming the radiation and unaccounted-for loss, but it is believed that the figures are reasonably correct.

The gas consumption for the natural-gas run was taken from the meter furnished by the gas company from which they bill for gas consumed, so that it can safely be assumed that the quantity shown is not low.

The steam flow was taken from a Bailey meter, which was put in service the day before and also was re-checked afterward by the service man.

One further item that may be of interest is a comparison of the costs of an air-cooled installation as against the combination of water walls and air-cooling. For this purpose, there is compared a unit rated at 1000 hp. with air-cooled walls against the Memphis unit. The costs omit all items that are common to both units and consider only the boiler, water walls, erection, and furnace construction.

COMPARISON OF BOILER AND FURNACE COSTS

	1000-hp. air-cooled	887-hp., 540-sq. ft. water wall
Boiler only	$12,724.00	.....
Boiler and water walls	.....	$24,616.00
Erection and brickwork	17,792.00	14,833.00
Totals	$30,516.00	$39,449.00
Maximum steaming rate, lb. per hr., without excessive maintenance	62,000	90,000
Cost per 1000 lb. of steam per hr	$ 49.76	$ 43.84

Up to May 1, 3912 hours have elapsed since the boiler was first put on the line. Of that item, it has been in service 3181 hours, and of that period it used wood waste as fuel for 2797 hours and natural gas for 384 hours.

Steam generated from wood waste was 120,000,000 and from natural gas 16,063,860. Gas consumed was 20,334,000 cu. ft., having a heating value of 960 B.t.u. per ft., or an actual evaporation of 790 lb. steam per 1000 cu. ft. of gas.

The first shutdown was in March, for about one week, to replace the fan wheel in the induced draft fan, and again in April, to make some changes in the fuel feeders.

An inspection of the furnace showed no signs of any deterioration of the refractories and it was apparently in as good condition as when first started up.

One of our plants is having trouble, due to an unlooked-for condition. The wood waste at this plant contains a considerable amount of glue, which is made from soyo beans, mixed with sodium silicate and caustic soda. This mixture, together with the potash from the wood ash, has caused a rapid breaking down of the refractories, as well as a bad slag condition on the grates. The use of water-cooled grate bars has aided considerably, but we have not yet decided what we will do with the walls. This is a comparatively small installation, without air-cooled walls.

Incidentally, as an experiment, we are trying out the use of monolithic walls in several furnaces, and while this material has been in use too short a time to make any statements as to its life compared to brick, the present indications are very favorable.

H. S. Colby.[4] Mr. Gladden is to be congratulated on the completeness of his presentation of this very interesting subject. The burning of fuels of high moisture content presents problems in the design and construction of furnaces quite different from other solid fuels.

It has been the writer's good fortune to have been closely associated with the burning of solid fuels for some years and to have had an opportunity to study the development of furnace designs for the burning of a wide variety of fuels, including some of the high-moisture-content fuels, such as hog wood refuse, bagasse, and lignites of the Northwest.

In presenting his paper the author touched on the fact that he advocated the use of preheated air when burning high-moisture fuels, but expressed regret that he did not have data available on the effect of preheated air on this practice. The writer has been closely associated with the application of preheated air on several high-moisture fuels and will accordingly confine his discussion to the advantages that apparently have been derived from the use of preheated air in this field.

It is obvious that the use of preheated air for the combustion of wet fuel results in an increase in boiler efficiency as a result of reducing the final gas temperature. However, the effect of reducing the fuel consumption is not always of extreme importance in the burning of waste fuel unless it should so happen that the steam demand is in excess of that which can be generated with the waste fuel available. The savings that can be accomplished in the burning of high-moisture fuels with preheated air are considerable, but are in fact secondary to the very pronounced advantage of greatly increasing the steam-generated capacity of the boiler unit with the same furnace volume or within the limitations imposed by the same overall setting dimensions.

The boiler furnace for the burning of waste wood or other high-moisture fuels which most effectively utilizes the preheated air is that furnace design which provides for the distillation of the gases in one section of the combustion chamber and arranges for the subsequent burning of these gases in a secondary combustion chamber of liberal proportions and exposed to the radiant-heat absorption of the boiler tubes. Provision should also be made for the admission of part of the combustion air over the fuel bed and preferably at such a point that it is brought into intimate mixture with the stream of gases liberated from the fuel bed deficient in oxygen. The intimate mixing of this air and contact with the gases, preferably at a point shielded from exposure to the boiler tubes to insure a high temperature at the point of mixing, results in very prompt and complete combustion and in some cases with considerably less excess air than is customarily possible when supplying cold air to the furnaces.

A most satisfactory and representative design for the burning of high-moisture-content wood refuse is the installation at the plant of the Union Bag and Paper Power Company at Tacoma, Wash., from designs of the H. S. Ferguson Company, consulting engineers, shown in Fig. 15. These boilers are operated up to a maximum rating of 250 per cent, at which rating the temperature of the air leaving the preheater is in the vicinity of 400 deg. fahr. We are advised by the management of the plant that with cold air supplied to the furnaces it is possible to obtain only about three-quarters of the steaming capacity that can be obtained when using preheated air.

Another striking example of the advantages of preheated air in the burning of a high-moisture fuel is the installation of the United Sugar Companies at Los Mochis, Mexico. In this plant there are four 500-hp. and four 700-hp. boilers fitted with bagasse-burning furnaces of the type shown in Fig. 16, from a design prepared by the Honolulu Iron Works Company, New York City.

[4] President, Air Preheater Corporation, Wellsville, N. Y. Mem. A.S.M.E.

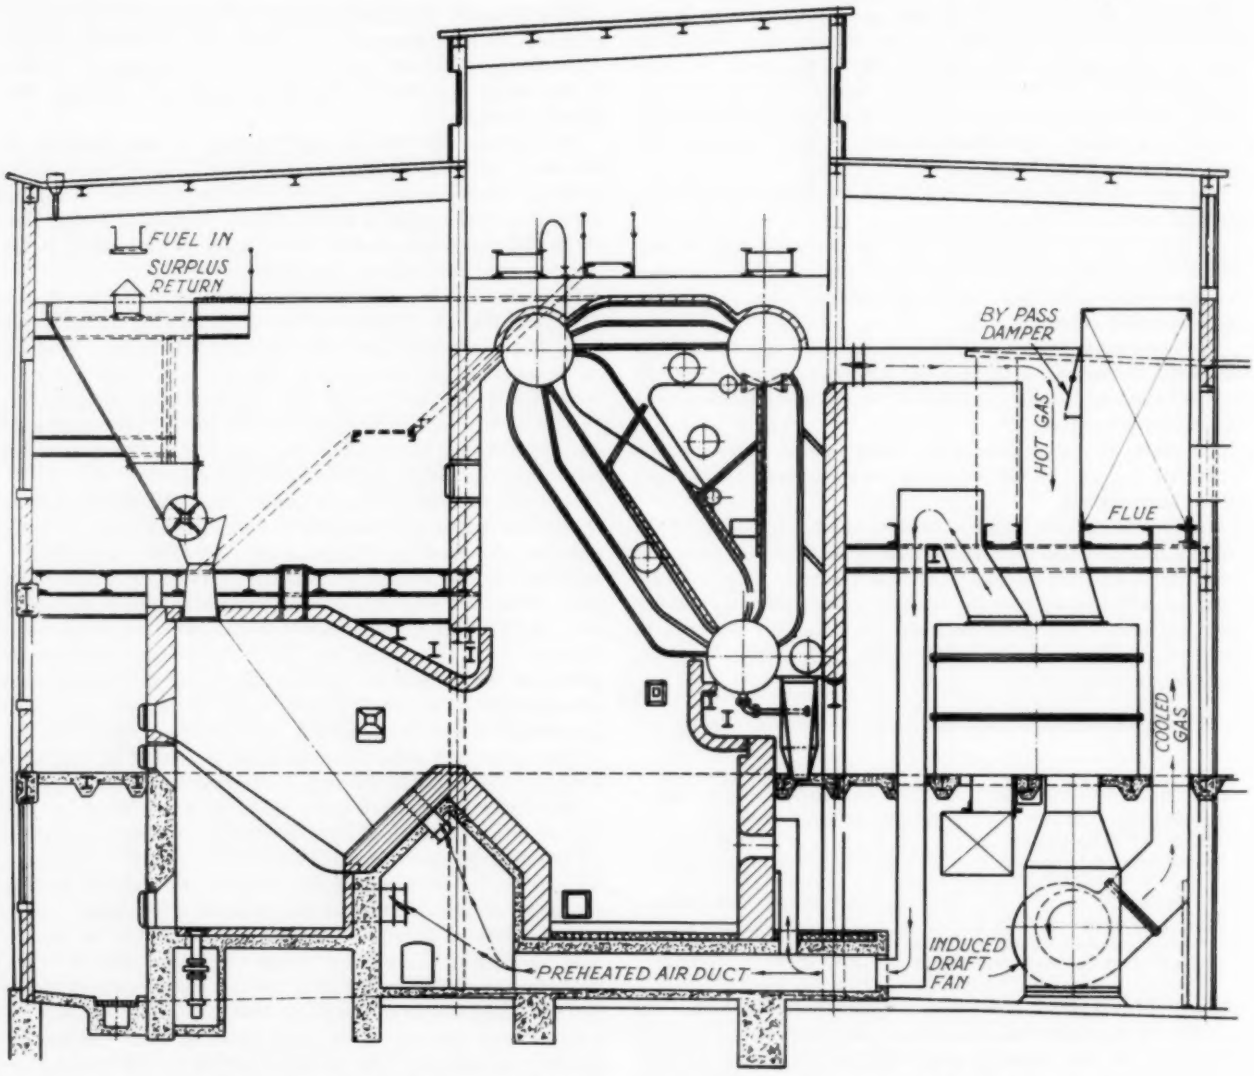

FIG. 15 INSTALLATION AT PLANT OF UNION BAG AND PAPER POWER COMPANY, TACOMA, WASH.

The fuel is bagasse having a moisture content of 40 to 50 per cent. In this plant steam is generated for the driving of the mill crushing the cane and the production of refined sugar. Before using preheated air it was necessary to supplement the bagasse available with fuel oil burned in the secondary combustion chamber of the furnace and in an amount averaging about 7 gal. per ton of cane crushed. The maximum rating that could be obtained from the boilers was in the vicinity of 85 per cent of boiler rating.

TABLE 5 COMPARISON OF PERFORMANCE WITH AND WITHOUT PREHEATED AIR, LUGNVIK SAW MILLS, LUGNVIK, SWEDEN

	With preheated air	Without preheated air
Moisture content of fuel, per cent	49.1	45.8
Fuel consumption per hour, lb	5511	5390
Fuel consumption per hour and sq. ft. grate surface, lb	93.5	91.5
Water evaporated per hour, lb	12,720	11,023
Water evaporated per hour and sq. ft. heating surface, lb	6.53	5.66
Average steam pressure, lb. per sq. in	263	263
Average temperature of steam, deg. fahr	648	637
Temperature of feedwater, deg. fahr	198	196
Temperature of flue gases entering air preheater, deg. fahr	552	.....
Exit temperature of flue gases, deg. fahr	303	.....
Temperature of air entering air preheater, deg. fahr	82	48
Temperature of air leaving air preheater, deg. fahr	456	.....
Temperature of flue gases leaving boiler, deg. fahr	568	539
CO_2 contents at boiler damper, per cent	14.75	14.62
Efficiency of boiler, per cent	73.0	60.4

Some two years ago one preheater was installed furnishing preheated air to four of these boiler units. It was found that the boilers operating on preheated air could be increased in steaming capacity from 85 to 135 per cent of rating. The preheating of the combustion air to a temperature of approximately 400 deg. fahr. resulted in a fuel saving which reduced the auxiliary fuel oil from 7 gal. to about $2^1/_2$ gal. per ton of cane crushed. The second preheater installed and placed in operation during the last grinding season, which now supplies the remaining boilers with preheated air, has resulted in a further economy, so that it is now possible to operate the entire boiler house at a rating of 135 per cent and without auxiliary oil fuel.

It is unfortunate that operating tests are not available on either of these installations so that a direct comparison of the performance with and without preheated air would be available.

However, Table 5 gives comparative performance data ob-

tained on an installation at the Lugnvik Saw Mills, at Lugnvik, Sweden. The furnace design (Fig. 17) parallels very closely the design used in this country, providing means for delivering air under pressure through the bridge wall and over the arch for the admission of secondary air into the gas stream passing up from the combustion chamber, which is located below the boiler room operating floor. The boilers are of the Babcock & Wilcox type, having a heating surface of 1949 sq. ft. and provided with a grate surface of 58.9 sq. ft. The fuel used is hog waste fuel having a moisture content as indicated in the table. It will be observed in this instance that the evaporation when using preheated air has been increased approximately 15 per cent, although the writer is not in a position to state whether this represents the maximum capacity that could be obtained.

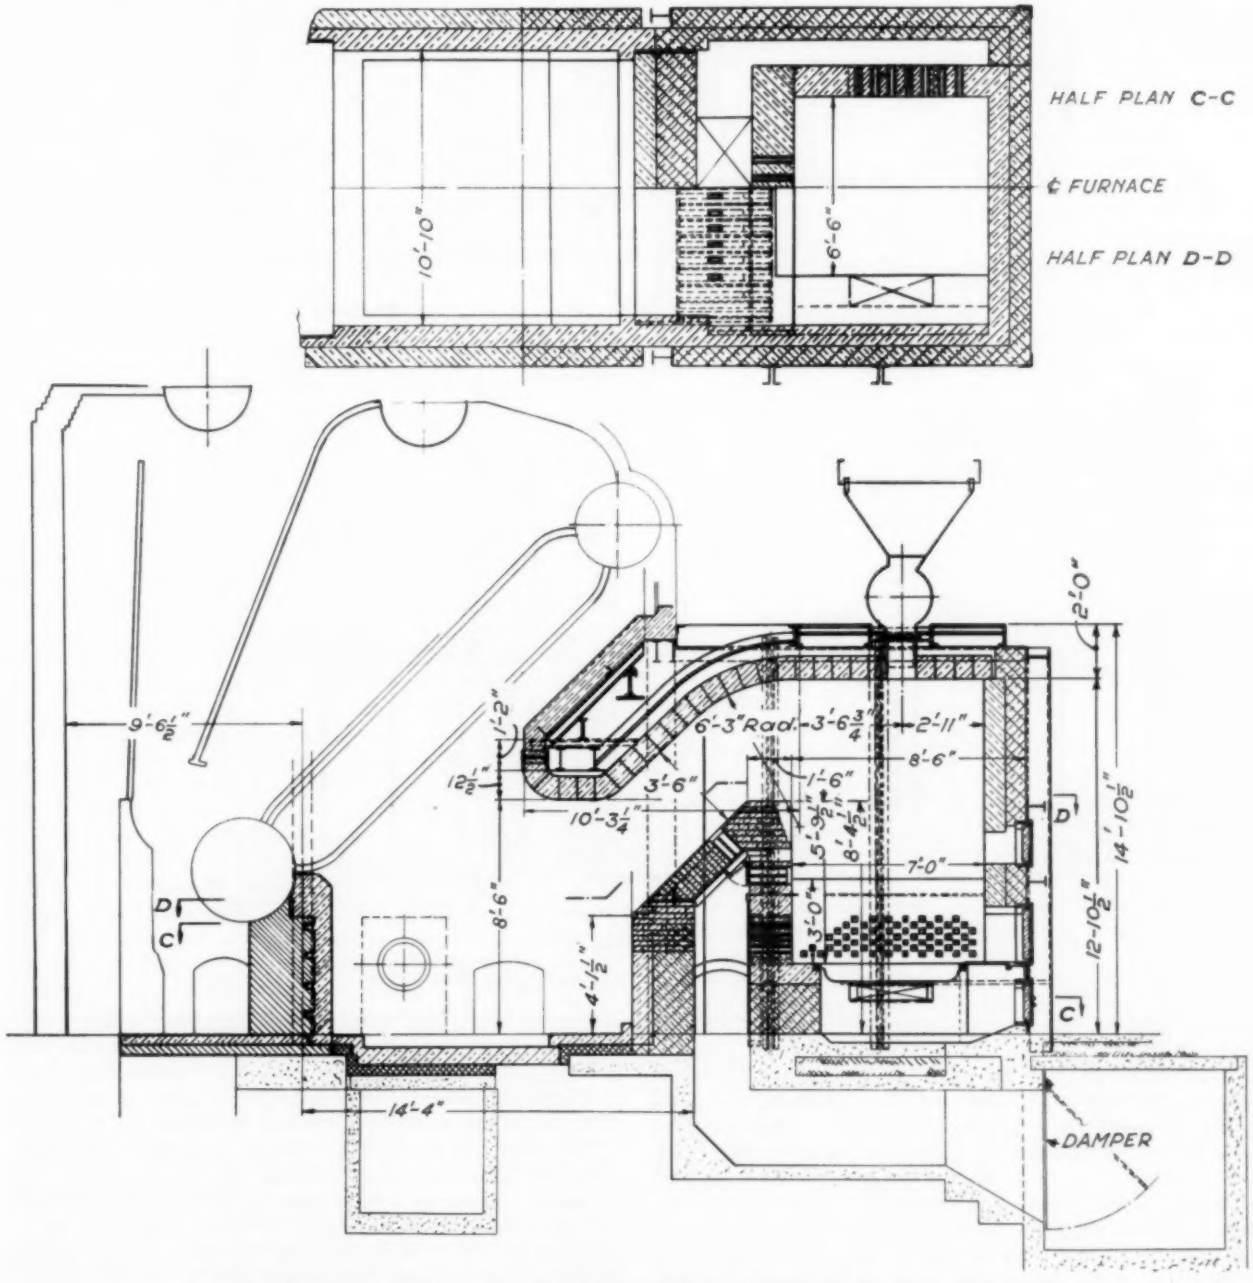

FIG. 16 BAGASSE-BURNING FURNACE TYPE, UNITED SUGAR COMPANIES, LOS MOCHIS, MEXICO

S. N. HEYMAN.[5] There are a few operating characteristics in the burning of dry wood refuse, to which the writer would like to call your attention.

In burning dry wood refuse in a furnace with air-cooled refractory walls or water-cooled walls, it is advisable to install a standby unit to burn oil, pulverized fuel, or natural gas. We find a unit pulverizer installation with each boiler a practical

[5] Fisher Body Corporation, Detroit, Mich.

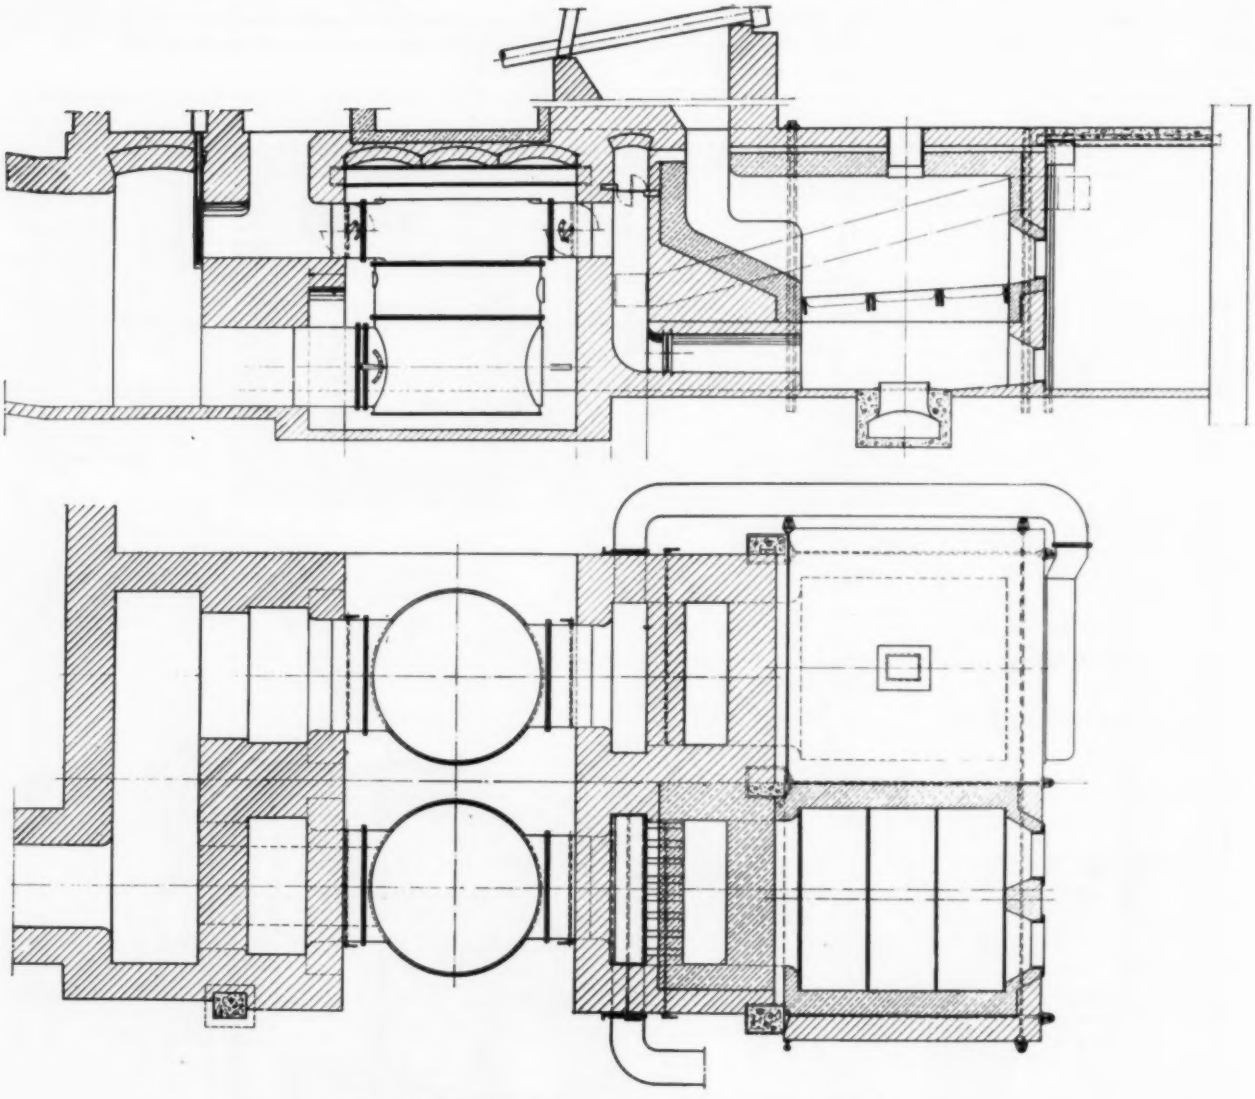

FIG. 17 FURNACE DESIGN, LUGNVIK, SWEDEN SAW MILLS

method, when dry wood refuse is not available on week-ends or shutdown periods.

In changing over from operation with shavings to pulverized coal, it is very essential that the wood refuse which has not burned in suspension and has collected on the bottom of the furnace be removed or burned completely before the pulverizer is started. The pulverized coal sometimes produces a hard crust of slag over the unburned shavings on the furnace floor. This pockets the gases created by the wood refuse, and when the boiler is down and the engineer decides to clean out this furnace, this crust is broken, releasing the gases, which may cause a dangerous explosion.

In the burning of wet hog fuel in Dutch ovens, from the description given by Mr. Gladden, it appears that nobody has conceived the idea of trying to dry the wet refuse with the stack gases. Since the temperature of the stack gases is around 600 deg. fahr. and the wet refuse is conveyed to the spouts on the Dutch oven, it seems to the writer that a very simple means of housing in the conveyor may be used, with a fan discharging the hot gases through the oven, thereby drying out as much of the moisture from the wet refuse as possible. However, there is one difficulty that arises. Although the average moisture content of the wood may be 30 to 50 per cent, there are "whiskers" and threads attached to the wood that are comparatively dry, and in trying to dry the wood with gases around 600 deg. fahr., these may burn and cause a serious fire. If the gases contain a high CO_2 content, the chance of a fire may be remote.

The writer understands that such an installation, with rotary driers, has been installed by the Ford Motor Company in Iron Mountain. Although they have had a few fires, there has been nothing serious. For the average plant, it is felt that the installation of rotary driers (although the best) would cost too much and that it would be necessary only to install a housing around the conveyor leading to the power house.

G. G. HOLLINS.[6] It has been mentioned in the discussion that it was not only a question of furnace volume, but the way the volume was arranged. The writer would assume that this refers to the relative length, breadth, and height of the furnace, and he wishes to emphasize the importance of the furnace width. Boilers are now available in so many types that a given amount of

[6] Chief Mechanical Engineer, J. G. White Engineering Corporation, New York, N. Y. Mem. A.S.M.E.

heating surface may be obtained with a furnace width most suitable for the combustion conditions. For instance, if a bent-tube boiler has approximately 14,000 sq. ft. of heating surface, practically the same amount of heating surface and vertical distance between the mud drum and the steam drum may be obtained with a furnace width of 20 ft. and with a furnace width of 26 ft. The figures, which are taken from actual design of furnace, show that for the wider boiler the furnace volume is increased 30 per cent while the area of the refractory furnace surfaces is increased only 18 per cent. The projected area of the tube bank, which is the heating surface directly exposed to the fire, is for the same drum spacing directly proportional to the width of the boiler and is 30 per cent greater for the wider boiler.

The manufacturer's data on the two types of boilers show nearly the same flue-gas temperatures for the same output and furnace conditions, so that the efficiencies are considered the same.

With the boilers operating at the same load, the boiler with the larger furnace volume and greater area of heat absorbing surface exposed to the fire might be expected so show better maintenance with the air-cooled walls, or permit higher ratings with the same maintenance.

ROBERT H. KUSS.[7] The writer lays no claims to recent contact with the problems of burning refuse wood, but feels that his experience with the art some years ago warrants these remarks.

Comparing the earlier forms of wood-refuse-burning equipments with those submitted by Mr. Gladden, it must be said that, with the exception of the more elastic furnace-roof constructions and the use of heat-absorbing walls, nothing new appears. It is true there is a greater liberality in the cubical contents of furnace or combustion chambers which may well be assumed to be a step in advance, but without taking full advantage of this place of possible improvement, the same problems persist as in the writer's experience more than a quarter of a century ago.

Specifically, there is one particular in which the paper is peculiarly silent, though being of outstanding importance. Reference is here made to the draft facilities or lack of such. Figs. 2, 6, 7, 8, 9, 10, 12, and 13 come within this category to a marked extent, and on this core alone can well account for many of the refractory failures which appear to be treated by the author as fundamental, whereas they are merely symptoms of fundamental faults elsewhere. In the majority of instances cited no precautions of oversupplying chimney capacities or induced-draft fans can overcome the draft restrictions offered by the baffling or the damper size, shape, or placement, or a combination of both faults. In some instances, notably Figs. 9, 10, and 14, the difficulties are accentuated by combustion deposits accumulating to still further restrict gas passages.

The use of excess air to afford oxygen to support delayed combustion by the admission through the rear of bridge walls or equivalent places, while perhaps better than none at all, is not as correct an attack as a distribution as early as possible into the gas-distillation zone.

A critical analysis of the settings offered by Mr. Gladden, viewed from the standpoint of the foregoing remarks, would probably direct attention away from his purpose and besides would become too voluminous. However, it may not be out of place to remark that in the related fields of the combustion of special fuels such as oil and pulverized coal the importance of the same points has been established after almost identical experiences with deficient draft facilities and misplaced auxiliary-air admission.

A. R. WAUGAMAN.[8] The author is to be congratulated on his excellent paper, which shows very clearly the development and trend of furnace design from the inefficient furnace using 0.8 cu. ft. per hp., which developed low rating and created a smoke nuisance, to the present-day furnace having 7.4 cu. ft. per hp. and developing continuous ratings as high as 300 per cent, with complete combustion and efficiency equal to or better than many present-day coal-fired installations.

The trend of development has been parallel to the improvement in design of coal-burning equipment and involves similar combustion principles. It is necessary to obtain intimate contact between fuel and air and maintain this condition until combustion is complete. The constituents of dry wood fuel shown by the average analysis of Table 1 indicate the necessity of relatively large furnace volumes to permit time for complete burning of the large percentage of volatiles in fuel before contact with the relatively cold boiler. To maintain these volatiles in a turbulent mixture presents difficulties which in the case of dry refuse furnaces are largely overcome by the method of feeding the fuel to the furnace. A large part of the fuel is burned in suspension as it falls through burning gases, and additional inherent oxygen is liberated by heat distillation at the proper time to assist the combustion process.

The method and distribution of the remainder of the air for complete combustion is very important, and a further study of the design of the bottom of the furnace where most of this air is admitted will probably further improve this type of furnace by changing the location and size of air openings to get the greatest sustained and distributed turbulence.

The proper application of water cooling or shading simplifies this problem by allowing better air control with a tighter furnace and less infiltration. It permits better turbulence and higher liberation rates without the excessive maintenance met in the earlier furnaces.

HERBERT S. WHITON.[9] The furnaces that the writer will describe are in the power station of the Mountain States Power Company at North Bend, Ore. The fuel is sawmill refuse, known as "hog fuel," and consisting largely of fir and hemlock which contain as high as 50 per cent moisture. Fig. 18 will serve to show you that the furnace consists of a Dutch oven equipped with an inclined step grate. Various details of this furnace have been altered since the first installation.' Fig. 18 gives the latest design in use at the North Bend Station.

The fuel is introduced into the furnace by gravity through diverging chutes across the full width of the front end of the furnace. It avalanches down the inclined grate due to the natural action of gravity. The fuel bed thickness is controlled by an adjustable refractory faced gate. Ashes and clinker are removed from the shelf at the lower end of the inclined grate by raking through openings immediately below the lower end of the inclined grate. The shelf is dimensioned to prevent an automatic flow of refuse into the ashpit so that the depth of the fuel bed at the back end of the furnace may be controlled.

Air is supplied by a forced draft fan, and the gases are removed by natural stack draft. Sufficient air is admitted under the inclined grate to distill the volatiles and drive off the moisture from the fuel, and in addition to burn the resulting charcoal. The air necessary for burning the volatiles is introduced through the bridge-wall tuyères, which face the inclined grate and are proportioned to give the necessary velocity to produce the desired turbulence of air and gases to hasten combustion. Some small particles of fuel carry over the bridge wall and are burned in the combustion chamber directly under the boiler heating

surface. The small amount of air required in the combustion chamber is admitted by natural draft through dampered openings in the bottom of the side wall.

The boilers have 9834 sq. ft. of heating surface. The feedwater temperature is 275 deg. fahr. The steam pressure is 245 lb. gage, and the steam temperature is 540 deg. fahr. at the superheater outlet. Steaming rates of 80,000 lb. per hour are easily maintained continuously with from 15 to 16 per cent CO_2 and no appreciable CO.

No tests have been run to date. Therefore, efficiency figures

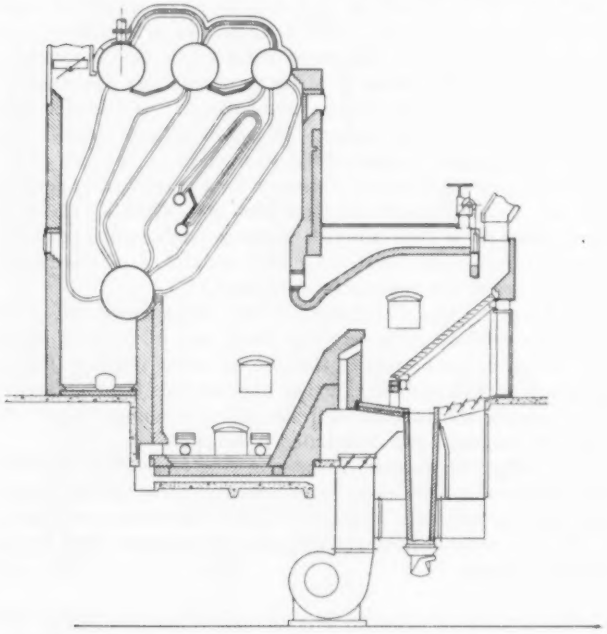

FIG. 18 DESIGN IN USE AT THE NORTH BEND STATION

are not available. However, since the installation of the two furnaces designed and the adoption of the draft adjustment, the station has generated as high as 950 kw. per unit of fuel, whereas previously the rate was about 750 kw. per unit.

AUTHOR'S CLOSURE

It is gratifying to note the interest taken in boiler settings for burning refuse wood, both by the considerable amount of discussion and by the variety of ideas brought forth.

Referring to the discussion by Mr. Beers, the author agrees with his suggestion that for certain plants, where both coal and wood must be used as fuel and especially where the wood may be relatively of minor importance and is subject to interruptions in supply, an underfeed stoker installation in a wood-burning furnace is undoubtedly a satisfactory arrangement. Care should be taken, however, to admit air above the coal for the combustion of the wood, and this should be under the control of the operator, in accordance with the rate of wood combustion.

In Mr. Cockburn's discussion he laid emphasis on the importance of uniform feed, especially when burning kiln-dried wood refuse. This is necessary, not only in the matter of obtaining high efficiency, but also in the prevention of smoke. With a system of feeding wood in which the wood is alternately admitted to the furnace in large quantities and then for a period of time in small quantities, there is the smoky condition of burning with insufficient air in the former case, and a condition of excessive heat losses when burning with excess air in the latter case. Careful attention to the uniform feeding of dry refuse wood, especially where burned in suspension, is desirable.

The evaporative tests given for the Memphis boiler, when burning wood, show excellent operation. The comparative costs of air-cooled and water-cooled boiler settings as given by Mr. Cockburn are of economic interest. The flexibility of control of the water-cooled furnace of the Memphis boiler is an excellent feature.

An application of preheated air to boiler furnaces designed for burning wet refuse wood is clearly illustrated and described by Mr. Colby. The advantage of being able to obtain one-third greater capacity, not to mention the increased efficiency by the application of an air preheater to a boiler furnace burning wet refuse wood, is decidedly worth investigation.

In the burning of bagasse, Mr. Colby has described an installation which, before preheaters were installed, would produce a maximum of 85 per cent of the rated capacity of the boiler by burning oil at the same time for supplementary firing. It is interesting to note that after the installation of the preheater it was possible to cease using oil for auxiliary firing, and the capacity of the unit was increased to 135 per cent of rating when burning bagasse alone. It is also interesting to note that the tests of the wet refuse wood-burning boilers in Sweden indicate that the application of an air preheater increased the efficiency 21 per cent, even though the wood which was burned without using the air preheater contained 7 per cent additional moisture.

Mr. Heyman has suggested a unique idea of utilizing waste furnace gases to dry the wet wood refuse before burning. In this process, care would have to be exercised not to drive off the volatile constituents other than moisture from the wood; that is, a balance between evaporation and volatilization would have to be carefully watched. It would be an interesting engineering study to compare the relative costs of equipment and operating expenses for power for such an installation, as compared with similar data for some of the designs illustrated in the preceding discussions of burning the wet refuse directly on grates in reverberatory furnaces and allowing the steam of the evaporated moisture to pass through the boiler setting carrying with it the heat losses which are inherent.

Mr. Hollins has pointed out a feature of boiler design for use in connection with the burning of refuse wood which is very important; that is, the relation of the heat absorbing area to the furnace chamber. The larger the area exposed to the combustion chamber, the greater the heat absorbing effect, which should result in lower furnace temperature and consequently less maintenance of refractories. The factor of having the side walls of the furnace as far apart as possible, consistent with good design, results in less overheating of the side walls by reflected radiant heat.

In the discussion by Mr. Kuss, the necessity for proper baffling and damper arrangements is mentioned. It is assumed that the baffling in all cases is of such a design that there is no unnecessary restriction of the flow of gases and that the gases are forced into as intimate contact as possible with the boiler tubes and also that there is sufficient draft to remove the products of combustion through the various boiler passages and damper connections. Numerous cases of faults of this kind are found, but if there is sufficient draft and the gases are properly taken away and refractory troubles exist, then it is the furnace design and not the boiler baffling and dampers that is at fault. The admission of air at the most suitable location in the furnace to support combustion of the volatile gases, especially in the cases of wet refuse furnaces, is one that depends entirely on the design of the furnace. It is the author's belief that a number of designs shown in the paper and in the discussion are worthy of careful investigation.

Mr. Waugaman has justly suggested the importance of a careful study of the distribution of air admitted at the furnace bottom for burning dry wood refuse which passes unburned through the

heated furnace. A thorough turbulence of air at the location where the pieces of unburned wood accumulate on the furnace bottom is most essential.

The author believes that the design submitted in discussion by Mr. Whiton for burning hogged fir and hemlock, containing as much as 50 per cent moisture, is of decided interest to engineers concerned with such problems. If an air preheater were also installed in connection with such an installation, it would appear that excellent arrangements for burning wet refuse wood had been provided.

FSP-53-4

Comparative Performance of a Pulverized-Coal-Fired Boiler Using Bin System and Unit System of Firing

By A. E. GRUNERT,[1] CHICAGO, ILL.

An experimental program had for its object the comparative performance of a modern boiler unit, served, first, with the bin system of pulverized-coal firing and, later, with the unit system of firing, thus making possible comparisons on a common basis. The paper deals with specific types of equipment, certain types of coal, and operating conditions, influenced somewhat by local conditions. The operation of these two systems is compared in three ways—first, on an evaporative-test basis; second, on a basis of actual overall performance; and, third, on an operating-cost basis. A record of the pertinent experiences with both systems is given. Owing to the specific nature of the program, no general conclusions are given, and there is no intention to contribute to the controversial phase of the matter.

THE BURNING of coal in pulverized form in large steam-generating units needs little if any argumentative support in view of the present state of development of the art. The controversy between advocates of pulverized-coal firing and of mechanical stokers, so much in evidence during the past few years, seems to have a tendency to settle itself. Each has its particular advantages in the general scheme of things which may make it preferential over the other according to the conditions to be met and the kind of results desired. However, engineering development in general, and more particularly that which concerns combustion processes, is not likely to be without its questions of a controversial nature sponsored by men keenly conscientious and anxious for the further development of the art.

Such a situation has and is further likely to manifest itself in connection with different systems of burning pulverized coal. Both the bin and unit systems are now used more or less extensively, the former probably with a greater span of development behind it, but the latter active with youthful vigor. Each system has appealing characteristics as exemplified by the choice between the two in recent installations. The bin system would naturally attract attention due to its inherent ease and flexibility of control over the combustion process. The unit system also appeals because of its simplicity and its adaptability to existing installations. Although the latter was a more recent arrival in central-station practice, both systems are now undeniably in successful large-scale operation.

There are, however, few definite data as yet available which would serve as a basis for comparing the economic performance of both systems. Owing to the rapid development of equipment and the complexity of so many conditions and the economics involved, this situation is not surprising at this time. Furthermore, it is not likely that any data could ever be presented which would conclusively prove the superiority of one method over the other in toto.

That each will eventually find its own field and enjoy profitable application seems a permissible prophecy in view of similar situations in the past. These data, therefore, are not presented with such a comprehensive scope in mind, but rather from the narrower viewpoint of certain specific conditions which are largely local in character.

No consideration is given in this discussion to the investment angle of the matter. While this is an important factor and perhaps the controlling one in many cases, it is broad enough to be dealt with as a separate study by those more familiar with it. Investment is primarily the concern of the designer and upon completion of a project becomes largely of retrospective interest, while the concern of the operator in subsequent performance of the equipment is continuous, perhaps for years.

Situated as we are with respect to coal supply, the economic necessity of using coal from the Central Illinois fields, as the major portion, is at once apparent. Although these coals have the generally well-known undesirable characteristics of low fusing ash, high sulphur content, and low heat values, they have, however, been successfully utilized by the chain-grate stoker when judged by the standards of a few years ago. That the development in the pulverized-coal process of combustion has forced a revision of former conceptions of good practice must be readily admitted, since there are now many outstanding examples of high capacity-efficiency performance which far surpass any stoker operation. While it is physically possible to build exceedingly large stokers, the growing tendency toward super-generating units served by a few steam-generating units places the stoker in an unfavorable position both in investment and operating considerations.

Such a situation confronted us in 1926. Chain-grate stokers had been developed to a size beyond which it would have been impractical to go. Turbo-generating units of 100,000 kw. were in contemplation, which meant, under the normal fuel and base-load conditions, a minimum of six steam-generating units. The prospect of still larger generating units required that serious consideration of the possibilities of burning Central Illinois coal in pulverized form was necessary.

The data available at that time contained little if any information on the pulverized-coal process of combustion with the kind of coal which we would have to use in future extensions; in fact, there seemed to be a preponderant usage of the better grades of coal with pulverized-coal-fired boilers. While this picture is

---

[1] Efficiency Engineer, Generating Station, Commonwealth Edison Co. Mr. Grunert was graduated from the University of Wisconsin in 1907 with the degree of B.S. He served as an apprentice engineer with Westinghouse, Church, Kerr Co., and then entered the employ of his present concern where he has held the positions of test engineer and boiler-room engineer. During the War he served from 1917 to 1919 with the E.O.R.C.

Contributed by the Power Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

somewhat different under present conditions, there still appears to be no striking enthusiasm on the part of operators to use low-grade coal if any more or less reasonable pretext can be found to avoid it.

The fouling characteristic of coals with low fusing ash makes boiler cleaning a major problem in operation, especially when high capacities are maintained. This condition is probably the most important factor in differentiating our problem from that of others. All the improved appliances and methods for coping with this situation seem to fail for one reason or another.

In view of this lack of definite information, an experimental program was obviously necessary, as the commitment to large-scale operation in a new field without previous experience and trial in a smaller way might have led to grievous mistakes. This plan, conservative from the standpoint of general policy, but ambitious from an experimental standpoint, led to the installation of the well-known steam-generating unit No. 22 at Calumet Station, the general plan of which is shown in Fig. 1. Here there are represented most of the innovations in recent development of steam-generating equipment and a type which has become distinctive in character. Having in mind its particular application to pulverized-coal firing with low-grade coals, it has the usual large combustion chamber which is almost completely water-screened. It utilizes the idea of a small boiler proper, to more fully obtain the advantages of increased heat absorption by direct radiation, open tube spacing to facilitate cleaning, combined with a direct-connected steaming economizer and a relatively large air preheater. That all these innovations, and others of minor importance, have their particular distinctive advantages needs no further mention. It is the forerunner of its type; the more recent installations differing from it only in size and more improved methods of handling slag ejection from the furnace. A more detailed description of this unit is given in Table 1, both as it was originally installed and as it is now.

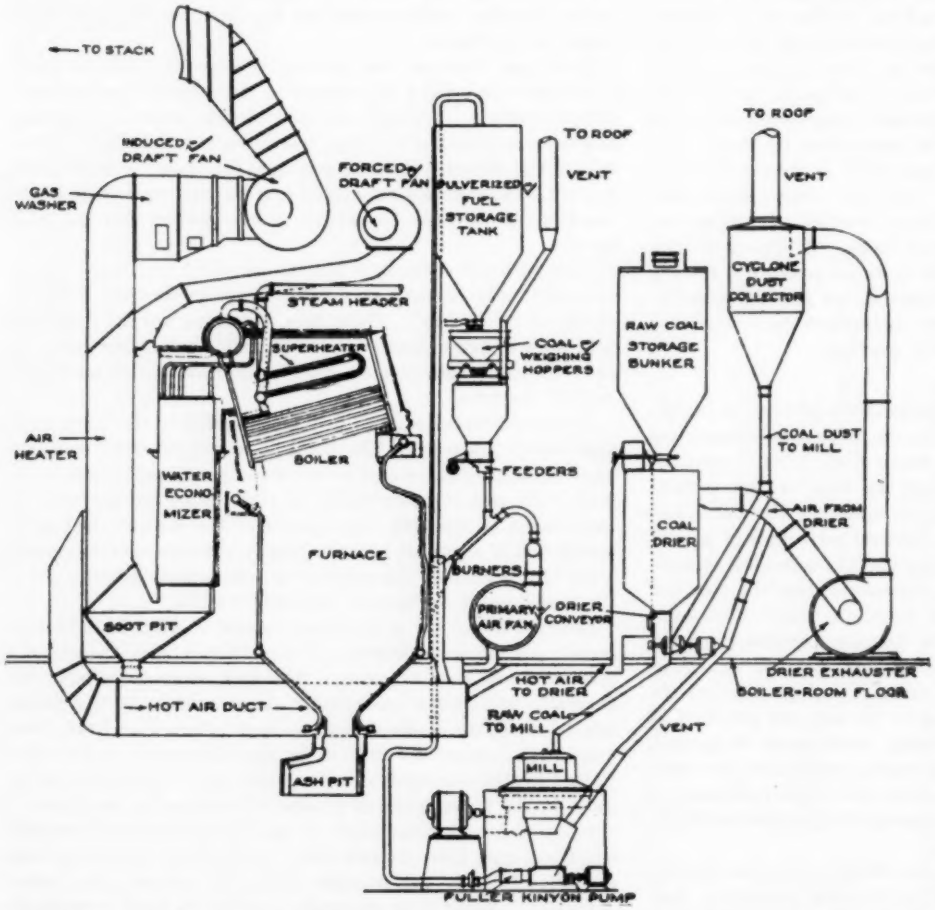

FIG. 1 BOILER UNIT NO. 22, CALUMET STATION, COMMONWEALTH EDISON COMPANY, WITH A BIN SYSTEM OF FIRING

This unit, as shown by Fig. 1, was first put in service November 8, 1926. Owing to certain plant conditions not related to this unit, it was necessary to adopt a 16-hour-per-day operating schedule, with Sunday and night outage, and, except at certain periods for experimental reasons, this has been substantially its normal operation ever since. A steady rating of about 140,000 lb. of steam per hour has been usually maintained during the day, with some increase at the evening peak and a noon-hour drop. During the night all auxiliaries are out of service, the dampers are closed, and the steam pressure is allowed to drop. From such a warm condition the unit could be brought up to normal steaming capacity in about 15 minutes. When the boiler has cooled off over a Sunday shutdown, bringing up requires 50 to 60 minutes. The flue blowing elements are operated on a routine schedule depending on coal conditions. The boiler unit is normally on automatic control, with manual load regulation except when starting up, during flue blowing operations, and when dumping the ashpit. These were the general operating conditions upon which the comparative operating data are based. The frequent shutdowns occasioned by such a schedule affected the operating efficiencies somewhat adversely, as would be expected.

Since the experimental plan was intended to be as thorough and comprehensive as practicable with the specific conditions involved, the operation of this unit has been in effect a continuous operating test. All the metering devices, particularly the steam-flow meters, were installed with adequate means for calibration at frequent intervals, so that the overall results would be within the degree of accuracy ordinarily accepted as good practice. While the burning of Central Illinois coal in pulverized form was the principal consideration, other coals were burned over sufficiently long periods to ascertain the effect on operating conditions, if any, caused by the coal quality. Table 2 summarizes the 24 months' operation of this unit when equipped with a bin and feeder system. From this record is drawn a summary of seven months of operation with Central Illinois coal, two months with Youghiogheny, Pa., coal, and three months with Western Kentucky coal. During the other twelve months not shown separately, various Illinois and Kentucky coals were burned in varying proportions. These months were left out of compara-

TABLE 1 DESCRIPTION OF EQUIPMENT, BOILER NO. 22, CALUMET STATION, COMMONWEALTH EDISON COMPANY

As a Bin System	*As a Unit System*
Boiler:	
Type: B. & W. cross drum	Same
Surface: 5,940 sq. ft.	
Furnace:	
Dimensions: Plan, 19 ft. 9 in. by 23 ft. 8 in.	Same
Volume: 12,397 cu. ft.	
Wall construction: Bailey water-cooled furnace walls and floor. Refractory-faced blocks on furnace walls and bare cast-iron and steel blocks on furnace floor. Blocks bolted to 3½-in. tubes spaced on 6-in. centers. Heating surface of walls; 2,468 sq. ft.	
Superheater:	
Convection, three-pass	Same
Surface: 3,000 sq. ft.	
Economizer:	
Type: B. & W. loop, counterflow	Same
Surface: 8,850 sq. ft.	
Air preheater:	
Type: Tubular, single-pass, counterflow	Same
Surface: 41,700 sq. ft.	
Induced-draft fan: Buffalo Forge Company	Same
Type: Duplex conoidal, size 13	
Capacity: 144,000 cu. ft. per min. at 880 r.p.m., 300 deg. fahr., 12-in. static pressure	
Drive: Two-speed motor	
Forced-draft fans: (2) Buffalo Forge Company	Same
Type: Duplex conoidal, size 6½	
Capacity: 58,000 cu. ft. per min. at 70 deg. fahr., 4-in. static pressure at 1,102 r.p.m.	
Drive: Two-speed motor	
Gas washer equipment:	
Washer: Carrier Air Conditioning Company. Spray capacity, 500 g.p.m. Pump capacity, 900 g.p.m. at 135-ft. head	Same
Drier: Fuller Randolph	Removed
Type: Vertical, tempered preheated air	
Capacity: 30,000 lb. per hour	
Raw-coal scales: None	Richardson Automatic
	Capacity: 400 lb. per dump
Drier exhauster: Buffalo Forge Company	Removed
Type: R, size 130	
Capacity: 57,500 cu. ft. per min. at 140 deg. fahr., 7-in. static pressure, 490 r.p.m.	
Drive: Variable-speed motor	
Cyclones: (2) Fuller Lehigh Company	Removed
Size: 144 in.	
Drag feeder: Fuller Lehigh Company	Fuller Lehigh Company
Drive: Variable-speed d.-c. motor	Variable-speed d.-c. motor
Pulverizer: Fuller Lehigh Company	Fuller Lehigh Company
Type: B, 70-in., screen separation, four-ball, pusher	70-in., air separation, five-ball, pusher type
Capacity: 30,000 lb. per hour	30,000 lb. per hour
Drive: Variable-speed, 375 r.p.m. maximum	Variable-speed, 510 maximum r.p.m.
Mill exhauster fan: None	Overhung paddlewheel type
	Drive: 1150-r.p.m. motor
Pulverized coal-transport system:	Removed
Fuller Lehigh Company	
Coal pump: Fuller Kinyon	
Capacity: At least 60,000 lb. per hour	
Drive: Constant-speed motor	
Pulverized-coal bunker:	Not used
Capacity: 200 tons	
Pulverized-coal feeders:	Removed
Four Bailey feeders	
Capacity: 10,000 lb. per hour each	
Drive: Variable-speed motor	
Pulverized-coal weigh bins and scales:	Removed
For test	
Primary-air fan: Buffalo Forge Company	Removed
Type: R, size 115	
Capacity: 15,000 c.f.m. at 200 deg. fahr., 10-in. static pressure and 570 r.p.m.	
Drive: Constant-speed motor	
Burners: (8) Bailey "Calumet" type	(6) Same type
Size of primary opening: 62 in. by ½ in.	62 in. by 1.12 in.
Control: Bailey Meter Company	Same
Meter: Steam-flow–air-flow type D 25	
Multi-pointer gage: Type P 12 F.	
Temperature recorders: Gas in and out of economizer, and water in and out of economizer; steam temperature, flue-gas temperature at preheater out and air temperature at preheater out	
Steam-flow–air-flow and furnace-draft contactors: Type RS 36	
Master drum-switch: Type R 65	
Control drive: Type RC 76 D.S.T. (draft control)	
Control drive: Type RA 76 ST (fuel control)	
Bank of rheostats: Type R 414	

tive summaries so as to eliminate any question of unfair comparison.

An accurate record of all pertinent operating costs was kept, and is summarized as shown by Table 3. In this cost-accounting schedule only those operating expenses are considered which are affected, directly or indirectly, by the method of burning coal. In general, these accounts include the operating expenses entailed in the plant system from the point at which coal is received into the car dumper to the point at which steam is delivered to the header system. This seemed necessary due to the specific nature of the problem. Some of the items might have a somewhat remote connection, but by simple arithmetical alterations the basis of comparison could be changed to suit the individual ideas of any one interested. Due to changing of the coal supply previously mentioned, it was not practical to attempt to separate the cost for each period, but rather to group them for the entire period of bin and feeder operation.

In October, 1928, the equipment was converted to the unit system of firing, the general scheme being that shown in Fig. 2. Although this change was not contemplated in the original plan, the many and varied experiences of two years of operation with a bin and feeder system were such that no particular pangs of regret were evidenced by those concerned when this change took place. It is not inferred that this conversion eliminated all objectionable conditions, because the unit system in its later opera-

tion also developed a few inherent mulish traits. Table 4 summarizes eleven months of operation of this unit with a unit system of firing, and Table 5 is the operating-cost record. The operation

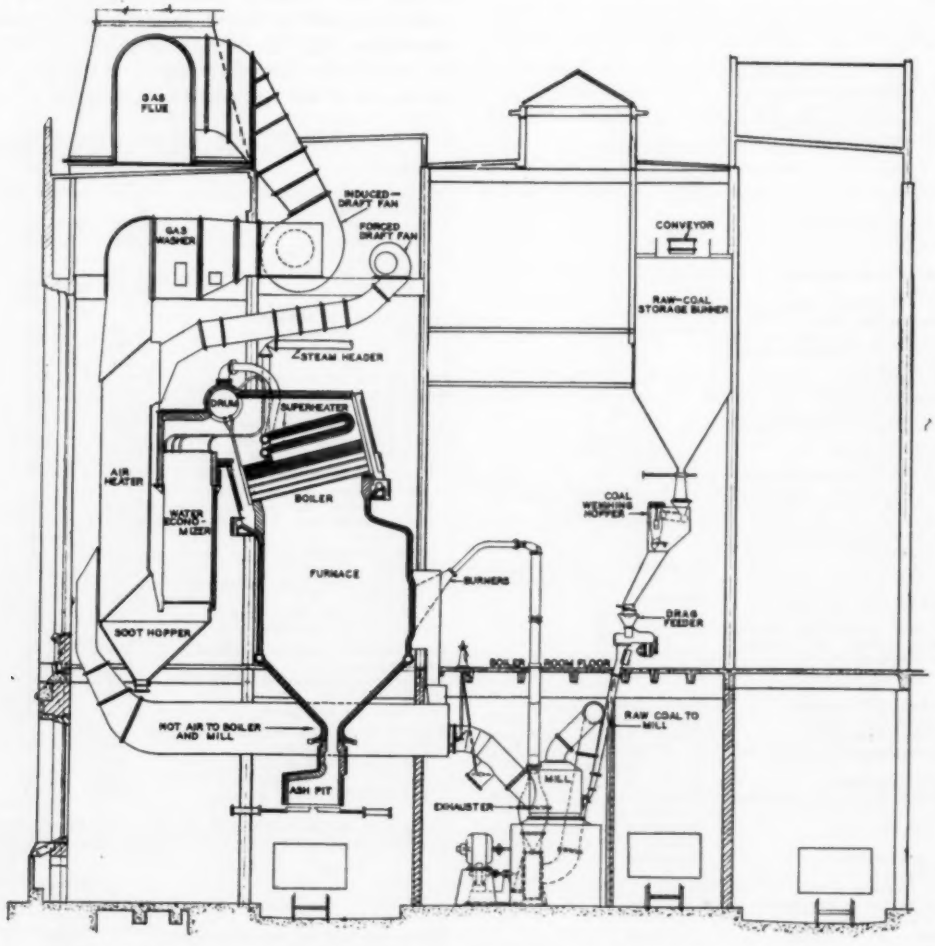

FIG. 2 BOILER UNIT NO. 22, CALUMET STATION, WITH A UNIT SYSTEM OF FIRING

and the experimental work thus far have made it possible to compare results in general, as follows:

BIN SYSTEM OPERATION

Furnace and Ash Disposal. The water-cooled furnace has probably been one of the most important factors contributing to the successful application of pulverized-coal firing to large-scale and high-rating operation. The exacting furnace conditions to be met with in many cases would make the refractory-lined furnace a sorry spectacle in comparison. This furnace design as then intended, and as verified later, so reduces the factor of destructive slag action that the operating problem in the furnace has become of insignificant importance. So far as the screen walls are concerned, only 30 blocks have been replaced in over three years, and this failure was largely due to the proximity and impingement of the end burners on the side walls. A more practical spacing of the burners was the logical solution. Other mistakes in the design of this furnace are exemplified by the refractory-lined spaces below the inlet header of the side screens and that above the outlet header of the rear screens, the former failing due to slag erosion and the latter largely due to inadequate anchorage. The furnace-maintenance cost shown is almost entirely confined to these areas. Fig. 3 shows an end wall as installed, and Fig. 4 shows the condition of the same wall after 38 months' operation. Any failure of these screen walls is likely to be a matter of the far-distant future.

During the early operation of this furnace a study was made of the heat-transfer condition with these screens. The typical conditions are shown by Fig. 5. Higher heat transfers were obtained over certain areas, such as the rear walls and part of the side walls, than the mean values shown, due to burner and impingement conditions. A maximum heat liberation of 34,000 B.t.u. per cubic foot per hour, for short periods, has been obtained in this furnace.

The method of slag and ash removal from the furnace developed no particular difficulties when firing coals having an ash with a low fusion point such as that from Central Illinois. The molten ash deposited on the walls runs down freely to the ashpit throat

and then drops into the ashpit. A condition which in so many other respects is objectionable is in this respect a distinct advantage. The slag formation is greatest on the rear wall due to burner position, as might be expected. The deposits in the boiler-tube bank that are dislodged in cleaning fall and roll into the pit quite freely. The slag and other deposits are quenched in the pit to facilitate handling. Occasionally slag formations will concentrate on the refractory area at the ends of the hopper throat and require rodding through the special doors provided.

When firing a coal having an ash of higher fusion temperature such as Youghiogheny, the fly ash deposits on the walls do not readily flow. This is apt to cause large accumulations which, on breaking loose during operation, may clog the bottom hopper throat. While some measure of control over this is possible with burner operation, this condition did cause a shutdown and several cases of emergency rodding operations. The throat width of 18 in. could probably have been made larger to advantage.

In firing the normal coal, no particular difficulties are encountered so far as ash removal from the furnace is concerned. However, the operation of dumping the refuse from the pit is a dirty, gassy job and not without conceivable hazards. Later develop-

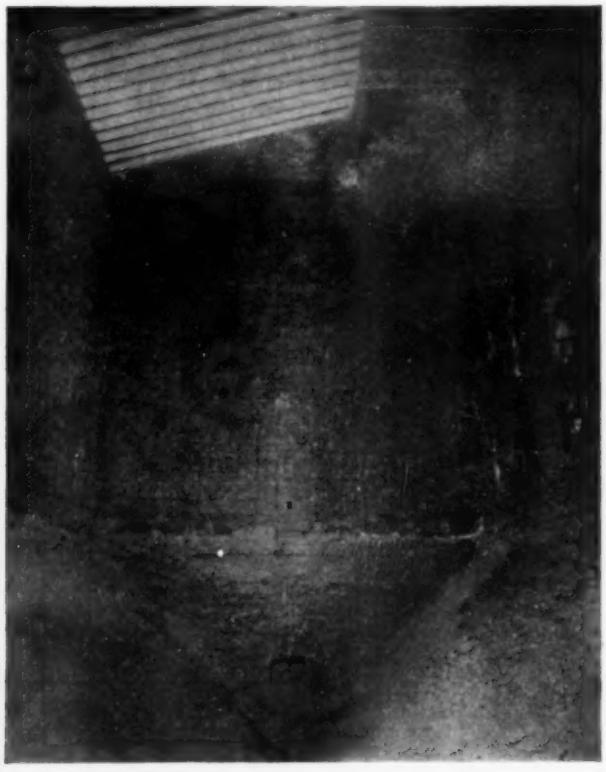

FIG. 4 PHOTOGRAPH OF FURNACE WALLS, BOILER NO. 22, CALUMET STATION, AFTER 38 MONTHS' OPERATION

ments in the manner of slag removal seem to offer improvement over this method.

TABLE 5 SUMMARY OF ACTUAL OPERATING COSTS, BOILER NO. 22, CALUMET STATION, AS A UNIT SYSTEM (SEE TABLE 4)

	Actual cost in dollars	Dollars per ton coal fired	Dollars per M lb. steam delivered
703-A coal- and ash-handling labor	712	0.02407	0.00141
703-B boiler-room labor	4,900	0.14093	0.00960
Total operating labor	5,612	0.16140	0.01101
717-A maintenance, furnace	1,009	0.02898	0.00198
717-C maintenance, boiler and superheater	530	0.01524	0.00104
717-D maintenance, feeders and burners	2,403	0.06916	0.00472
718-A maintenance, economizer	354	0.01017	0.00069
718-D maintenance, soot blowers	251	0.00722	0.00049
718-E maintenance, air preheater	....	....	....
718-F maintenance, all fans	817	0.02349	0.00160
Total maintenance except coal and ash equipment	5,364	0.15426	0.01052
718-B Pro-rate of maintenance, station coal and ash equipment	1,396	0.04015	0.00274
718-B Maintenance, No. 22 coal and ash equipment	478	0.01375	0.00094
718-C Pro-rate of maintenance, crusher and breaker	1,916	0.05510	0.00375

Total maintenance, coal and ash equipment	9,999	0.28757	0.01961
Auxiliary power, actual	7,684	0.22099	0.01507
Fuel cost	125,592	3.61196	0.24633
Total cost	154,251	4.43618	0.30254

The economizer and preheater hopper deposits are piped and flushed to the ash car. Clogging of these drains is an occasional annoyance. Normally, about 40 per cent or less of the original ash in the coal is accounted for by way of the ashpit; the remainder is carried out of the furnace as fly ash in the flue gas.

Boiler, Superheater, Economizer, and Preheater. Although burning Central Illinois coal in pulverized form has greatly reduced the operating difficulties due to fouling of the boiler heating surface at ordinary ratings, the situation at relatively high sustained ratings still leaves much to be desired. The rate of fouling in the lower deck increases faster than the increase in rating until finally a rating is reached where the usual methods of cleaning during operation fail miserably. Probably no operating problem has

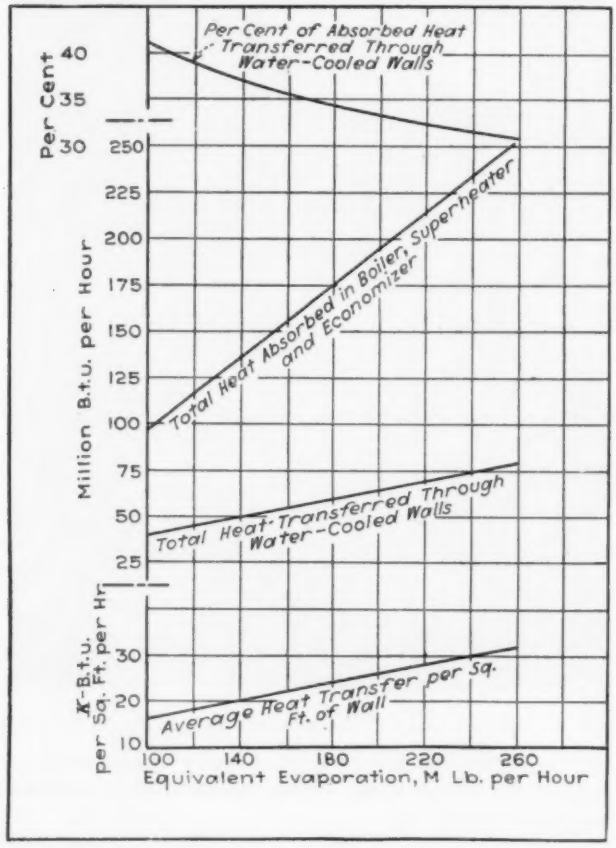

FIG. 5 TYPICAL HEAT TRANSFER THROUGH FURNACE WALLS, BOILER NO. 22, CALUMET STATION

been given more thought and attention than this, and invariably all the pet schemes contrived fall short of obtaining the desired results due to one cause or another. The flue blowing equipment in the fouling zone is subjected to temperatures beyond the limitation of the metal involved. This matter was an important factor in limiting the capacity of every-day operation to that shown, although short-time operation at much higher ratings was possible. Sustained ratings up to about 200,000 lb. per hour could be obtained with reasonable efficiency by frequent blowing and rodding. Beyond this capacity fouling difficulties increase to such an extent that continued operation was increasingly difficult if not impossible. After operating at a rating of about 275,000 lb. for a few hours it was usually necessary to shut down for cleaning.

The situation with the better grades of coal is greatly improved due to lesser ash quantities involved and more favorable fusion temperatures. In fact, a sustained rating of 250,000 lb. was not only possible, but could be maintained with reasonable efficiency. The idea that pulverized-coal firing is better suited to the poorer grades of coal seems to have suffered a relapse in this case.

The cleaning of the economizer and preheater surfaces has not been a serious problem. The nature of the deposit is such that it can be removed by ordinary means. It does not adhere like that from stoker firing, due to its different character. The corrosive action of these deposits is far less; in fact, after three years' operation, none is in evidence. During the early operation of the preheater the inlet ends of the tubes would plug shut. A special movable blowing element which, in moving across the preheater inlet-tube sheet, allowed each tube to receive the full force of a steam jet, gave quite satisfactory results. Some manual work is required occasionally on the outlet ends and upper tube sheet during an outage period.

Gas Washer. Public opinion forces attention to the consideration of fly ash and sulphur fumes ejected with the flue gases. This is true of any method of burning coal, but more particularly of pulverized coal. The experimental program included investigations as to the efficacy of the washer principally in eliminating these nuisances. The washer-type equipment installed between the preheater and the induced draft fan is practically the same as ordinarily used for cleaning generator cooling air. A separate 900-g.p.m. pump supplies water to the spray nozzles. Much has and is yet to be learned about equipment for this purpose.

In its early operation, serious corrosion due to the sulphur acids manifested itself. As a means of protection, all duct work between sprays and fan suction were covered with "gunite." Rubber-lining the drain piping was necessary due to the acid conditions. Subsequent operation for about three months so corroded the spray elements and support work that further operation was useless. The eliminator plates at the bottom were badly eaten away and somewhat embrittled. It follows then that use of this type of eliminator with high-sulphur coals requires materials highly resistive to corrosion. Experiments with special alloy metals are now under way. In a large installation satisfactory disposal of the drain water would present certain problems.

The effect of the flue gases on the induced-draft-fan runner is important. The eroding effect of fly ash over the periods of no washing was severe, resulting in a fan wreck after 20 months' operation. On the other hand, although the period of washer operation was short, some corrosion was evident, which may indicate a choice of two evils.

It was expected that the washer would not only eliminate dust, but would also considerably reduce the amount of sulphur in the gases. Upward of 90 per cent of the solid matter in the gas can be eliminated by this method, which compares quite favorably with other methods in use, but no appreciable reduction of the SO_2 and SO_3 could be found. As these gases existed in the flue gases to the extent of about 0.3 to 0.4 per cent by volume, it follows that a high degree of spray atomization would be necessary for complete effectiveness. Since the solubilities of these gases decrease with their partial pressures, it would follow that the degree of absorption would become increasingly difficult, involving large quantities of water and possibly multiple-stage spray banks for high humidity. That the refinements claimed to be necessary to the process were only crudely met in this case is readily admitted. It seems that a treatment which has the inherent possibilities of removing both dust and noxious gases is one worthy of serious consideration and effort to overcome the difficulties involved.

Pulverizer. Pulverizing this high-ash coal by either method of firing still leaves much to be desired, and the developments taking place in this case show it to be no exception. The operator

visualizes the situation as one that costs a lot of money for maintenance of such equipment and something which falls short of ordinary ideas of dependable service. Bin-system operation makes mill emergency outage of less importance than unit-system operation because of its principal premise. In this case ordinary repair and emergency outage affected the boiler operation but little, which is a point of importance in comparing the two systems.

The bin-system pulverizer was a pusher, ball, and screen type. Although it could have been operated at varying speed, it was usually operated at a fixed speed favorable to drying and sizing considerations. The maintenance of this mill was mostly confined to the renewal of balls, broken pushers, ball race, and screens. Chilled-iron balls gave more service than forged-steel balls. The balls became egg-shaped after a time, with the usual consequences of sliding and causing the breakage of other parts. The wearing of the working parts was also dependent upon the kind of coal being milled. The conditions with Central Illinois coals were much more severe than with the others, due to the abrasive action of ash and impurities. The maintenance costs over this period were influenced favorably due to milling more friable coals over part of the time.

Drier. This type of separate drier gave only the usual commonplace difficulties, but ones that could be agreeably dispensed with. Firing of the coal due to hanging up was frequent. This was particularly the case when coal was allowed to lie in the drier for a considerable length of time. The milling conditions in this case were tied up to a large extent with this drier. When the mill capacity was increased too much, there was insufficient drying, which resulted usually in plugged screens. At low capacities the coal was apt to be overdried, causing smoldering. Careful control over the temperature conditions was necessary at all times. As this drier was sectionalized, some approximate control over these conditions was possible. The best milling conditions were obtained with Central Illinois coal when the original moisture of 14.5 per cent was reduced to about 9 per cent and with Kentucky coal when the moisture was decreased from 8.5 per cent down to about 3 per cent.

Vent Cyclones. Two cyclone separators were installed to take care of the mill vent and drier dust combined. Their early operation was in parallel and later in series; and still later a supplementary washing apparatus was installed in the cyclone discharge. Of course, the usual amount of separation took place, the recovery being returned to the mill, but the amount of dust getting through in spite of all the opportunities given it to separate was sufficient to be a nuisance, not only to the plant itself, but to the neighborhood as well. The coal loss was insignificant, but a small amount in this form becomes an intolerable nuisance. Some consideration was given to installing special equipment for separating this residue but the fact that such equipment was necessary is an objection in itself. Perhaps no single item influenced those concerned in deciding to change to a unit system more than this particular situation. It is doubtful even if any great measure of satisfaction would have been obtained with such a system had the elimination been perfect.

Transport and Bunkers. The method of coal transport offered no particular difficulties. Those experienced at the bunker were confined to irregular flow and bridging of the coal at the outlets. One bunker fire was experienced and successfully smothered with carbon dioxide. Hanging up and packing of coal on the sides of the bunker due to reabsorption of moisture necessitated infrequent cleaning. In general, bunker conditions were probably no different from those of many others.

Feeders, Weigh Scales, and Burners. Excessive wear on the feeder mechanism, due to the abrasive action of the coal, developed early in the operation. "Stelliteing" of the wearing parts improved this situation, but probably not permanently. The volumetric metering feature of this feeder was not satisfactory for accurate measurement. The weighing of coal in pulverized form developed certain difficulties. This scheme, used only for evaporative test purposes, was similar to that used for water. It was found that the weigh tanks must be positively vented above and below to prevent diaphragm action. This system of weighing coal has many discouraging aspects.

The burners as first installed gave an unequal coal distribution through the primary openings, which resulted in an excessive amount of coal running out at the bottom. This was a burner condition and was remedied by placing deflector plates so that no reduction in velocity could occur in the burner. The combustion conditions obtained with this type of burner as changed leave little to be besired.

Control System. The automatic combustion-control equipment used on this boiler serves the purpose of regulating the air supply to the furnace and the furnace draft. The control of boiler output is entirely manual. Corrective adjustments to the air supply originate in the air-flow-steam-flow meter, which also records the result. The control is arranged to supply 25 per cent excess air at normal output and 30 per cent at low rating to avoid smoke.

In order to avoid any hazardous situation that might arise due to the failure of any electrically driven boiler auxiliary, an interlock system is provided. The principle of this system is shown in the following example; if the induced- or forced-draft fan should trip out, the delivery of coal to the furnace would cease, due to the automatic stopping of the necessary equipment. This system forces a definite sequence in the starting up and shutting down.

Unit-System Operation

The operation of the boiler unit proper was influenced very little by the conversion to the unit system. The conditions described as to the furnace, ash disposal, boiler, economizer, and preheater are much the same except as explained in the following.

The unit system reduced the maximum capacity obtainable in this case because of the limitation of mill capacity. This is obvious with this system. Ordinarily more than one mill would be provided for such a steam-generating unit, but inasmuch as we were concerned primarily with the experimental angle of the problem, one mill was installed—that one being the former mill rebuilt.

Drying of the coal for suitable pulverization was accomplished in the mill, the air being taken from the main duct at about 350 deg. fahr. and the coal-air mixture discharged to delivery ducts at about 140 deg. fahr. About the same amount of drying was obtained by this means as in the bin system, which is quite satisfactory with the kind of coal handled. The coal-air mixture is split two ways, each stream serving three burners. The coal sizing is controlled somewhat by cone classification and primary air volume, these methods having certain limitations, as might be expected.

Probably the reliability and satisfactory operation of a unit system of firing will in general be dependent upon the milling problem and related factors. As continuity of the combustion process is directly dependent upon these, the better position of the bin system in these respects must be admitted whether that advantage be considered small or large. We must accept the premise that an emergency outage of a unit will immediately affect steam output; and hence duplication, and perhaps multiplicity of mill units, is required to maintain continuity. Also there are the requirements of the proper air volume for milling, the required air for the best burner conditions, and the matter of distribution to various burners. That the coordination of these three more or less conflicting requirements is difficult developed

[1] Prorated figures based on total figures of three months' operation.

in the experience with this system. While this situation was in no sense important enough to condemn, these inherent factors of unit operation must surely be recognized in making further refinements.

Operation was at first attempted with a table mill having a single set of 11 15-in. balls with no pressure springs for holding the balls to a fixed course. Although successful operation of this type of mill has been obtained in the smaller sizes, it failed in this case to give the desired capacity and proper sizing. The mill was reconverted to a five-ball pusher type, using the same motor and reduction gearing. The operating performance over the period shown is based on this mill as thus changed.

The high maintenance costs of this mill were due to the same causes as experienced in the operation of the original screen mill—viz., breakage of pushers, scoopers, ball race, pusher arms, and renewal of balls due to wearing egg-shaped. The wearing of the various mill parts was much more severe, due to the necessity of operating at a variable capacity on the unit system rather than at a fixed capacity as on the bin system. In other words, this particular mill as altered for the unit system was not suitable when running at the speeds at which it was necessary to run to give the desired capacities.

The experience thus far in the mill problem still leaves much to be desired. At the present time further investigations are being carried out with an improved type of table mill and a tube mill, on which data are not yet available.

With this background and the difficulties of coordinating mill speed, primary air volume, and sizing, the idea of a relatively slow constant-speed mill with primary-air volume interlocked with coal feed begins to have appealing aspects, not only from the standpoint of maintenance and regulation, but also from that of automatic control.

Among the indirect effects of unit-system operation may be mentioned those in connection with the superheater. In the starting-up procedure it is difficult to hold down the coal feed to three burners and retain ignition due to requirements at the mill in the way of primary air volume. As practically all of the air at this time is primary air, long flaming results, causing excessive superheater-tube temperatures, with resultant sagging and damage to the supporting structure. This situation was improved by increased venting of the superheater boxes, although the resultant losses were not desirable.

Some improvement in this respect was obtained incidental to changes in the burners. Unit-system operation was started, using the same burners as were used with the former bin system. The greater primary-air volume requirements and the resulting longer flame caused excessive slag deposits on the rear wall and lower boiler tubes. More satisfactory conditions were obtained by increasing the burner throat openings from 62 in. by 0.50 in. to 62 in. by 1.12 in. The primary-air requirements are normally about 33 per cent of the total air used in this system. With bin-system operation the primary-air requirements were about 20 per cent.

Test Performances

Test data are of value in determining the optimum possibilities of equipment and furnish a means of analyzing performance in detail. While many factors may enter into it, the best evaporative efficiency is the item given primary consideration, and for this reason the efficiency characteristics only of both systems using the various coals are graphically compared in Fig. 6. The net efficiencies shown are the actual evaporative efficiencies corrected for the equivalent of the total auxiliary power used. The complete data for each series of tests are given in Tables 6, 7, 8, and 9.

The evaporative efficiencies obtained with Central Illinois coal

Overall efficiency, per cent	82.00	81.60	83.00	80.80	81.90	80.90	81.80	81.20

are about 2½ per cent lower than those obtained with the better coals. This is due somewhat to the greater inherent moisture losses, higher excess air requirements for smokeless combustion, and the usual fouling of surfaces. These three conditions characterize this coal and are in effect a penalty.

It will, however, be noted that there is no appreciable difference between the evaporative efficiencies of the bin system and the unit system when firing Central Illinois coal. As this same conclusion is also verified by actual performance, it seems fair to conclude that in this respect there really is not much difference between these methods of firing. There seems to be a tendency to detract from the unit system for reasons based mostly on theoretical considerations, but in actual performances these differences do not seem to be very noticeable.

The high capacity of 290,000 lb. per hour obtained with Kentucky coal is not necessarily confined to this particular coal. It so happened that during this series of tests the gas washer was in operation. The lowered gas temperatures permitted of much higher induced-draft-fan capacities. All of the other test series were performed with the washer out of service. It is quite probable that with the washer in operation such a high capacity could have been obtained with Central Illinois coal for short periods. The limit of capacity obtained with unit-system operation is that imposed by the mill.

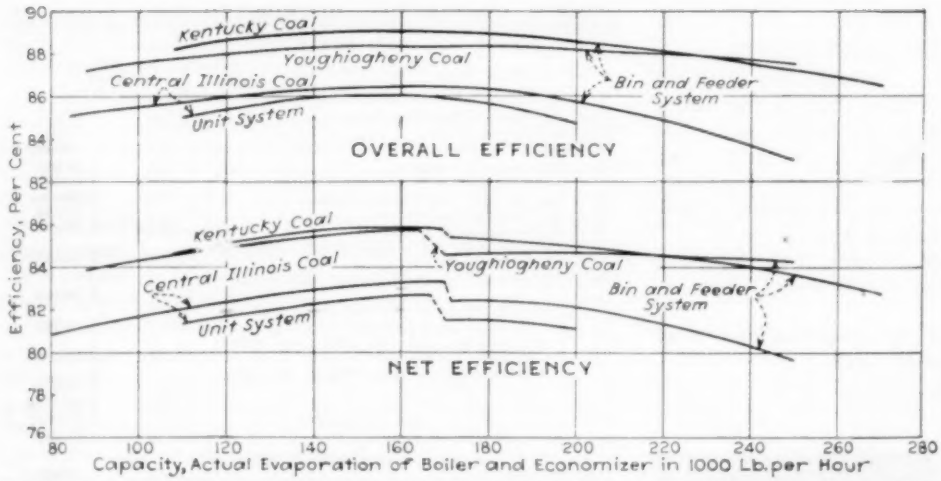

FIG. 6 COMPARATIVE EFFICIENCIES, BOILER NO. 22, CALUMET STATION, WITH DIFFERENT COALS, WITH BOTH BIN AND UNIT SYSTEMS OF FIRING

OPERATING PERFORMANCE

The actual overall result of a system of firing coal is probably the most important consideration in judging the commercial value of it. One cannot operate a system usually without having contingencies of some kind or other—routine outages for cleaning and repairs, occasional errors in operation, fluctuating load conditions, and a host of other things detract from the ideal possibilities. The difference between evaporative efficiency as determined by test and that of actual operation is somewhat a measure of all these as a whole. In this case these differences are about 2½ to 3 points for the bin system of firing with the coals used, which may be regarded as remarkably good practice with the conditions described. The actual performance of the unit system using Central Illinois coal compared to its test evaporative efficiency shows about the same result. We may therefore conclude that there is little if any real grounds to regard the unit system unfavorably on a commercial operating basis under the conditions as outlined.

On the other hand, the matter of reliability did favor the bin system in this case. Practically all emergency outages of the unit system were those caused by the mill. While multiplicity of units may be regarded as an assurance of continuity, it nevertheless follows that greater reliability of mills themselves is desirable.

The auxiliary power consumption of the unit system was lower, although the possibilities are not shown by the actual figures. The high energy consumption of milling was due to poorly adapted motor equipment with high rheostat losses, which could, in a more suitably designed combination, be avoided or at least reduced.

Automatic control is becoming more and more closely associated with the various combustion processes, as it undoubtedly should be. In this case, automatic control, while limited somewhat, was enough to demonstrate the advantages of steadier operation and with far less attention to detailed regulations than would be the case in manual operation. Far better pressure regulation is also possible. While the justification of the control system from an efficiency standpoint is not clearly demonstrated, nevertheless, for the other reasons, automatic control in some limited form with our future installations will be given quite serious consideration. It seems out of place to contemplate large steaming units with no other control than that of a man with divided attention, as is usually the case.

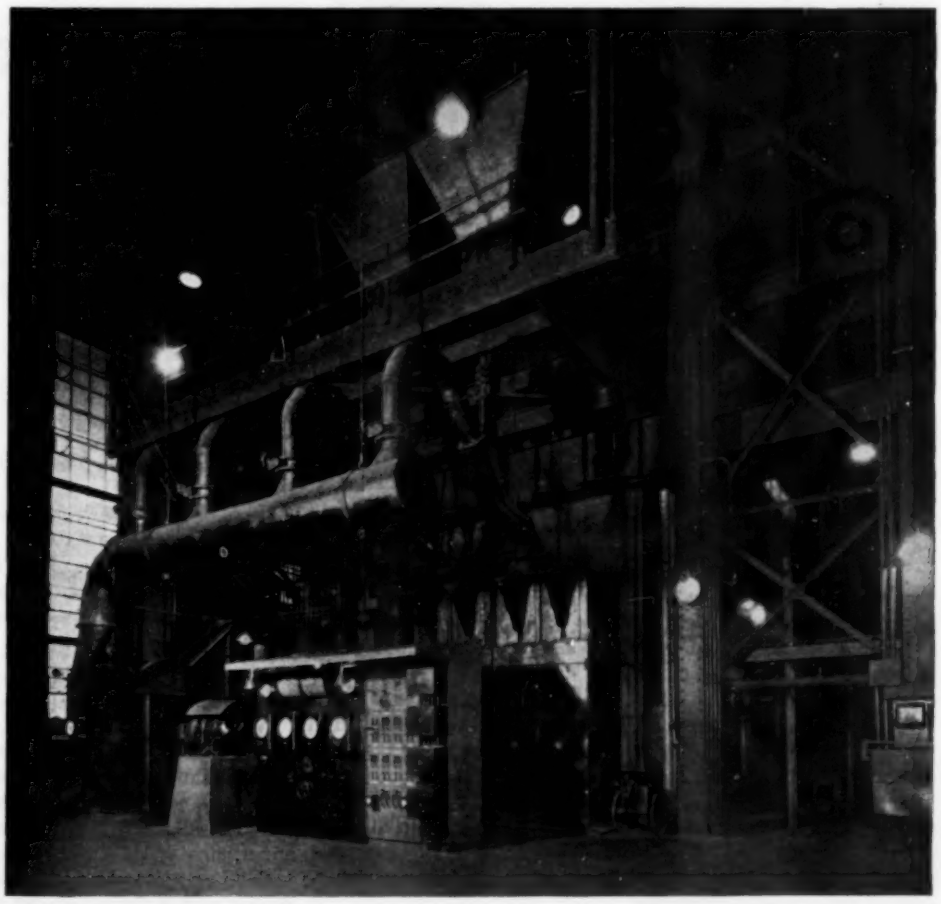

FIG. 7 CONTROL PANEL AND FRONT VIEW OF BOILER NO. 22, CALUMET STATION, WITH A BIN SYSTEM OF FIRING

Operating Costs

The operating costs of Tables 3 and 5 have been arranged on a more comparative basis in Table 10. The final cost unit selected was the cost of 1,000,000 B.t.u. input to the steam-header system, and in order to eliminate the effect of varying coal cost, a standard fuel-heat cost of $18 per 100,000,000 B.t.u. was used. Thus Table 10 shows actual costs with the exception of the fuel item. Inasmuch as these accounts may be somewhat influenced by local conditions, a more detailed explanation of them follows:

Operating labor accounts include the labor of preparing and firing coal, cleaning boiler and furnace, disposing of refuse, and water tending.

Maintenance accounts include the labor and material for repair and maintenance of the equipment listed.

Account 718-B (coal- and ash-conveying equipment maintenance) was divided, because a portion of this cost was prorated from maintenance charges on equipment common to all boiler units in the station.

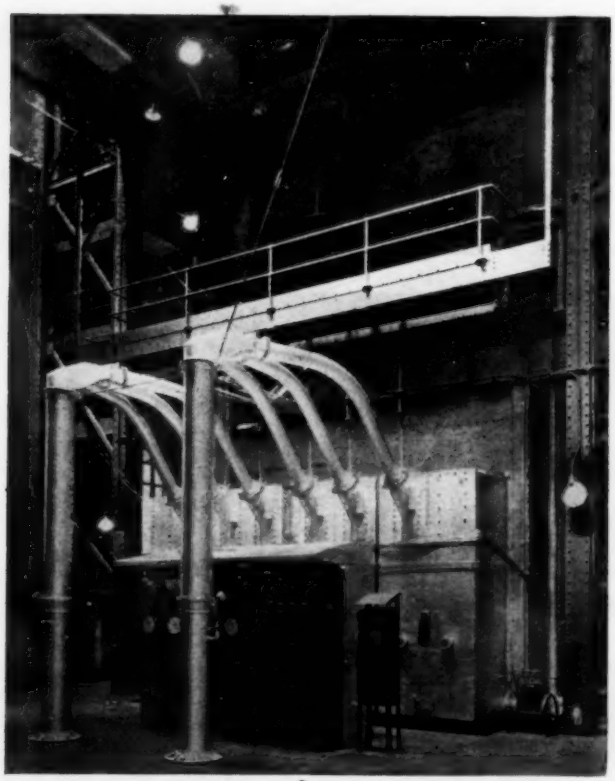

Fig. 8 Control Panel and Front View of Boiler No. 22, Calumet Station, With a Unit System of Firing

Account 718-C (crusher and breaker maintenance) was also prorated for the same reason.

Auxiliary power costs were taken as the station cost per kw-hr. at the bus, after the coal portion of this cost had been adjusted to allow for the advantage in efficiency of boiler No. 22 over that of the boiler room as a whole.

The costs shown in Table 10 are directly comparable between the two systems except as they may have been affected by the conditions explained in the notes. These costs do not include any expense of manufacturers as a result of being required to meet original guaranteed performance.

No attempt is made to draw any general conclusions from either these costs or the operating performance. As they apply to the specific problem of this report, the results should speak for themselves.

TABLE 10 COMPARATIVE DISTRIBUTED UNIT COSTS OF BOILER NO. 22, CALUMET STATION, BIN SYSTEM VERSUS UNIT SYSTEM

	Dollars per million B.t.u. delivered	
	Bin	Unit
703-A coal- and ash-handling labor	0.00095	0.00120
703-B boiler-room labor	0.00920[a]	0.00815
Total operating labor	0.01015	0.00935
717-A maintenance, furnace	0.00228	0.00168
717-C maintenance, boiler and superheater	0.00102	0.00088
717-D maintenance, feeders and burners	0.00047	0.00400[e]
718-A maintenance, economizer	0.00126	0.00059
718-D maintenance, soot blowers	0.00272[b]	0.00042
718-E maintenance, air preheater	.....	.....
718-F maintenance, all fans	0.00214[c]	0.00136[f]
Total maintenance except coal and ash equipment	0.00989	0.00893
718-B Prorate share of station maintenance, coal and ash equipment	0.00211	0.00233
718-B Maintenance, No. 22 coal- and ash-conveying equipment	0.00197[d]	0.00080
718-C Prorate share of maintenance, crusher and breaker	0.00026	0.00318
718-C Maintenance, mill	0.00334	0.01034[g]
Total maintenance coal and ash equipment	0.00768	0.01665
Auxiliary power	0.01140	0.01279
Fuel cost (reduced to a standard basis of $18 per 100,000,000 B.t.u.)	0.21462	0.21496
Total cost (labor, maintenance, auxiliary power, and fuel)	0.25374	0.26258

[a] One fireman and one mill operator for No. 22 bin system alone for nine months.
[b] Additional soot blowers installed (50 per cent of account).
[c] New rotor for induced-draft fan (45 per cent of account).
[d] Coal gates on weigh bins for tests (40 per cent of account).
[e] New burners (80 per cent of account).
[f] Repairs on spare induced-draft fan rotor (35 per cent of account).
[g] Unusually high maintenance costs due to changes in mill and high operating speed.

It would be perfectly natural to compare the principal final results of these two systems to other methods of combustion at this same station using the same unit basis. They are as follows:

	18 stokers	No. 22, bin system	No. 22, unit system	Another type, unit system
Period covered	93 mos.	24 mos.	11 mos.	26 mos.
Total cost in dollars per 1,000,000 B.t.u. delivered, with a coal cost of $18 per 100,000,000 B.t.u.	0.26847[a]	0.25374[b]	0.26258[b]	0.26216
Evaporative efficiency, per cent	77.4	83.85	83.7	81.1[c]
Auxiliary power, kw-hr. per ton	13.56	55.33	51.31	54.41

[a] Unusual expenses incurred by outages, maintenance, and renewal of all economizers included.
[b] Unusual expenses cited in Table 10 included.
[c] Records of the last few months indicate that rehabilitations have improved performance.

In concluding this presentation an attempt has been made to record herein only the facts, as they were and are in this particular case, for what they may be worth to the increasing store of information on these matters. It has been borne in mind that a precise critical analysis of the two methods of firing may as yet be premature in view of the many complications of the situation and developments at present in progress. It is as such that the author prefers to leave it.

Discussion

R. J. Bender.[2] Mr. Grunert's paper has over any previous similar studies the marked superiority of relating actual experience in an existing power plant and covering several years, and the author should be congratulated for the completeness and impartiality of his study.

But one point should be emphasized more than was done in the last part of the paper—not at all to criticize the paper, but to

[2] Whiting Corporation, Harvey, Ill. Mem. A.S.M.E.

warn against any rash conclusion as regards the financial ends of the two types of pulverized-coal firing; this is the fact that, during the period in which observations were made and records kept, considerable work had to be done on the equipment to adapt it to its needs, and the cost of this work has been included, of course, in the cost figures given in Tables 3, 5, and 10. As a fact, this should not be considered at all as inherent to any bin system or direct-fired system in particular; these costs were due to the fact that the equipment was of a comparatively new type and that improvements had to be made during this experimental period.

For instance, a furnace-maintenance cost of 0.042 is given for the bin system against 0.028 for a direct-fired system. Is this not due to the fact that the water-cooled furnace, as mentioned in the first part of the paper, had to be slightly corrected in the first period, while no repairs at all were done during the 11 months of the second period? It would be unfair to draw the conclusion that a difference of about 50 per cent should be expected in the cost of furnace maintenance between the two types of firing.

Further, a mill-maintenance cost of 0.061 is given for the bin system against 0.178 for direct firing. Here again it would be impossible to conclude that a direct-fired system is almost three times as hard on the mills as a bin system. But the paper states that the pulverizer, although modified, was not entirely suitable when running at the speed at which it had to run to follow the desired capacities and that changes had to be made for a better adaptation; then it is clear that the figures are not comparable.

In other words, it is safe to state that if Mr. Grunert would install today two boiler rooms, one with a bin system and one direct-fired, he would pick out his equipment such as to overcome those difficulties which have increased the costs of the plant described in the paper; and the comparative figures might be entirely different from what they are in Tables 3, 5, and 10.

It would therefore be very valuable if, at one of the next meetings, Mr. Grunert or some other engineer could compare the two types of firing not taken as two consecutive phases of the life of a boiler, but taken from two boilers of similar type, burning the same fuel, one direct-fired and the other fired with a bin system, and after a stage of perfection, or, rather, almost perfection, has been reached.

In this comparison it would be extremely interesting to take into account the comparative initial costs and fixed charges, and also to compare the room required for each type and to establish a cost balance of all these conditions—first, for a constant load and, second, for an extremely variable load.

Another point should be mentioned. Mr. Grunert figures the costs with the assumption that the cost of 1 kw-hr. is the same during 24 hours of a day; this is true in this case. But in some plants, and especially those making steam for processing purposes, it is possible to have cheaper power during the night than during the day, in which case a difference would show in favor of the bin system; and it remains to be seen whether this difference is sufficient to compensate the higher initial cost of such an installation.

E. G. Bailey.[3] Mr. Grunert is to be congratulated on his impartial analysis of the advantages and disadvantages of these two systems of firing pulverized coal as they apply to the Calumet installation and upon the completeness of his comparison of operating results. No. 22 boiler at Calumet was a distinct innovation in power-plant equipment at the time it was placed in operation, and the success of this pioneer installation has been an important contribution to the art. This installation has demonstrated to the engineering world that the use of low-grade coal in pulverized form is not only possible but highly practicable for large, high-capacity steam-generating units.

[3] President, Fuller-Lehigh Company, Fullerton, Pa. Mem. A.S.M.E.

At the time the original design was under consideration, a furnace capable of high-capacity operation using coals having a high ash content with a low ash-fusing temperature had not previously been developed. The Calumet furnace was the first completely water-cooled, hopper-bottom type furnace with water-cooled, intertube-type burners to be installed.

Experience with low-grade Midwestern coals on stoker settings had demonstrated that the accepted refractory furnace constructions were subject to high maintenance and periodic outages for furnace repairs because of the damaging scouring action of molten ash. The burning of this coal in pulverized form meant that the destructive action of the coal ash would be even more severe on any refractory-furnace construction.

The operation of this unit over a period of approximately 42 months, with results such as reported in this paper as to combustion efficiency and furnace maintenance, most certainly makes this installation an achievement from the standpoint of overall economy and reliability of this type of furnace construction. The basic design features of this furnace have been applied to many later installations. It is of interest to note that an undertaking in furnace construction of the magnitude of the Calumet furnace has required no major alterations. Improvements have been made on later similar installations as regards extending the water-cooling further down in the sides of the furnace hopper, widening the throat opening in the hopper, and the use of a more satisfactory junction between the top of the water-cooled front and rear walls and the boiler proper.

Although later developments have indicated the desirability of periodically removing the ash from the furnace in a molten condition through a tap hole, where the ash-fusing temperature is less than 2600 deg. fahr., nevertheless this water-cooled hopper bottom furnace has proved entirely satisfactory from an ash-removal standpoint. Ash having a high fusing temperature is removed in a dry condition, while low-fusing-temperature ash runs down the hopper floors and drips into the ashpit, so that the type of coal used has no ill effect on ash removal from this furnace.

The burners, which are of the horizontal intertube type, were the first turbulent burners of this type to be installed. They worked out very satisfactorily in this and many subsequent installations.

Joe A. Bergin.[4] From the valuable data presented, it appears to be a toss-up between stokers and pulverized-fuel firing when selecting power-plant fuel-burning equipment. The greater demand for steam per boiler is probably the deciding factor in favor of pulverized-fuel firing. The 80 lb. of coal per square feet of grate per hour is nearing the maximum fuel-burning rate for a stoker, and 300,000 lb. of steam per hour from a stoker-fired boiler is about the upper limit. Therefore, when the demand for steam exceeds that figure, it becomes necessary to pulverize the fuel for burning.

It is possible that efforts to increase the dollar efficiency of the power plant and the necessity for greater quantities of steam from a given space in the power-plant building will result in pulverized-fuel burning becoming more popular.

O. Von Voigtlander.[5] It would be desirable to know whether charges for capital investment, insurance, etc., have been considered in the author's set-up. It appears to be rather difficult to place a bin system into the same space occupied by a unit-mill system; therefore, considerable difference in plant cost will exist.

[4] Superintendent, Ohio Power Company, Philo, Ohio. Mem. A.S.M.E.

[5] Assistant Mechanical Engineer, Allied Engineers, Inc., Jackson, Mich. Mem. A.S.M.E.

Furthermore, the insurance rate on a bin system is in some known installations three times as great as the unit-mill system. This increased insurance rate may apply to the complete boiler room depending upon the method of construction used. Before a financial set-up for an appropriation can be made, both the operating and construction costs must be known in their entirety.

CONWAY PIERCE.[6] Engineers will appreciate the practical step made by the author in presenting an authoritative report in this form. In addition to the valuable data already presented, many engineers, particularly those from the Middle West, would be glad to learn how the two pulverized-coal systems performed with respect to their ability to handle various grades of coal efficiently and practically as compared with the chain-grate stokers.

Many of us are confronted with the problem of using coals purchased from numerous sources. For this reason, information of this matter is particularly acceptable when available.

AUTHOR'S CLOSURE

In reference to Mr. Bender's discussion, the cost figures in Tables 3, 5, and 10 are actual expenses incurred. They do not include any expense on the part of the manufacturer to meet contract guarantees. The equipment in both systems was supposedly "adapted to its needs" by contract agreement, and wherever it failed in this respect it was regarded as the responsibility of the manufacturer until accepted.

As stated, there was no attempt to make general conclusions on the various item costs. The footnotes to Table 10 were an attempt to point out why direct comparisons on individual items should be made only with reservations. The wide differences between 0.061 for the bin-system mill maintenance and 0.178 for the direct-firing apparently is not clear from footnote *g*, Table 10. When this mill was changed over to a unit mill, one-half the expense of conversion was taken over, as it was a mutual experimental program. Inasmuch as only 11 months' expense was available at the time of preparation of this paper, this one-half reconstruction cost had to be distributed over this relatively short period. If this cost had not been included, the unit-mill maintenance costs would have been nearly the same, and if the direct comparison is to be considered, this would probably be a fair conclusion.

In the furnace maintenance cost of 0.042 as against 0.028, here again the relatively short period of 11 months causes a seeming discrepancy. It so happened that a repair job was done on this furnace shortly following the period taken, which, if included, would have made the unit costs much the same. There is no reason why the furnace costs with both systems on this unit should not be the same in the long run and practically all of that confined to the refractory sections shown. The expense of removal of the 30 blocks in the furnace during the bin-system operation is included, but is relatively of minor consequence in the account.

While the cost figures as given are comparative between the two systems as described, except as to certain irregularities pointed out, they would have to be interpreted in a hypothetical plant. One would certainly attempt to overcome "those difficulties which have increased costs." Some of these reservations might be pointed out. The unit-boiler-room labor item could be reduced, because the same personnel could handle more equipment. The newer improved screen construction should reduce furnace maintenance costs to little or nothing, and it would certainly be expected that developments in mill design should reduce mill-maintenance costs and power consumption. However, these are opinions, while the data given are the actual facts in this particular case. The author makes no attempt to conclusively settle this generally controversial matter.

In regard to Mr. Von Voigtlander's discussion, the investment matter has not been dealt with. This is an important angle to the problem and might even be the controlling factor.

The author is in substantial agreement with the remarks of Mr. E. G. Bailey and Mr. J. A. Bergin.

FSP-53-5

Recovery of Fly Ash From Pulverized-Fuel Stacks by Use of Stack Sprays

By J. W. MACKENZIE,[1] JACKSON, MICH.

One of the first central stations designed for the unit system of pulverized-fuel operation with preheated air encountered difficulty due to fly ash from the stack. The extent of the trouble was determined by locating boards freshly painted with white paint throughout the district. A water spray installed in the stack stopped all complaints, but necessitated lining the stack with acid-resisting material. Tests show that with the spray in operation about 5 per cent of the coal is discharged as solids from the stack, and that the spray takes out about 35 per cent of the solids coming to the stack. A detailed description is included of the equipment and methods used for collecting representative samples of the solids in the flue gases.

This paper outlines the influences which led the Consumers Power Company to adopt a spray system in the stacks of its pulverized-fuel fire plants as a means of combating the fly-ash problem, and shows the results which operation and tests have revealed as to the effectiveness of the system.

STARTING of the Kalamazoo steam-generating plant of the Consumers Power Company in 1927 marked the advent of this company into the field of pulverized-fuel firing, and was in a sense a pioneering step in unit-system operation. While several industrial plants had been designed and built for this method of firing coal, and a few central stations had substituted unit pulverizers for a portion of their stoker equipment, the Kalamazoo plant was one of the first of the larger central stations to be designed and built entirely for this method of operation.

A general survey of the field before this plant was designed showed that while the use of preheat for both primary and secondary air had been experimented with by several companies, there was very little of accurate data to show what could be expected from the continuous operation of unit mills under these conditions. It is, therefore, not surprising that a few changes to the equipment were found desirable after the plant was started. Indeed, the surprising part was that so few changes were necessary.

The matter of possible complaints due to the settling of fly ash in the vicinity of the plant was carefully considered before the plant was designed, and visits were made to quite a number of existing pulverized-fuel plants to learn what had been the experience of others. From the information thus gained, it was thought that, with proper furnace design and good operation, cinder eliminators would not be required. Space, however, was provided so that cinder traps could be installed later.

Determining Extent of Nuisance

During the early operation of the plant, trouble with coarse pulverization and burner difficulties resulted in more solids being discharged from the stack than was expected, and before these troubles could be overcome the complaints made it necessary to do something at once. To get some record of the actual conditions, the area surrounding the plant for a radius of about 12 city blocks was divided into sections. Each morning a board about 16 in. square was placed near the center of each section, the upper side of the board having been freshly painted with white paint. Any particles of dust which settled on the board were caught in the surface of the paint, and when the paint dried this made a permanent record. By watching the wind direction and comparing the record of each test location obtained when the stack gases were passing over that district with records of the same location when the wind carried the gases in another direction, the relative effect of the stack discharge was determined.

These records showed that objectionable quantities of material were being deposited from the stack, with the worst condition about three or four city blocks from the plant, and disappearing at a radius of about nine blocks. A considerable part of this deposit appeared to be carbon in the form of small particles of coke which was undoubtedly largely the result of poor pulverization. To correct this condition necessitated changes in the mills and equipment requiring time, so in view of the local complaints, it was decided to install a water spray in the concrete stack serving these boilers, in the hope of washing out part of the solid materials.

Stack-Spray Arrangement

This stack is 12 ft. inside diameter, with a double breeching connection about 21 ft. above the floor of the stack. A group of four spray nozzles located about 20 ft. above the top of the breeching connection and arranged to form a combined downward spray to fill the cross-section of the stack was first tried out. The results were rather better than was anticipated, but the pipe connections to the spray nozzles soon corroded, and a single center spray with a capacity of about 30 gal. per min. when supplied with water at 10 lb. pressure was substituted in an arrangement shown as the main spray in Fig. 1. This arrangement has the advantage that it can be inspected and repaired from outside the stack, and operation has shown that when the spray covers the area of the stack, an increase in the quantity of water has but little effect on the results.

The water and entrained ash were drained from the bottom of the stack into the sump of the ash-sluice system installed for handling the ashes from the plant, and was discharged from the plant with the regular ash pumps.

[1] Mechanical Engineer, Consumers Power Company. Mr. Mackenzie was graduated in 1916 from the University of Michigan, where he took the mechanical engineering course. Upon graduation he worked for a year and a half for automobile companies, resigning to enter the employ of the Consumers Power Co. in 1917, as efficiency man in their Jackson plant. He has continued in their employ since then, having held the position of mechanical engineer since 1924.

Contributed by the Power Division and presented at the Semi-Annual Meeting of the A.S.M.E. at Detroit, Mich., June 9 to 12, 1930.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

After about a week's operation trouble was experienced due to flakes of accumulated fine ash coming from the stack and settling in the immediate vicinity of the plant. These deposits were confined to a radius of less than 500 ft. An investigation showed that an accumulation of this fine moist ash had collected

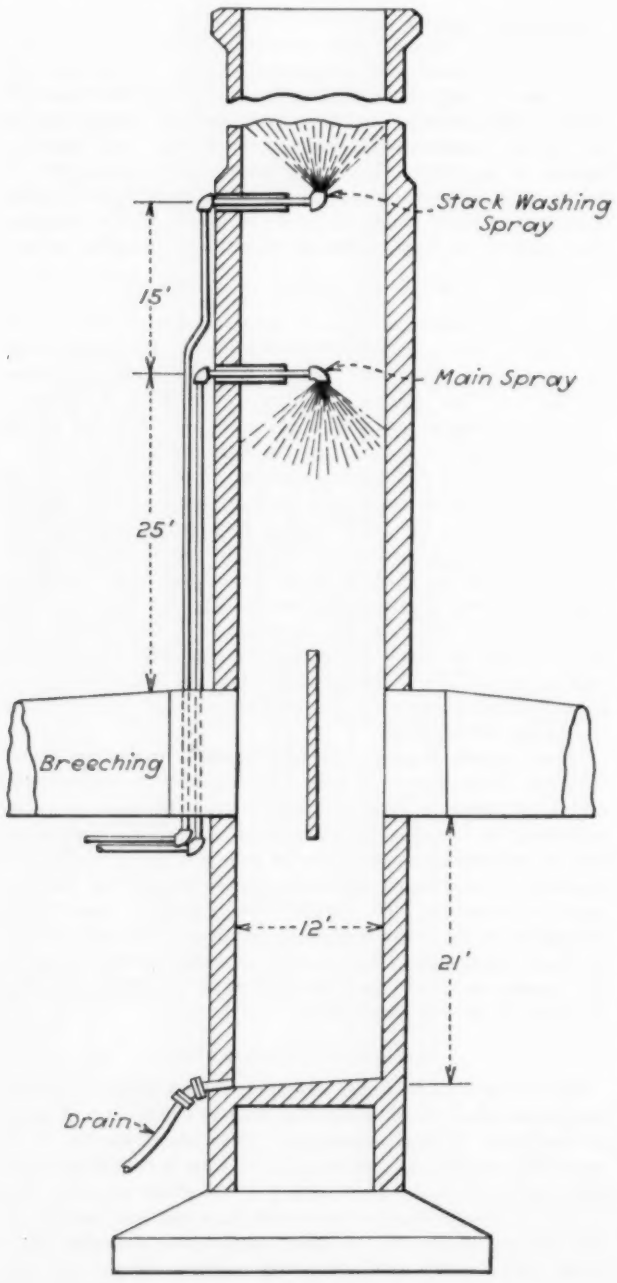

FIG. 1 ARRANGEMENT OF STACK SPRAYS

in a circular band about 3 in. thick and extending from a point about 15 ft. above the level of the spray nozzle upward for about 3 or 4 ft. The moist ash gradually builds up at this point until it begins to flake off and is carried out of the stack. This difficulty was readily overcome by installing a second, or stack washing spray, about 15 ft. above the main spray as shown in Fig. 1. This second spray is a duplicate of the main spray, but is turned upward so that the water from it strikes the wall of the stack at a point above the ash deposit, and this water running down the stack wall washes the accumulation down. The use of this stack-washing spray about 20 min. a day is sufficient to eliminate all trouble from this source.

Some attempts were made to measure the per cent of material removed from the gases by the spray, but the breeching arrangement made it impracticable to obtain samples where the gases were traveling in a vertical direction, and it was found that due to a much higher concentration of solids at the bottom of the horizontal ducts, it was impossible to obtain anything like a representative sample or measurement of the solids under these conditions. The records obtained by means of the painted boards, however, indicated that, with the spray in operation, the amount of dust settling per square foot of area was not perceptibly different when the wind was carrying the gases from the stack over that district from that when the wind was in another direction.

In view of the results obtained at the Kalamazoo plant, it was decided to incorporate the same system in the design of the company's Wealthy Street plant No. 2 located at Grand Rapids, Michigan. This plant is inside the city limits, and no complaints have been received after about one year's operation.

MEASUREMENT OF FLY-ASH RECOVERY

A breeching arrangement at this plant, which includes a fairly long vertical duct from the induced-draft fan of each boiler, offers excellent facilities for obtaining characteristic samples of fly ash in the gas, and a number of tests have been made.

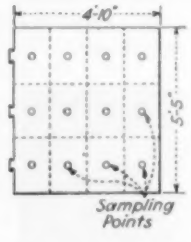

FIG. 2 A CROSS-SECTION OF THE DUCT WAS DIVIDED INTO TWELVE EQUAL PARTS, AND A SAMPLE OF GAS ASPIRATED FROM THE CENTER OF EACH SECTION

The method adopted in making these tests was to divide the cross-section of the vertical duct into 12 equal parts as indicated in Fig. 2, and to aspirate a sample of gas with its entrained solids from the center of each section.

It is very important in obtaining a sample of this kind that the rate of flow into the entrance of the sampling tube shall be the same as the velocity of the gases past the tube. Not only will the total quantity of solids vary with the velocity of the gases entering the tube but the percentage of fines is also affected. This is more readily understood by referring to Fig. 3. If the velocity into the sampling tube exceeds the velocity of the surrounding gases, some of the materials which would otherwise pass the sampling pipe are diverted from their normal path and carried into the sample, and since the finer particles are more easily deflected, the percentage of fines in the sample will show too large. If, on the other hand, the velocity into the sampling tube is lower than that of the surrounding gases, some of the gases are forced outside the area of the sampling-pipe entrance, resulting in less total solids in the sample with too low a percentage of fines. By maintaining the same velocity within as without the sampling pipe, the least possible disturbance in the gas stream is obtained with a quantity and quality of sample which is characteristic of the total material in the gases. To insure this minimum disturbance at the entrance of the sample pipe, it is desirable to use a thin straight-walled tube for this purpose, with the entrance edges sharpened.

The apparatus used for collecting the samples in these tests is indicated in Fig. 4, and consists of a thin-walled sampling pipe (*a*) connected to a vacuum cleaner bag (*b*) through an air-operated ejector (*c*) with a valve (*d*) for controlling the flow in the sampling pipe. The sensitive inclined draft gage (*e*) is

connected to indicate the differential pressure between the pitot tube (*g*) with its open end in the entrance of the sampling pipe and the pitot tube (*h*) with its open end outside the sampling pipe.

It will be noted that the pitot tubes are turned with the flow of the gases, which would theoretically show the static head minus the velocity head. This arrangement was adopted due to the fact that if the pitot tubes are turned against the flow of the gases they become clogged with the fly ash. While this arrangement is not accurate for actually measuring velocities, tests made with a sampling tube equipped with both types of pitot tubes showed that the arrangement adopted was satisfactory for establishing the same velocity into the tube as existed in the surrounding area.

The procedure followed in collecting samples was to set the sample tube to draw from the center of one section of the duct area, and with a vacuum-cleaner bag in place the ejector was started and the flow in the sample tube adjusted by means of the valve (*d*). The vacuum-cleaner bag was then removed, and a duplicate bag which had been dried and accurately weighed

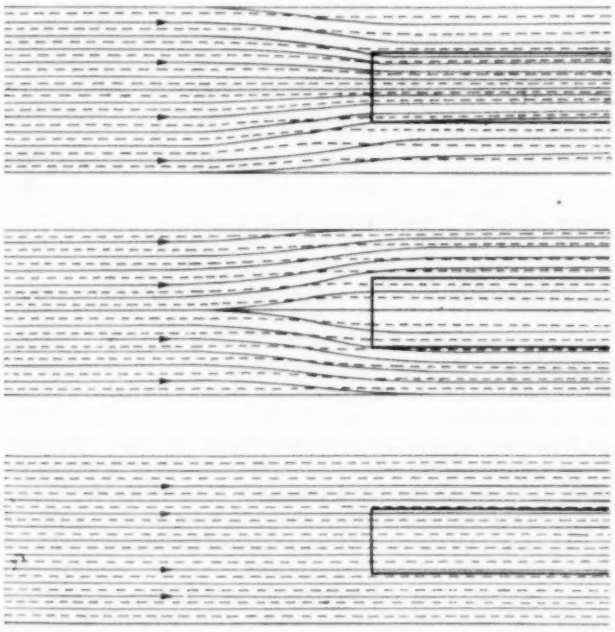

FIG. 3 QUANTITY OF SOLIDS AND PER CENT OF FINES VARY WITH VELOCITY OF GASES

(Above, velocity in sampling pipe greater than surrounding gas; center, velocity in sampling pipe less than surrounding gas; at bottom, velocity in sampling pipe equal to that of surrounding gas.)

was substituted, and a three-minute sample collected, after which the sampling tube was moved to the next section of the duct area and another three-minute sample taken. In this way a three-minute sample was gathered from each section of the duct, careful watch being kept of the gage (*e*), and the flow controlled so as to maintain equal velocities at the sampling end of the tube. The vacuum-cleaner bag containing the sample was then dried and reweighed. The increase in weight times the ratio of the area of one section of the duct to the area of the entrance of the sample tube equal the total solids passing through the duct in a 3-min. period.

The sample was then removed from the bag and tested for fineness, and analyzed for percentage of combustible. Some of the very fine particles became imbedded in the bag so that it was impossible to brush them out; this varied from 15 to 40 per cent of the total weight of the sample. In making up the data showing the fineness of these samples it has been assumed that all material lost would pass through the 200-mesh screen, and has been included in this figure. This undoubtedly is slightly in error, but it is believed that the error is within the limits of the accuracy of the other data.

The percentage of combustible is given as determined from the amount of material actually recovered from the bag, and takes no consideration of the percentage of combustible in the

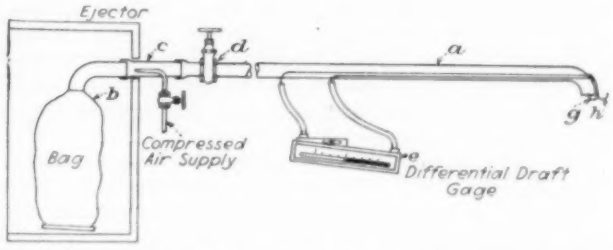

FIG. 4 ARRANGEMENT OF APPARATUS FOR COLLECTING SAMPLES

material lost or left in the bag. Preliminary tests, together with the data given here, show quite consistent results when the same firing conditions were maintained, indicating that the results are fairly accurate. The following procedure was used for determining the quantity and nature of the material removed from the stack gases by the spray.

While the samples of fly ash were being collected as outlined, all of the water and ash discharged from the bottom of the stack was diverted for a short time into a small tank, the actual time being determined by means of a stop watch. This sample was filtered, and the residue dried, weighed, and tested for fineness and combustible. From the data then available, the total weight, as well as the percentage of carbon and ash recovered from the stack per hour, was easily determined.

RESULTS OF TESTS

The results of these tests are shown in the accompanying tables, and represent conditions from about three-quarters of normal

TABLE 1 HOURLY RESULTS OF TESTS

Test number	1	2	3	4
Number of boilers in use	2	2	2	1
Total lb. coal fired	23,183	17,711	16,888	11,644
Fly ash to stack, lb.	1,951	997	1,498	1,299
Fly ash recovered, lb.	756	624	463	437
Ratio, fly ash to coal, %	8.42	5.63	8.87	11.16
Carbon in fly ash, %	.....	49.0	35.9	40.4
Carbon in recovered fly ash, %	.....	46.2	37.4	46.8
Per cent of fly ash recovered	38.8	46.16	30.90	33.60

TABLE 2 FINENESS OF ASH

Test no.		Through 200	Through 100	Through 48	Through 28	Over 28
2	Total fly ash	62.7	81.2	95.6	99.6	0.4
	Recovered fly ash	43.6	62.3	91.2	99.6	0.4
3	Total fly ash	60.4	81.5	96.4	99.8	0.2
	Recovered fly ash	60.3	79.9	96.5	99.9	0.1
4	Total fly ash	47.4	62.5	95.1	99.8	0.2
	Recovered fly ash	53.2	71.1	96.0	99.8	0.2

TABLE 3 PER CENT CARBON AND FINENESS OF RECOVERED ASH

Test no.		Per cent carbon	Through 200	Through 100	Through 48	Through 28	Over 28
5	With spray	34.0	61.1	86.6	98.8	99.9	0.1
	Without spray	56.4	27.3	56.2	93.4	99.6	0.1
6	With spray	38.8	73.5	93.0	99.6	99.9	0.1
	Without spray	48.3	48.6	75.4	97.4	99.8	0.2

boiler capacity to full normal capacity. The ratio of the fly ash to the coal fired is undoubtedly much lower with the reduced velocities at lower ratings, but no satisfactory data have been

obtained at the lower ratings, due to difficulty with the solids settling out in the breechings with the reduced velocities.

It will be noted that, under the conditions covered by these tests, the ratio of the fly ash to the total coal varies from about $5^1/_2$ to 11 per cent of the coal used, and with the spray in operation about 37 per cent of this amount is recovered. The tests show that under normal operation with the stack spray in use there is still about 5 per cent of the total weight of the coal discharged from the stack.

The average velocity of the gases in the stack under normal full load has been determined to be about 1000 ft. per min., with a volume of 127,500 cu. ft. per min., which gives a loading of about 0.156 lb. of solids per 1000 cu. ft. of gas, and of these solids more than 65 per cent will pass through a 100-mesh screen, a loading and fineness which apparently give sufficient dispersion to avoid detection.

Tests were also made to determine the per cent and the relative fineness of the solids which would be deposited in the stack without the use of the spray. These tests show that with the spray in operation from three to four times as much material is recovered as without it. The spray also greatly increases the recovery of the fines, and is much more effective on the ash than on the carbon in the gases.

Effect of Water on the Stack

After about nine months' operation, an inspection of the inside of the Kalamazoo stack showed that the concrete surface was being seriously eroded by the use of the water. The effects were most marked at the bottom of the stack, diminishing in an upward direction.

While the spray had originally been installed only as a temporary measure, it was decided best to keep it in operation after all firing troubles were corrected. Accordingly, an acid-resisting lining was installed extending from the base of the stack to a point about 50 ft. above the spray. This lining is constructed from vitrified tile laid with thin joints with an acid-resisting cement; a similar lining extending the full height of the stack was installed in the stack at the Grand Rapids plant, and to date these linings are showing no signs of erosion.

From the experience thus far obtained it appears that where a spray is to be used in a stack for removing fly ash from flue gases, the spray should be installed at least 20 ft. above the point where the gases enter the stack, and that there should be a distance of at least two stack diameters from the bottom of the breeching connection to the bottom of the stack.

Conclusions

From the data obtained thus far it appears that, providing the gas velocities do not exceed approximately 1200 ft. per min., a spray in the stack of a pulverized-fuel installation can be used as one means of reducing the fly ash discharged, and that a recovery of about 35 per cent of the solids can be expected. The use of larger quantities of water offers no advantage providing the spray covers the cross-sectional area of the stack. Means must be provided for periodically washing down accumulations of ash which will collect on the stack wall above the spray. An acid-resisting lining is necessary to protect the stack interior.

It appears that reducing the dust loading of the gases increases their carrying power, thus increasing the dispersion. Experiments and tests should be continued to determine the effect of different types of sprays.

Discussion

Ralph A. Sherman.[2] All will agree that the discharge of fly ash from the stacks of boiler furnaces, whether stoker- or pulverized-fuel-fired, is one of the most serious problems of power-plant operation. Much study is being given to means of abatement or of elimination of the fly ash and to methods of its disposal. The author's paper is of value in that it shows the limitations of the stack spray rather than its success. Although a recovery of 35 per cent of the solids is a step in the right direction, one cannot be content with that, even though it is true that the remainder is so dispersed that it avoids detection or complaint at present.

One of the first requirements of the problem is accurate knowledge of the amount of ash being discharged from stacks. The author has outlined the principles which should be observed in the determination of the fly ash and has made careful measurements. More similar data are needed, and it would be valuable if some central body would sponsor their collection in a large number of plants, either by the individual operators or, better, by the same observers going from station to station.

It is impossible to calculate, from the data which the author presents, the percentage of ash in the coal fired which was carried up the stack, because the author has not given the ash content of the coal. This value appears to the writer to be a more significant value in such determinations than the percentage of the coal fired, for the ash and carbon are then calculated separately. If we assume that the coal contained 10 per cent of ash, the percentage of the total ash carried as fly ash was about 28 per cent for Test 2 and 70 per cent for Test 4, as shown in Table 1. This is a wide variation for the change in rate of firing and is probably accounted for by other factors.

It may be recalled that some determinations made by the writer[3] at the Toronto, Ohio, Station of the Pennsylvania-Ohio Power & Light Company showed less than 50 per cent of the ash fired carried to the stack with a dry-bottom furnace and not more than 30 per cent when firing similar coal to the same type of furnace except that it was changed to a slagging bottom furnace.

Author's Closure

Referring to the discussion, the author wishes to state that the fuel used during these tests was West Virginia nut and slack coal with a moisture content of about 4 per cent, B.t.u. value of about 13,200 as fired, and an ash content of slightly less than 9 per cent.

Apparently there is some error in the amount of fly ash to the stack as shown in the No. 2 test, as it is noted that this figure does not agree with the rest of the data, whereas the amount of ash recovered by the spray during this test is consistent with the other data. Also, from tests made on the quantity and quality of ash removed from the bottom of these furnaces, it has been found that under normal conditions about 35 to 40 per cent of the ash in the coal remains in the furnaces, which agrees fairly well with the calculated results for the No. 3 and No. 4 tests. The figures shown in the No. 2 test were included, notwithstanding this discrepancy, due to the fact that the per cent recovery with regard to the total coal fired appears to be correct, and the data obtained therefrom are correspondingly valuable.

The author is not inclined to agree with Mr. Sherman regarding the importance of the ratio of the ash discharge from the stack to the total ash in the coal, since it is the total quantity of solids emitted from the stack which must be considered, and in the experience at the Kalamazoo Plant there has probably been more complaint from the surrounding neighborhood when an appreciable percentage of unburned carbon was present in the deposit than in cases when it was made up largely of the lighter-colored ash particles.

FSP-53-6

Tests of the Resistance to Repeated Pressure of Forged, Riveted, and Welded Boiler Shells

By H. F. MOORE,[1] URBANA, ILL.

Data regarding the performance of welded joints in resisting repeated stresses are very important in any consideration of the adoption of welded construction for power boilers, and it is the object of this paper to present such data. Comparative tests were made on (1) a standard A.S.M.E. riveted drum, (2) manganese-steel riveted drum, (3) forged seamless-steel shell, (4) two forge-and-hammer-welded shells, and (5) eight fusion-welded (metallic-arc) shells, each drum or shell being subjected to applications of pressure well above the allowable working pressure.

The results indicate that under repeated stress properly made welded joints are stronger than the plates themselves when weakened by "stress raisers" such as small holes or surface defects. The tests also give useful data on the strength of drum heads when subjected to intermittent pressures.

THE use of welding for the joints of seams in pressure vessels is of great interest at the present time to the American Welding Society and to the Boiler Code Committee of The American Society of Mechanical Engineers, which has under consideration the revision of its rules bearing on unfired pressure vessels, and which has published "Proposed Specifications for Fusion Welding of Drums or Shells of Power Boilers" and has solicited discussion thereon. About three years ago tests were started at the Barberton works of the Babcock & Wilcox Company on the performance of welded and riveted vessels under repeated applications of pressure. A preliminary report on these tests was made by the author and published in the *Iron Age*, September 5, 1929. There had previously been published some test data of repeated stress tests on small specimens, but there was little knowledge of the performance of fusion-welded joints on full-size pressure vessels.

In making fatigue tests of small specimens of metal, six or more specimens of each metal are ordinarily tested under various stresses, and usually some tests for each metal are run to at least 10,000,000 cycles of stress. Thus for nearly all metals it is possible to determine the "endurance limit" below which the metal will withstand an indefinitely large number of cycles of stress without fracture.

This method of testing six or more specimens of a kind was not feasible for application to full-sized test shells on account of the expense and time necessary for preparing the shells and for making the tests. It was necessary to cut down the number of specimens below that which would be required for making exact determinations of the "endurance limit;" however, the tests which were made to study the relative length of endurance of full-size test shells have given data which are directly applicable to the problem at hand. In the ordinary service of a boiler, the cycle of stress on the shell due to internal pressure is repeated at most a few thousand times, and the stress is not reversed, varying from zero to a maximum with slight fluctuations near the maximum stress. Thus it was feasible to run the tests to numbers of cycles of stress greatly in excess of the number of cycles in the normal service of a boiler or of a pressure vessel.

Test Specimens

Two types of test specimens were used. For the testing of riveted drums the test specimen is of the type shown in Fig. 1.

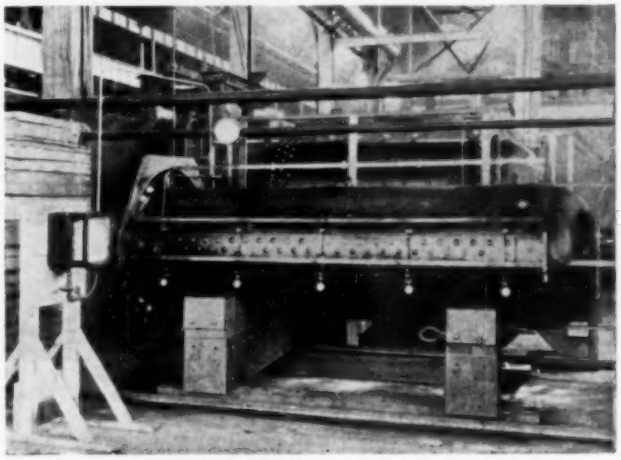

Fig. 1 Riveted Drum Arranged for Tests

This type of specimen is referred to as a test drum. Two test specimens of this type were used, one of A.S.M.E. code boiler plate having a minimum tensile strength of 55,000 lb. per sq. in., and the other of manganese-steel plate having a minimum tensile strength of 105,000 lb. per sq. in.

Fig. 2 shows the second type of test specimen used. This type of specimen is referred to as a test shell. The details of the arrangement are shown in Fig. 3. The test shell is placed around an inner shell, leaving an inner annular space between the two shells. Packing and packing glands close the ends of this annular space and water under pressure is admitted into it. With this type of specimen, the stresses set up are thus limited to hoop tension, and only a small quantity of water is required. Eleven specimens of this type were used: (1) A forged seamless test shell, (2) two forge-and-hammer-welded test shells, and (3) eight fusion-welded test shells, all welded by the metallic-arc method.

Test Apparatus

Fig. 4 is a diagrammatic view of the apparatus. Water under

[1] Research Professor of Engineering Materials, University of Illinois. Mem. A.S.M.E. In connection with the tests given in this paper Mr. Moore served as special consulting engineer for the Babcock & Wilcox Company. He has served as instructor in science and mathematics at Colby Academy, instructor in machine design at Cornell University, and mechanical engineer for Riehle Brothers Testing Machine Company and Assistant Professor of Mechanics at the University of Wisconsin. He is the author of many technical papers and bulletins of the University of Illinois Experiment Station.

Contributed by the Power Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

a pressure of 1600 lb. per sq. in. was taken from the pressure mains of the Babcock & Wilcox Company's works, and this pressure was regulated by an accumulator. The water passed through a reducing valve and then through the mechanically operated valves, shown diagrammatically in Fig. 4, which by their action, alternately admitted water to the test shell and allowed the pressure to be relieved through an exhaust pipe. This operating valve was driven through link work by an electric motor with variable speed. The link work was fitted with a revolution counter, which indicated the number of cycles of pressure applied. The set-up of apparatus comprised six sets of valves, so that six test shells could be tested at one time.

The pressure applied to each specimen was shown by a Bourdon gage, which was attached directly to the specimen, and was also measured on a recording-pressure gage. The rate of application of pressure averaged about 13 cycles per minute. The

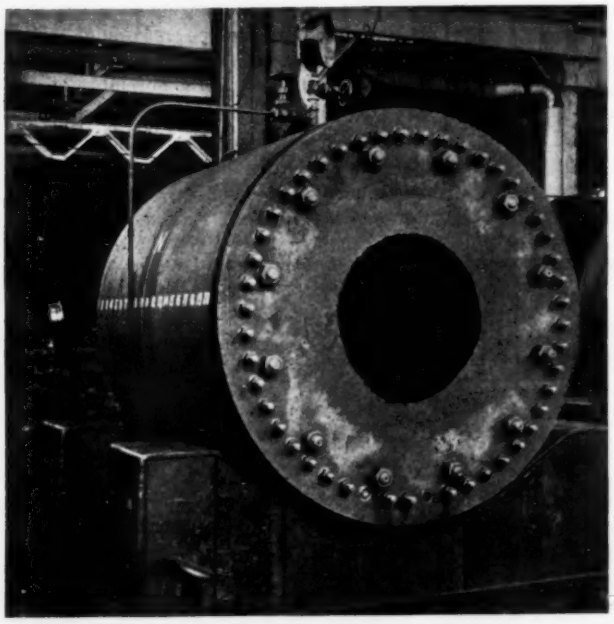

Fig. 2 Test Shell Arranged for Tests

deformation of test specimen was measured at intervals during the test by means of strain gages, which indicated any marked distortion of a specimen during the progress of the test.

A careful watch was kept to detect incipient fracture. Any cracks developed by the repeated pressure started on the inside of the shell, but before failure had extended very far the crack worked through to the outside, and it was detected by the leakage of a fine stream or spray of water. Table 1 gives a summary of the tests up to date, and the numbers assigned to the test shells refer to this table.

Manganese-Steel Test Drum

The manganese-steel drum was constructed of plate having a minimum tensile strength of 105,000 lb. per sq. in., was designed for the working pressure with a factor of safety of five, and the test pressure was alternated from zero to that corresponding to 50 per cent more than the working pressure. The heads were figured in accordance with the Massachusetts standard except that a tensile strength of 105,000 lb. per sq. in. was used in place of 55,000 lb. per sq. in. Fig. 5 shows the principal dimensions of this drum. The deflection of the manganese-steel heads on applying the pressure was greater than if they had been made of A.S.M.E. standard boiler plate, both on account of the high-tensile-strength steel stretching more than the lower-tensile-strength steel for a stress corresponding to a given factor of safety, and on account of the effect of the cross strains in the heads, which are not fully covered by the formula when steel of a higher tensile strength is used.

During the progress of the test, slight leaks appeared around the buttstrap, and after 130,225 cycles of stress, a leak developed near the manhole opening in the head of the drum, which was so large that a fracture was indicated. The test was stopped and examination showed a definite fracture. An attempt was made to patch this fracture by chipping out the fracture to form a double

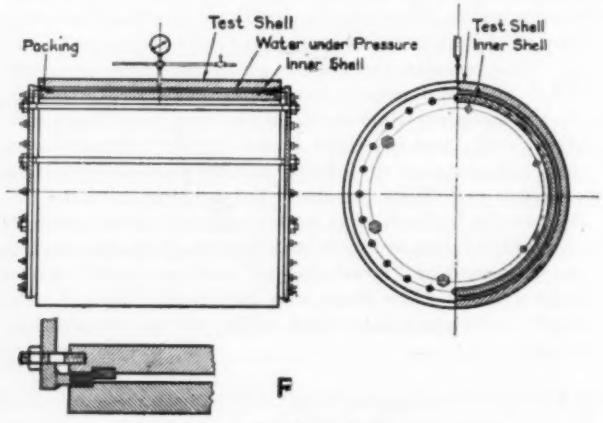

Fig. 3 Test Shell

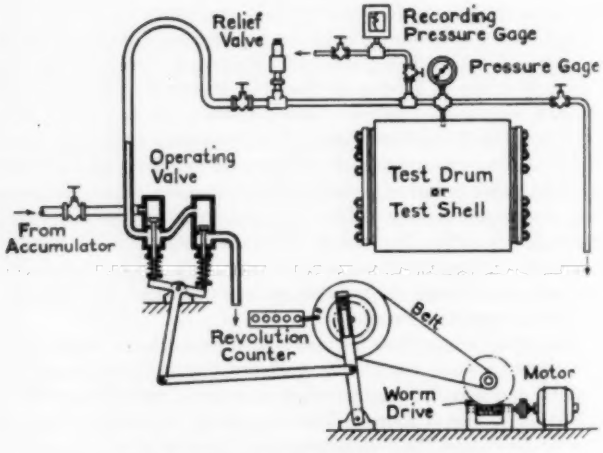

Fig. 4 Diagram of Test Equipment

V and welding. After 143 additional cycles of pressure, the drum head split violently through the crack repaired by welding. The measurements of strain during this test showed no evidence of appreciable distortion of the drum, except in the immediate vicinity of the crack.

A.S.M.E. Standard Drum

The riveted drum of A.S.M.E. code plate was constructed in accordance with the A.S.M.E. standard except that the heads were Massachusetts standard. The reason that the heads were made Massachusetts standard was because the Boiler Code Committee proposed at the time to revise its code to make the rules for heads more nearly in line with those contained in the Massachusetts code. The A.S.M.E. code as revised requires a thicker manhole head than was used in the test drum. Fig. 6 shows the principal dimensions of this drum. It was calked on the inside and not on the outside.

The test pressure was alternated between zero and that corresponding to 50 per cent more than the maximum allowable working pressure given by the A.S.M.E. code. Small leaks developed during the first part of the test, which were stopped by internal re-calking. A total number of 1,013,840 cycles was applied to the drum and no fracture resulted. The measurements of strain gave no evidence of permanent distortion during the test.

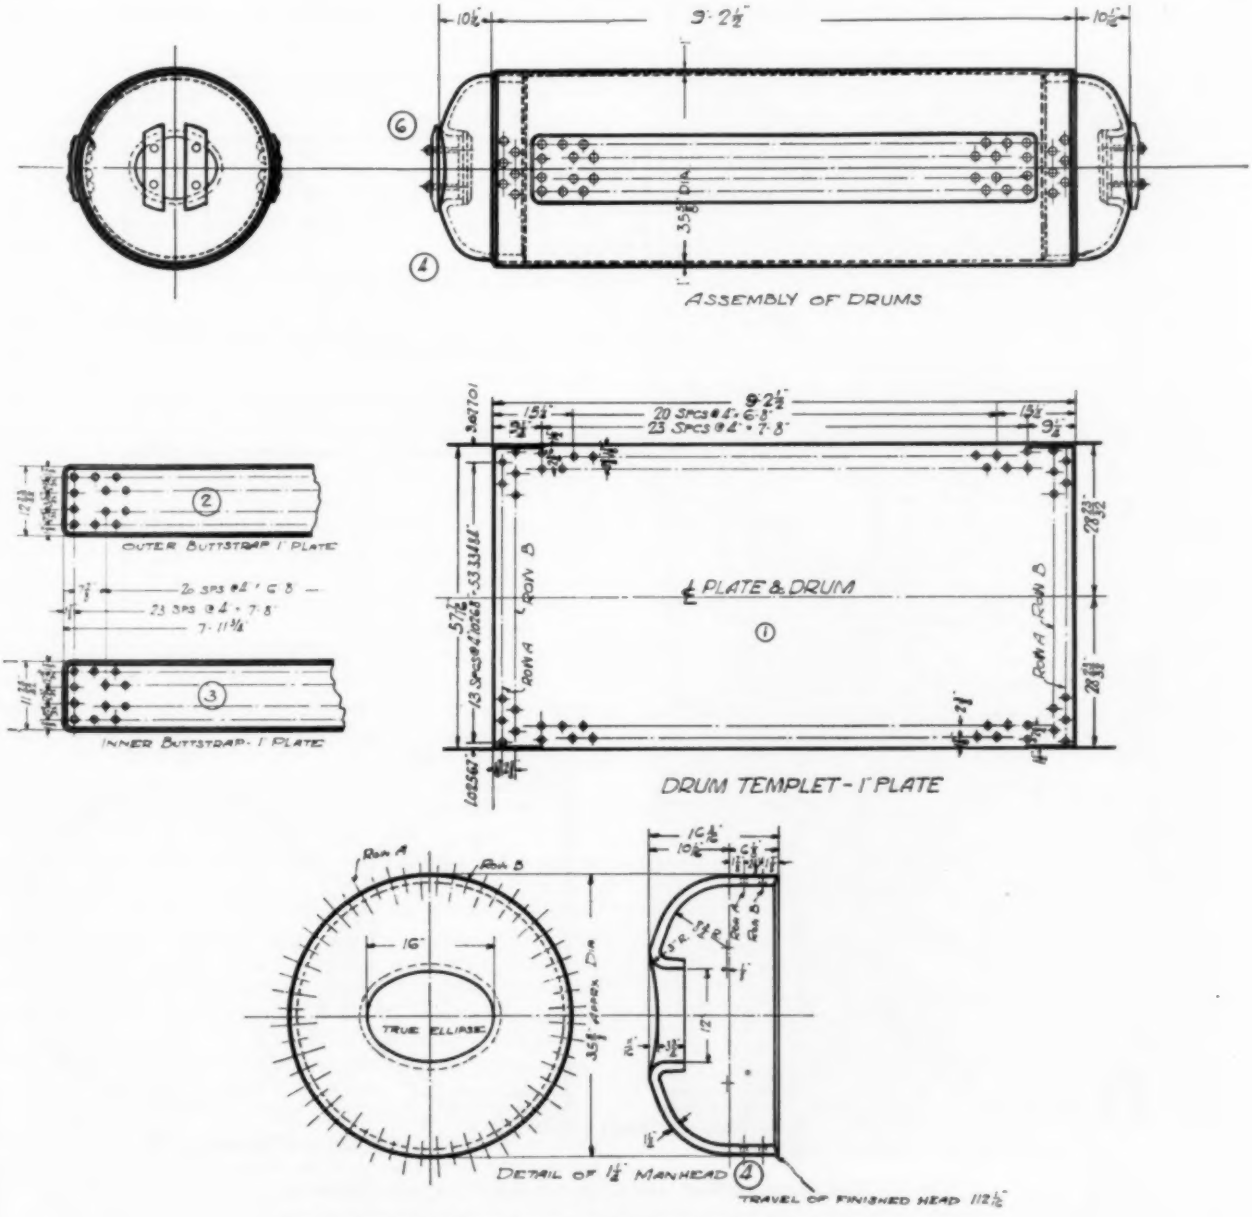

FIG. 5 SPECIAL 36-INCH DIAMETER DRUM OF HIGH-TENSION STEEL PLATE

FORGED SEAMLESS TEST SHELL

The forged seamless test shell was made of steel in accordance with the A.S.M.E. Boiler Code specifications for seamless-steel drum forgings for steel having a minimum tensile strength of 60,000 lb. per sq. in. All the tests called for by the A.S.M.E. Boiler Code for this class of steel were met and the drum was annealed above its critical temperature as called for by the code. The test pressure was alternated from about zero to that corresponding to 50 per cent more than the maximum allowable working pressure given by the A.S.M.E. code.

The seamless forged test shell was subjected to 446,950 cycles of pressure, at which point the test shell fractured at a tapped hole provided for the pressure-gage connection. In this test, as in several others, it was quite evident that this tapped hole acts as a region of stress concentration, where a spreading fatigue crack is liable to start. During the test the strain measurements showed no evidence of permanent distortion.

FORGE-AND-HAMMER-WELDED TEST SHELLS

The first forge-and-hammer-welded test shell (No. 12) was of German manufacture and was constructed of open-hearth quality plate of 35 to 44 kg. per sq. mm. tensile strength with corresponding elongation, the quality of the plate conforming to the pro-

visions of the German steam-boiler laws. The foregoing tensile strength corresponds to a tensile range of approximately 50,000 to 62,500 lb. per sq. in. This test shell had one longitudinal forge-and-hammer weld, made by the so-called gas-welding process prevalent in Germany, the weld being of the same thickness as the plate.

This test shell had no tapped hole in it, the pressure gage being attached to the inner shell of the test apparatus. This 611,184 cycles of stress when it cracked in the plate quite a distance from the weld. This shell had no tapped hole for gage connections, but the failure took place at a well-marked longitudinal surface defect, consisting of a groove about $^1/_{16}$ in. wide, $^1/_{32}$ in. deep, and some 2 ft. long. This fracture is shown in Fig. 8, and it is to be noted that the defect seemed sufficient to locate the start of fatigue failure, although, through being near one end, it was not at the point of maximum stress.

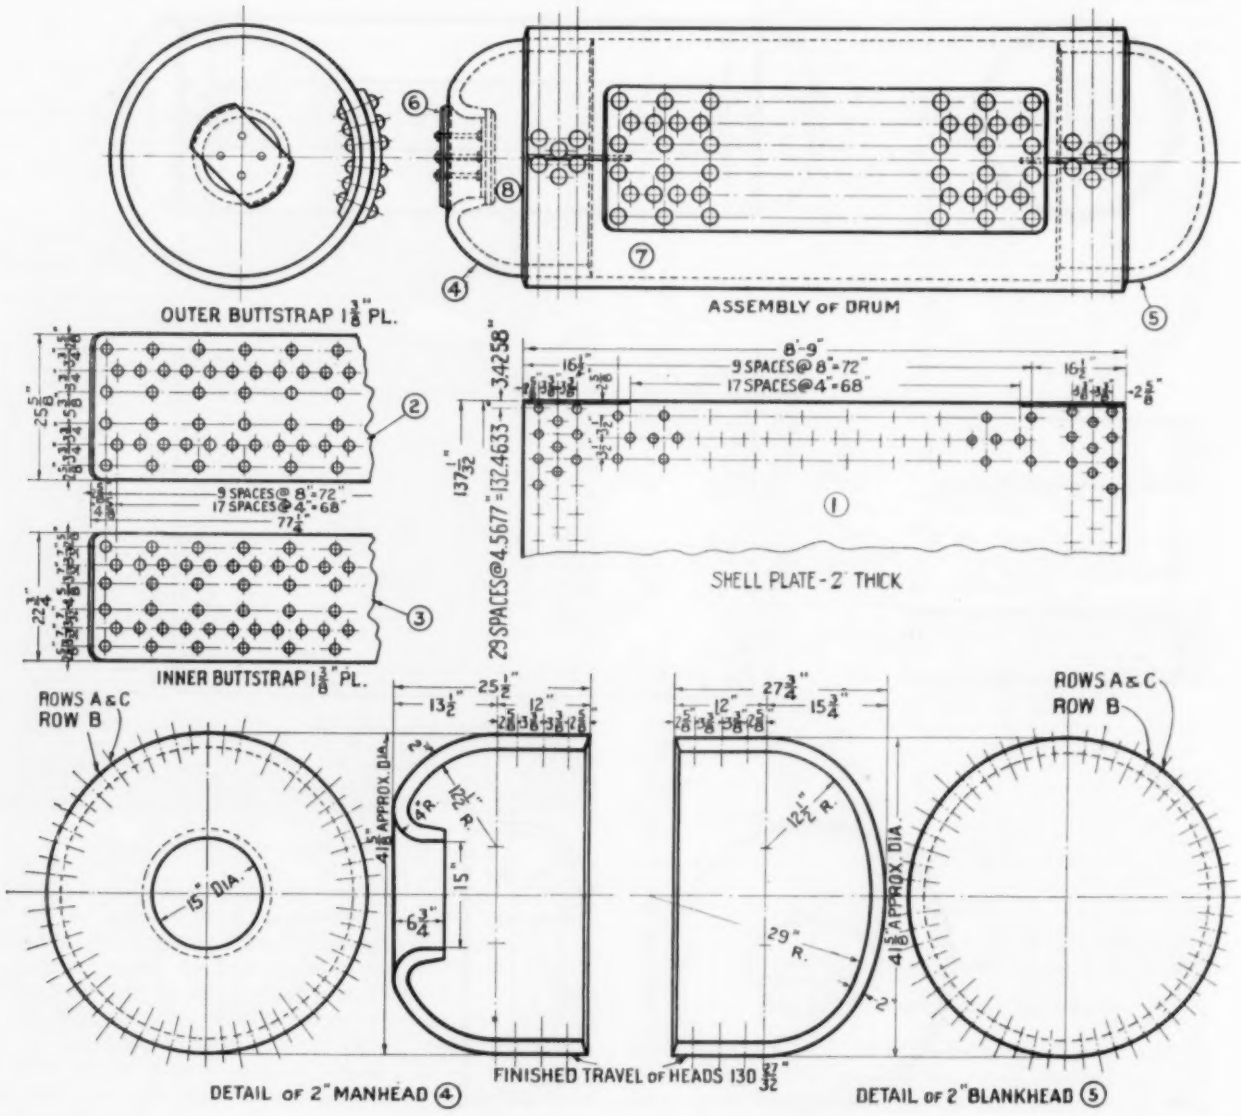

FIG. 6 EXPERIMENTAL TEST DRUM OF A.S.M.E. STANDARD MATERIAL

specimen has withstood 890,000 cycles without failure and the test is still in progress.

The second forge-and-hammer-welded shell (No. 13) was made of A.S.M.E. code plate having a minimum tensile strength of 45,000 lb. and the test pressure was alternated between zero and that which produced a stress of 16,500 lb. per sq. in. in the plate. The thickness at the weld was $2^1/_4$ in. or $^1/_4$ in. more than that of the plate. Strain-gage measurements showed that the stress in the welded seam was 14,000 lb. per sq. in. when the stress in the plate was 16,500 lb. per sq. in.

This second forge-and-hammer-welded shell was subjected to

The A.S.M.E. Boiler Code specifies that the stress shall not exceed 7000 lb. per sq. in. for forged-welded joints for power boilers and 8000 lb. per sq. in. for unfired pressure vessels. The forge-and-hammer-welded shells were tested at a higher pressure than that corresponding to 50 per cent more than the allowable A.S.M.E. code pressure in order that the results might be directly comparable with those secured from the fusion-welded shells.

FUSION-WELDED TEST SHELLS

The fusion-welded test shells were made of A.S.M.E. code boiler plate having a minimum tensile strength of 55,000 lb.

per sq. in. Each test shell had one longitudinal arc-welded joint, this longitudinal joint extending the entire length of the test shell. The excess weld metal on both the inner and outer surfaces was chipped and ground off so that no reinforcement of the weld metal was present. All arc-welded test shells were strain annealed at 1200 deg. fahr. previous to testing. The test pressure was alternated from zero to that which produced a stress of 16,500 lb. per sq. in. in the plate and across the weld. This would correspond to basing the working pressure for a factor of safety of five on a stress of 11,000 lb. per sq. in., which involves the use of a welded joint as strong as the plate. The proposed specifications base the working pressure on 80 per cent of this stress.

Arc-welded test shell No. 1 was welded with ordinary bare welding wire. After 5530 cycles of pressure, fracture developed in the welded seam at the junction of the base metal and weld metal.

Arc-welded test shell No. 2 was the first test shell made in the early stage of the development of the welding technique now perfected by the Babcock & Wilcox Company. A special welding rod was used. After 267,603 cycles of pressure, a fracture $1^1/_4$ in. long developed at the junction of base metal and weld metal near the middle of the length of the longitudinal seam. On examination of the fracture, it was found to extend through some slag inclusions in the weld. Strain-gage readings showed that permanent distortion in the vicinity of the point of failure began to be evident at 240,000 cycles of pressure.

Arc-welded test shell No. 3 was welded using a covered welding wire. After 417,381 cycles of pressure, the test shell fractured, not in the weld, but at the tapped hole where the pressure-gage connection was made. During the test, there were no signs of permanent deformation.

Arc-welded test shell No. 4 was also welded, using a B & W processed electrode. After 561,984 cycles of pressure, the shell cracked at the tapped hole for a gage connection in a manner similar to the failure of the forged shell and of arc-welded test shell No. 3. There were no signs of permanent distortion during the test.

Arc-welded test shell No. 5 was a duplicate of shell No. 4 and the same methods of welding were used. After 435,883 cycles of pressure, failure occurred at the gage connection as in the case of shell No. 4.

Arc-welded test shell No. 6 was welded using a B & W processed electrode, and to study further the effect of the gage connection, an unreinforced tapped hole for the hydraulic-gage connection was put through the weld metal. After 58,842 cycles of pressure failure occurred at this tapped hole. A comparison of this test with tests of shells 3, 4, 5, 7, and 8 shows clearly the disastrous effect of the tapped hole, and shows that such a "stress raiser" is especially dangerous in the weld metal.

Arc-welded test shell No. 7 had no tapped hole for a gage connection. It was subjected to 1,035,037 cycles of pressure without failure. After the test was finished, specimens were cut from the weld and showed no change in physical properties. Other specimens were examined carefully under the microscope. In one of the specimens so studied, a small blowhole was discovered, and what looked like a small fatigue crack about 0.02 in. long leading from it. Whether this crack would have eventually spread to cause failure is an interesting question. In any event, the shell stood many more cycles of stress than would be met with in the ordinary period of service of a boiler.

Arc-welded test shell No. 8 was without a tapped hole for the gage connection. It withstood 1,993,450 cycles of stress without failure, the range of stress being from zero to 16,500 lb. per sq. in. Then the pressure was increased so that the stress ranged from zero to 22,000 lb. per sq. in. At this increased range, the shell has withstood 24,400 cycles of pressure with no sign of failure; the test is still in progress.

In addition to the fatigue tests conducted on the test shells herein reported, there are eight additional test shells made by different methods of welding, which are now being subjected to the application of pressure. At present these test shells have not been subjected to a sufficiently large number of applications of pressure to embody the results in this paper.

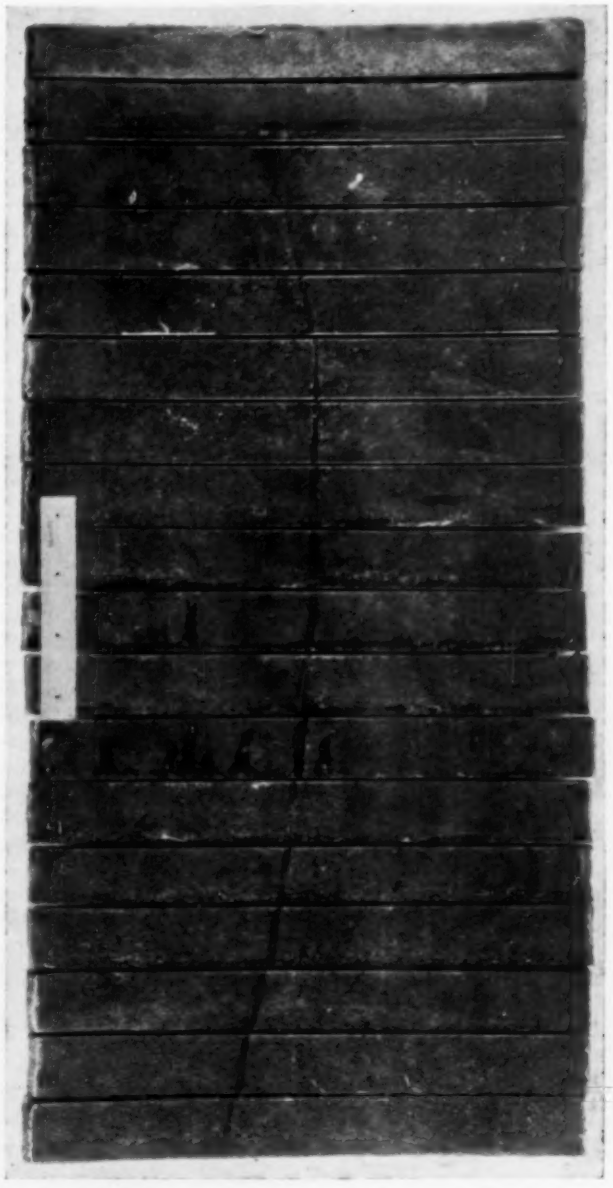

FIG. 7 DEFECT ON SURFACE OF PLATE WHICH CAUSED FAILURE
(Plate was cut into a number of test specimens, which were placed side by side.)

CONCLUSIONS

As noted in the introduction, it is not feasible to make fatigue tests of such large specimens as the full-sized test shell therein described, in the same manner in which fatigue test of small laboratory specimens are made. Endurance limits for the test shells have not, in general, been determined. However, certain

TABLE 1 SUMMARY OF TEST RESULTS

[a] Given by A.S.M.E. Power Boiler Code except for arc-welded shells where the maximum allowable working pressure is that given by the "Proposed Specifications for Fusion Welding of Drums or Shells for Power Boilers."

[b] Stress across welded seam, which is 1/4 in. thicker than plate.

conclusions may be reached as to safe values of stress for boilers and other pressure vessels.

The effect of local defects other than those inherent in the welds is emphasized by the failure of a number of test shells at the tapped hole for a gage connection, and also by the failure of shell No. 13 at a longitudinal defect on the inside surface of the plate well away from the weld. A quantitative value for the effect of such "stress raisers" cannot be given, but they evidently diminish very materially the strength of the plate.

The tests indicate that properly made arc-welded joints in drum shells have greater resistance to repeated stress than the plates themselves have when weakened by rather small surface defects or by tapped holes. The results obtained on arc-welded shell No. 6 indicate that a "stress raiser" such as a hole is particularly dangerous when located in the welded joint; however, the proposed specifications provide against this hazard by stating that no holes shall be located in a welded joint.

The tests also show that wide variations in fatigue strength will result from different types of welding. The necessity for the development of a good welding technique is obvious. The necessity for a rigid system of inspection of the finished welded vessel is also obvious.

In view of the fact that in its normal period of service, a boiler would be subjected to a few thousand cycles of repetition of pressure, together with a larger number of cycles of stress with a very small range, it would seem that all the drums and shells tested (with the exception of arc welded shell No. 1) might be expected to resist the action of repeated stress of the magnitude developed in the tests over a period longer than the normal period of service of a boiler.

In the proposed specifications for fusion welding of drums or shells of power boilers which have been published by the Boiler Code Committee the allowable working stress is give as 1/5 of 80 per cent (16 per cent) of the minimum of the specified tensile range of the plate used. This stress would be 53 per cent of the stress corresponding to the test pressure. A consideration of the test data, wherein properly welded test shells withstood without failure a very large number of applications of a high stress (16,500 lb. per sq. in.), should leave no doubt as to the safety in regard to failure due to service stresses of properly inspected welded boiler drums, designed under the proposed rules, wherein the expected service conditions represent but a few thousands of applications of a relatively low stress which is 8800 lb. per sq. in. as a maximum.

For most constructions the stress would be much lower than this due to the weld being subjected to a lesser unit stress than other parts of the drum.

Acknowledgments

The laboratory force at the Barberton works of the Babcock & Wilcox Company designed and developed the testing equipment described in this article and planned and carried out the tests herein reported. The author served as consulting engineer and cooperated in making the tests.

Discussion

H. E. Jenks.[1] So far as giving information as to the relative strength of plate and weld, tests on arc-welded shells 3, 4, 5, and 6 and on forge-and-hammer-welded shell 13 do not yield much of value. They do serve, however, a useful purpose in making clear the point that regions of stress concentration must be avoided so far as possible in designs where repeated stress is to be encountered.

The weakening effect of a tapped hole is well brought out here. For the case of unidirectional stress such as in these tests, the theoretical coefficient of stress concentration at the circumference of a small circular hole is 3; that is, the stress is three times that at points remote from the hole. Therefore, a failure at the hole instead of at the weld in such cases merely indicates that under fatigue conditions the weld is stronger than one-third the strength of the plate. It does not tell how much stronger.

Taking Professor Moore's figures of 16,500 lb. per sq. in. as the average stress in the arc-welded shells there is 49,500 lb. per sq. in. concentrated at the circumference of the hole. This value must be well over the endurance limit for the material of which the shells were made, as is in fact proved by the failures of shells 3, 4, 5, and 6.

Evidently reinforcement of the plate adjoining tapped holes is necessary to eliminate such points of weakness. The radius of reinforcement should be at least twice the radius of the hole in order to insure a strength in the material around the hole comparable with that of other parts of the design.

The failure of forge-and-hammer-welded shell 13 at an inside surface defect affords another instance of the effect of stress concentration where fatigue stresses exist. It has been shown

by experiment that accidental surface scratches may reduce the endurance limit of test specimens as much as 16 per cent, and the reduction of endurance limit in such specimens by V-shaped notches may be as much as 60 per cent. That this defect which was $^1/_{16}$ in. wide and $^1/_{32}$ in. deep must have produced heavy stress concentration is then evident. The need for careful inspection of finished pressure vessels, not only at joints but at all other points both inside and outside, is emphasized.

It is to be hoped that the tests on forge-and-hammer-welded shell 12 and on arc-welded shell 8 have been carried to failure, and that from these shells in which there are no tapped holes more specific information may be obtained as to the relative strength of plate and the two different kinds of welds when properly made.

R. E. Peterson.[5] The test data show that arc-welded shells are capable of withstanding a stress in the weld varying from zero to 16,500 lb. per sq. in. for at least two million cycles. From published test data[4,5] it may be expected that a stress much higher than 16,500 could be carried indefinitely as far as the welded joint is concerned. If the above mentioned data are plotted on a combined stress chart, the result is as shown in Fig. 8. If the line connecting endurance limit (s_e) and the

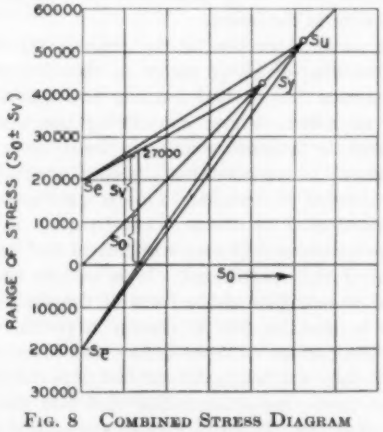

Fig. 8 Combined Stress Diagram

yield point (s_y) is considered a design criterion of failure[6] (which is shown by existing test data to be on the safe side), a stress varying from zero to at least 27,000 is necessary to produce failure. This would indicate that the margin of safety is still larger than indicated in the paper.

One further point may be of interest in this connection. In testing welded fatigue specimens $2^1/_4$ in. diameter, a considerably lower value of endurance limit has been obtained than for small specimens. No satisfactory explanation has been found for this as yet. Inasmuch as the test shells described in the paper were 2 in. thick, further research into the variable of weld size should be of value in interpreting data from tests of boiler shells.

J. M. Duncan.[7] The tests reported in this paper, or any other tests relating to welding and forging methods of steam-boiler fabrication, are of interest to the boiler user in the degree to which they reassure him as to the merits of the newer methods, as compared with the commonly accepted riveted joint or with the solid forged drum.

It is not likely that the results of these tests will contribute greatly to a more general acceptance of fusion welding as a safe practice for power boilers. Consider the accompanying tabulation of the results reported:

In Table 2 the writer has added in the last column what he would regard as a desirable endurance range which should be obtained with consistent uniformity in any weld metal, and in any junction of weld and base metal, before fusion welding can be regarded with confidence as compared with alternative methods available. Endurance range is not to be confused with endurance limit. The endurance limit assumed as attainable and desirable in estimating the endurance range for the particular stress cycle employed in these tests was plus or minus 40 per cent of the ultimate.

Presumably carried out to ascertain roughly the factor of safety of the fusion-welding method when applied to full-scale models, the tests appear to have demonstrated only the following:

a That any of the older techniques using bare electrodes, or any of the techniques which are at present available to the average boiler shop, are exceedingly dangerous.

b That special care must be used in any fusion-welded boiler to avoid surface or hidden defects, holes in the weld metal, or any other feature of design or construction which might result in unforeseen localization of stress.

c That the endurance range of a welded joint using electrodes prepared according to one proprietary formula may be greater than 30 per cent of the ultimate strength of the base metal and may be greater than 40 per cent of the ultimate strength of the weld metal.

While these results of the tests may appear meager and negative as a direct contribution to the knowledge of the art of welding on the part of the general public, they no doubt form a useful contribution toward the perfection of the technique of welding as developed by the company sponsoring the tests, and

in this manner contribute to the benefit of the boiler user.

It is, however, somewhat disturbing to find the Boiler Code Committee putting forward a proposed code covering fusion welding of power boilers with so little published data available to members of the Society or to boiler users in general, technical or non-technical, upon which to form an intelligent opinion as to the dependability of this method. It is even more a matter of remark that no specification appears in the proposed code calling for strain annealing after welding, while the tests of the qualifying work of welders do not include any which would determine even the ductility of the metal.

Any welding method used in power boilers of conventional design should produce a ductile material in the weld and at the junction of weld and base metals. While endurance limits cannot be expressed in terms of ultimate strengths alone, it would be well to assume, in the present state of ignorance concerning fatigue properties of weld metals, that a safe weld metal should have ductility equal to mild steel, and an ordinary endurance limit in air equal to or greater than plus or minus 40 per cent of the ultimate tensile strength. For the test pieces prescribed by the Boiler Code Committee to be made up by fusion welders seeking to qualify for power-boiler welding, this endurance would correspond to plus or minus 16,800 lb. per sq. in., or an endurance range of 33,600 lb. per sq. in. for a purely alternating stress cycle.

Since the stress cycle used in these tests is necessarily a pulsating and not an alternating one, the endurance range for this particular stress cycle should lie above plus 25,000 lb. per sq. in. minus zero inches and probably could be plus 35,000 lb. per sq. in. minus zero inches.

It appears evident, therefore, that in testing these shells through a range of only 16,500 lb. per sq. in. any failures obtained would indicate that the particular technique used in the weld was exceedingly unreliable and dangerous, while the few cases where no failure was produced offer only negative evidence of little actual value.

It is recommended that, before the present or any future proposed code on fusion welding is indorsed, a series of tests, similar in scope and character to those completed by the author of the paper, be carried out. The recent work of McAdam, demonstrating the great influence of certain types of waters in lowering the endurance limit, compels the Boiler Code Committee and the Society to protect the boiler user by including a most searching investigation of the corrosion-fatigue properties of weld metals in any research which is to be the basis for any proposed fusion-welding method for power boilers. The Society and the Committee cannot escape responsibility, if a welding method should be sanctioned which might prove unreliable under any of the numerous boiler-water conditions which may arise in actual operation, whether such operation is conducted with care and intelligence or not.

J. C. Hodge.[8] All of the arc-welded drums were subjected to a stress-relieving operation by heating the finished welded test shells to 1200 deg. fahr., holding them at that temperature for one hour per inch of thickness, followed by cooling in a furnace. In this way all residual stresses set up by the welding operation were fully relieved.

A question has been asked as to the effect of a tube hole within the welded joint on the resistance of a welded drum to repeated applications of pressure. At the present time there are no data available on this condition, but a test shell is now in process in the Barberton shops, this test shell having been constructed to answer this question. Standard tube holes are being placed at standard intervals along the longitudinal welded joint of the test shell and also along an element of the cylinder in the boiler plate. Blind nipples will be rolled into the tube holes several different ways and the test shell then subjected to repeated applications of pressure. The results of this test will undoubtedly be published some time in the near future.

A question has also been asked as to why failure under repeated applications of pressure did not occur through the rivet holes in the riveted test drum of standard A.S.M.E. construction. If failure occurred through the tapped hole for the hydraulic gage connection in several of the test shells after approximately 500,000 applications of pressure, then it should be expected that failure should have occurred through the rivet holes in the riveted test drum after 1,000,000 applications of pressure, whereas no actual failure was found in the riveted test drum after this large number of applications of pressure. Prof. Moore has stated that the absence of failure through the rivet holes was probably due to the pressure on the rivet heads equalizing the stress and distributing the stress around the rivet holes. However, the predominating factor in this connection is the fact that the butt strap and boiler-drum sheets are pressed closely together by the tension in the hot-driven rivets, and a considerable portion of the load on the riveted joint is sustained by the friction between the two plates, thus reducing the stress around the rivet holes.

J. C. McCabe.[9] In view of the fact that there is a high-pressure boiler to each 200 of population the reasonable safety of steam boilers is of vital importance. From the date of the organization of the Manchester Steam Users Association on Feb. 14, 1855, to the present time, much study and speculation has been given to problems relating to steam boilers.

It seems natural to ascribe mysterious reasons for many of the ills of steam boilers. Robert Bewick Longridge, the first Chief Inspector of the Manchester Steam Users Association, attributed the many boiler explosions in and around Manchester to the formation of "an unknown explosive gas which formed within the boiler and exploded with violence and disaster." The questionable quality of the slag-laden iron plate used did not attract attention. Little attention was paid to the manner of using the plate in the boiler.

The paper calls attention to the present-day tendency to ascribe the cracking of boiler plates to chemical action rather than high stresses due to bad forming and loading the plate transversely as rolled without considering the actual tensility of the plate and the fatiguing existing in the structure.

It is customary to consider that the shell or drum of a boiler is uniformly loaded in tension. This is practically true in a correctly formed shell or drum. Unfortunately in the general run of shop practice the importance of correct and true forming is not appreciated and understood. It is seldom that a correct checking and observation of the form of the shell or drum are made. The hydrostatic test is usually a perfunctory gesture without an observation of form before and after test. If the shell or drum does not fail under the test, it is considered a safe article of commerce, notwithstanding that bad forming has as definitely limited the life and utility of the article as disease in the human.

In an investigation made by the writer recently on the failure by cracking at the ligament of the longitudinal joint of drums 60 in. diam., 24 ft. long, and made from $1^{5}/_{16}$-in. plate, radii under the strap were found varying from 28 in. to over 68 in. The normal external radius was $31^{5}/_{16}$ in.

It must be evident that in the region of the 28-in. radius the inside of the plate would be in tension when riveted up and that where the external radius was 68 in. a heavy tension load would

[8] The Babcock & Wilcox Co., Barberton, Ohio.

[9] Chief Boiler Inspector, State of Michigan, Detroit, Mich. Mem. A.S.M.E.

be on the outer fiber and a corresponding compression load on the inner surface with no load at the neutral axis of the plate. In this case the stresses in the outer surfaces would be about 13,000 lb. without internal pressure. It is evident that the internal pressure would greatly increase the already overloaded plate and result in an early and progressive cracking of the plate. The thought of a large shell or drum under high pressure, with 57 varieties of radii at the longitudinal joint and elsewhere, is not pleasant to contemplate, but it is more common than realized.

The A.S.M.E. Boiler Code gives no definite instruction or rule for the proper forming of boiler shells or drums. With the templets ordinarily used by the inspectors a rather "tolerant" view is taken as to how close the plate should be made to conform to the templet. When the hydrostatic test is made it is a rare occasion to make measurements before and at the time of the hydrostatic test to determine the evidence of bad forming and the inevitable internal stresses. The A.S.M.E. Boiler Code should definitely require the systematic observation of the forming and the behavior of the various areas under pressure.

The fact that rivets along calked joints and the straps are stressed to the yield point is well understood and needs no comment. When a plate is loaded transversely as rolled the tension tests should be made in the same direction. The cracking at the gage-pipe hole indicates that a deflection occurred at this point which threw the outer fiber into tension with the inner surface in compression. This behavior changed the affected section from direct and uniform tension to a loading comparable to a beam.

The writer favors the approval of fusion welding under proper control as to procedure. This will of course include correct and definite limits as to forming and annealing. This will be a worthwhile achievement for the engineer. The same consideration should be given the welded boiler that is given the riveted structure. The welded boiler can be made much safer and desirable than the riveted boiler.

A. B. Kinzel.[10] The tests in this paper are most illuminating, and the author and his collaborators in this work are to be both congratulated and thanked for presenting these results. There are several items of interest, particularly if the work is considered from the point of view of the proposed specifications for fusion welding of drums or shells of power boilers. It would indeed be very interesting to know whether or not any or all of these shells had been subjected to non-destructive tests before, as well as after, the repeated-pressure test. It would also be interesting to know the cause of the failure of the bare-wire arc-welded shell 1. Was there a defect in the weld? Was there lack of fusion at the base, or was the phenomenon connected with the physical characteristics, that is, tensile strength and bend ductility of the weld metal in question? In other words, could this failure have been predicted?

In connection with the manganese-steel test drum, was the head and manhole reinforcement designed according to more recent ideas on this subject?

The conclusions to be drawn from the paper, aside from the very important ones which the author has stressed regarding the seriousness of unreinforced openings in the shell and defects in the plate, would seem to bear on the application of this test to service. As the author very rightly points out, this is probably a great deal more severe than a similar stress variation in service. For example, arc welded shell 2, with 267,000 cycles and a fiber-stress variation of 16,500 lb. per sq. in., would probably have shown a life in service far beyond the expected average of 20 years. It seems that any test of this kind, if applied as a routine test, would merely have to differentiate between the type of construction which fails in 5000 cycles as against some hundred thousand cycles. If the cause of failure at a low number of cycles can be determined by other tests, such as the non-destructive test or analysis of the physical properties of the material, the use of such a test in routine application would not be warranted. This is particularly true if it be considered that many believe that the repeated-stress test may have a deleterious effect on the drum.

C. S. Gladden.[11] Ordinary riveted construction, when calked on the outside only and when in service with boiler water having low ratios of sulphate to carbonate alkalinity, is the source of many failures from embrittlement of the steel. If the riveted joints are calked on the inside and the spaces between the butt straps and the main plate can be definitely sealed, most of the difficulty from embrittlement may be eliminated. However, if boiler drums can be constructed without riveted joints and butt straps, that is, by the method of forge-and-hammer welding or electrical-fusion welding with the joint equally as strong as the plate, nearly all embrittlement troubles would be eliminated, regardless of the water condition, and the ideal boiler drum would be developed.

There is one point, however, concerning which additional information is needed; that is, concerning the effect of rolling tubes into holes in the drum. Have any tests been made of repeated pressure on drums in which blank-ended tubes have been installed? A number of the fractures, especially in the arc-welded shells as given in the table of this paper, occurred at the tapped hole for the gage or in the region where the "stress-raiser" was located. Does the nature of the tapped hole with sharp grooved edges influence these failures more than a round hole of larger size and subjected to the additional stress due to the rolling in of the tube?

No drum, however perfect it may be, is of practical use without having tubes rolled into tube holes cut through the sides of the drum. The writer is therefore interested particularly in what results are obtained with shells under these conditions.

Author's Closure

Several of the discussions of the paper point out important questions which have not been settled by the tests herein reported. That there are many things as yet unknown about fusion welds is of course quite true. The author would like to comment on the statement of Mr. Duncan that "It is not likely that the results of these tests will contribute greatly to a more general acceptance of fusion welding as a safe practice for power boilers." Whether these tests will contribute "greatly" to the acceptance of fusion welding is a matter for the future to decide. However, it seems that in his discussion Mr. Duncan has overlooked the fact that for boiler shells subjected to only a few thousand cycles of stress during their period of service, the *practical limit of strength* may be appreciably higher than the endurance limit based on tests of tens of millions of cycles of stress. As the author has frequently pointed out, the numbers of cycles of stress above the endurance limit which a metal will endure without failure is no reliable criterion of its fatigue strength under millions of cycles of working stress. However, when a boiler shell withstands 100 times the number of cycles of stress it will be called upon to stand in actual service, it would seem to be reasonably safe so far as mere fatigue strength is concerned. Of course, conditions of boiler water which may lead to corrosion bring in a very different problem, both for the weld material and for the plate steel. The author believes that the tests do show that, so far as fatigue strength is

[10] Union Carbide and Carbon Research Laboratories, Long Island City, N. Y.

[11] Director, Power and Maintenance Section, General Motors Corporation. Mem. A.S.M.E.

concerned, boilers welded by modern, closely controlled methods will stand the cycles of stress which they meet in ordinary service under ordinary allowable working stresses. The author does believe that, as pointed out in discussions, the tests show that there is a wide range of strength for different techniques of welding.

Some of the figures given in Table 2, which was prepared by Mr. Duncan, and some of his statements are not correct. The tensile strength of the joints which were fusion welded by the "processed" electrodes is given in the table as 42,000 lb. per sq. in., as compared to 55,000 lb. for that of the shells, whereas the strength of these fusion welded joints was greater than that of the shell. His statement that it is even more a matter of remark that no specification appears in the proposed Code calling for strain annealing after welding is also incorrect, as can be seen on examining the Proposed Specifications for Fusion Welding of Drums or Shells of Power Boilers published in the March, 1930, issue of "Mechanical Engineering." These Proposed Specifications also include the requirement that the minimum elongation of the outside fibers of the weld metal in bend test specimens shall be 30 per cent, whereas his remarks might make it seem that there are no requirements for ductility.

Mr. Duncan's principal criticism is that the testing of the shells through a stress range of 16,500 lb. per sq. in. did not give conclusive results. This stress is 50 per cent higher than that which would exist in the most highly strained parts of a boiler drum constructed in accordance with the A.S.M.E. Boiler Code, which stress comes in the ligaments between tube holes and between rivet holes. As the proposed Code does not sanction the placing of holes in the welds, the stress in the welds in a boiler drum would be considerably lower than the maximum stress in other parts of the drum. The allowance of 80 per cent for the efficiency of the joint given in the proposed rules for fusion welding results in the tests being made at pressures of from two to over three times the strain on the welded joint for boiler drums of the usual construction when pierced with holes, which has been criticised as being too high rather than too low for a test pressure. As all but one of the failures with the shells welded with the "processed" electrodes were in the solid part of the plate and not in the weld, Mr. Duncan's criticism, if valid, would apply to the plate much more than to the welds. The plate was firebox steel which met the requirements of the A.S.M.E. Code so that his criticisms in reality apply to a material which is generally recognized as being suitable for the use to which it is put and not to fusion welding.

Concerning the effect of stress concentration of holes, fatigue tests show that the actual weakening of steel by such "stress raisers" is less than the theoretical, but that the weakening due to the holes, nicks, and scratches is very pronounced, sometimes producing an effective strength concentration of twice the computed stress.

Mr. Gladson asks an interesting question about the effect of rolling tubes into the holes in the drum, and the author would refer him to Mr. Hodge's discussion of this paper.

Some of the discussions emphasize the need of fatigue tests of welds to insure the proficiency of the operator. Fatigue tests of large specimens, either on flat plates bent back and forth or on turned round specimens, can be made without difficulty. However, the author believes there is still greater need for the development of some non-destructive test to detect incipient fatigue cracks in actual seams. He hopes that the simple stethoscope tests proposed by Mr. Kinsel, the heating test used in some welding shops, and the elaborate Sperry test and X-ray tests will all be studied. A test which has occurred to the author, but which he has had as yet no opportunity of studying, consists in measuring the minute change in electrical resistance in a piece of metal between a stressed condition and an unstressed. Possibly an incipient fatigue crack might cause abnormal change in this resistance.

The Dry Quenching of Coke

By WILLIAM O. RENKIN,[1] NEW YORK, N. Y.

This paper describes the process of dry quenching or cooling of coke with automatically formed inert gases, the sensible heat in the glowing coke being used to heat the cooling gases, which in turn pass through boilers, producing steam at useful pressure and economic cost without the consumption of any other fuel. Formulas, curves, and data regarding heat available and method of calculation are given, together with descriptions of installations and illustrations of plants in operation.

A detailed economic study is given which shows the savings to be expected and the approximate cost of a dry-quencher plant to cool 1500 net tons of coke per day; and composite charts giving actual operating records as well as output data and the cost of power for one plant by months for the year 1929 are included.

Analyses of coal and coke are given which show conclusively that dry-quenched coke carries less dust than wet-quenched coke.

Data giving actual results obtained by using dry-quenched coke in blast furnaces, and the advantages of substituting dry-quenched coke fines for high-priced bituminous gas coal in gas producers, are discussed in considerable detail.

A dry-quencher plant at a power station in Flint, Mich., the latest to be installed, is described in some detail and the principal technical data given.

WHILE there have been many articles published on this subject and much literature is available describing the operation of dry-quencher installations, this paper will present some new economy data, as well as a description of the latest plant, located at Flint, Michigan.

Dry quenching of coke, or more correctly speaking, the cooling of coke without the use of water, has been brought about by the need of coke plants to eliminate the operation difficulties and dust-laden vapor clouds so common to water-quenching installations, as well as by their desire to reduce operating expenses and make use of the sensible heat in the glowing coke.

The process of dry quenching of coke may be briefly described as a circulation of cooled inert gases by means of a fan, upwardly through a container intermittently charged with hot coke at the top, and from which the cooled coke is intermittently withdrawn from the bottom.

The rising inert cooling gases absorb heat from the slowly intermittently descending coke mass, and these heated gases are thence passed through a waste-heat boiler for cooling, and then through the fan for recirculation to the coke container again, the process being continuous as well as remarkably simple.

Dry quenching of coke is as great an improvement over wet quenching as the modern by-product coke plant is over its predecessor, the beehive oven.

Dry quenching not only produces a better coke, but reduces the quantity of fines and produces them in a more commercial form. Dry-quenched coke is stronger, resists further handling better without degradation, screens more easily, and gives a cleaner product than wet-quenched coke, and gives superior results in producer and water-gas machines.

Dry Quenching an Economic Necessity to the By-Product Coke Industry

Throughout all industry there is a strong trend toward conservation and the elimination of waste. Almost every one who has witnessed the great clouds of steam produced by the wet quenching of coke has wondered if it were not possible to stop this seemingly needless waste of heat. A few figures are sufficient to demonstrate clearly what a tremendous waste of energy wet quenching represents.

In the United States alone 53,475,481 net tons of by-product coke were produced in 1929. Assuming an average temperature of the hot coke going to the quencher as 1800 deg. fahr., there can be recovered approximately 480 B.t.u. per lb. of coke by dry quenching, which means the possible production, utilizing the available sensible heat in the coke, of practically fifty-two billion pounds of steam per year from and at 212 deg. fahr. In other words, a waste of fuel equivalent to two and one-half million net tons of 13,500-B.t.u. coal in boiler plants operating at an overall efficiency of approximately 75 per cent is the result of wet quenching.

The entire steam consumption of a standard coke-oven installation may be secured from the waste heat of the glowing coke alone, and in most instances an excess of energy is available which may be diverted to other departments. An analysis of this situation provided the incentive to seek a solution of the problem.

The dry-quenching process developed by Sulzer Brothers represents a most efficient and reliable method of reclaiming the sensible heat of glowing coke. Numerous installations have proved the correctness of the process by years of continuous satisfactory service.

Description of the Process

In the Sulzer system of dry quenching, the cooling is accomplished by circulating the inert gases in a closed cycle, first through the glowing mass, where the gases extract the sensible heat from the glowing coke, thence through a steam boiler where the hot gases transfer the heat to the water in the boiler circulation and convert it into steam.

Referring to Fig. 1, the glowing coke is conveyed to the sealed cooling chamber, and the air of the system, including that en-

[1] Engineer, Dry Quenching Equipment Corporation. After leaving school Mr. Renkin was connected with various iron and steel plants, and was resident engineer for the organization and construction of the steel works for Tata Iron and Steel Company, Sakihi, Bengal, India. Returning to the United States he spent a year in special work and some time as chief engineer for A. M. Byers Company, Pittsburgh. He had done much work in the development of pulverized-coal equipment in the metallurgical field. Mem. A.S.M.E.

Contributed by the Fuels Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

trained in the interstices of the coke mass, is put into circulation by means of a fan.

When the system is first started, a small portion of the coke is converted into a mixture of carbon monoxide and carbon dioxide, the percentage of each depending on the temperature at that particular time. However, the oxygen of the encased air is quickly consumed, and a mixture of inert non-combustible gases remains. This mixture of gases, in passing through the glowing coke, absorbs its heat, which is carried to the adjoining steam generator. The cooled gases leaving the boiler are conducted back to the fan and again forced through the glowing coke. The coke is drawn off from below, which is the coolest zone, and fresh charges of glowing coke are introduced from above.

In this manner continuous performance is established and, by regulating the fan speed, a relatively close relation may be maintained between the cooling of the coke and the generation of steam.

The possible loss of coke through burning has been determined

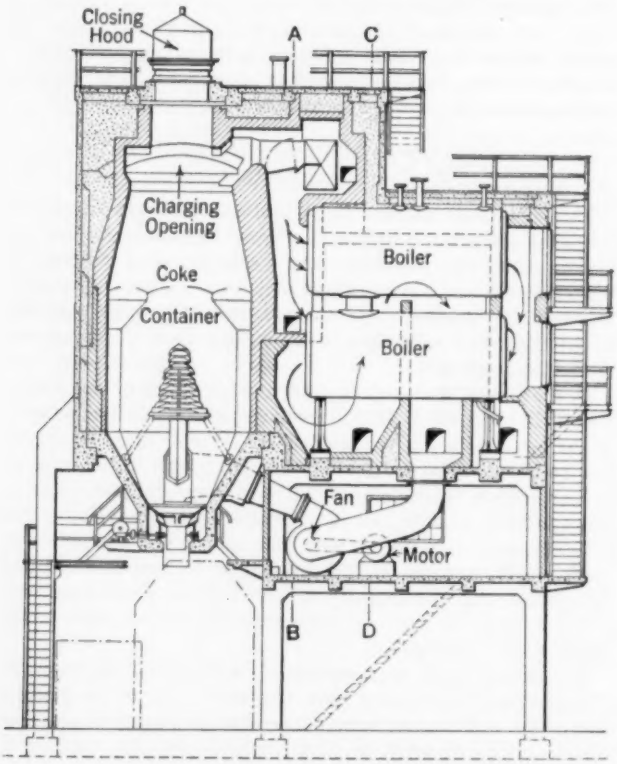

FIG. 1 EARLY TYPE OF INSTALLATION COMPOSED OF COOLING CONTAINER UNIT WITH TWO FIRE-TUBE HORIZONTAL BOILERS

by numerous tests to average 0.04 per cent, a quantity practically negligible, even if greatly increased.

PHYSICAL ELEMENTS OF THE PROCESS

Having adopted the idea of utilizing the waste heat of glowing coke, the question arises as to the actual amount of heat contained therein. This quantity of heat is determined by the weight, temperature, and mean specific heat of the coke. Through the investigations of Otto,[2] Schlapfer and Debrunner,[3] *Stahl und Eisen*,[4] Wöhler,[5] *Glückauf*,[6] Terres and Schaller,[7] *Gas und Wasserfach*[8] the specific heat of coke has been established as shown in Fig. 2.

The divergences of the different values are due to differences in methods of measuring and to the variance in the ash content. In the chart, therefore, the curves of the mean specific heat of graphite,[9] i.e., practically pure carbon, and of quartz[10] have

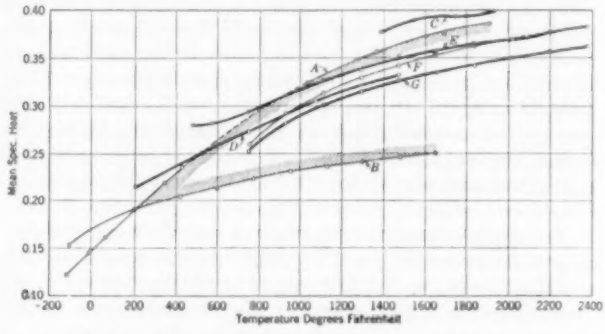

FIG. 2 MEAN SPECIFIC HEAT OF GRAPHITE, QUARTZ, AND COKE

A—Graphite referred to 32 deg. fahr. with range to 523 deg. fahr. and referred to approximately 72 deg. fahr. with range above 1034 deg. fahr.[9]
B—Quartz referred to 68 deg. fahr.[10]
C—Coke[2]
D—Coke with 10.5 per cent ash referred to 64 deg. fahr.[4]
E—Coke with 9.45 per cent ash referred to 68 deg. fahr.[6]
F—Coke with 15 per cent ash referred to 70 deg. fahr.[5]
G—Coke with 30 per cent ash referred to 70 deg. fahr.[6]

been plotted, assuming that the greater part of the coke ash is composed of silica. The lines for graphite and quartz therefore represent value limits for coke with 0–100 per cent of ash, between which are to be found the values of the other species of coke.

TABLE 1 MEAN SPECIFIC HEAT OF COKE
(According to Wöhler)

Range of temperature		Mean specific heat
Deg. cent.	Deg. fahr.	C_m
20– 250	68– 482	0.2798
20– 300	68– 572	0.2810
20– 400	68– 752	0.2938
20– 500	68– 932	0.3107
20– 600	68–1112	0.3269
20– 700	68–1292	0.3381
20– 800	68–1472	0.3528
20– 900	68–1652	0.3582
20–1000	68–1832	0.3652
20–1100	68–2012	0.3695
20–1200	68–2192	0.3762

TABLE 2 MEAN SPECIFIC HEAT OF COKE
(According to Terres and Schaller)

Range of temperature		Mean specific heat
Deg. cent.	Deg. fahr.	C_m
21– 250	70– 482	0.230
21– 422	70– 792	0.267
21– 506	70– 943	0.292
21– 609	70–1128	0.315
21– 708	70–1306	0.331
21– 811	70–1492	0.345
21– 912	70–1674	0.354
21–1009	70–1848	0.361
21–1107	70–2025	0.369
21–1297	70–2367	0.376

Schlapfer and Debrunner[3] have found that the specific heat of coke depends also upon the content of volatile constituents, and they have given the following formula to calculate the mean specific heat of coke of different composition:

$$C_m = \frac{X}{100} C_a' + \frac{Y}{100} C_k' + \frac{Z}{100s} C_g'$$

where X = content of ash in per cent
Y = content of fixed carbon in per cent

[10] Stierlin Quarterly bulletin of Naturforschende Gesellschaft, Zurich, 1907, p. 411.

Z = volatile constituents in per cent by weight
C_a' = mean specific heat of ash (quartz)
C_k' = mean specific heat of graphite
C_g' = mean specific heat of gas per unit volume
S = specific gravity of gas (about 0.45).

Assuming the initial temperature of glowing coke to be 1800 deg. fahr., and the final temperature after cooling to be 400 deg. fahr., the amount of heat in B.t.u. utilized equals

$$1800 \times C_{m1800} - 400 \times C_{m400}$$

The mean specific heat, according to Table 2, equals 0.361 between 70 and 1800 deg. fahr. and 0.230 between 70 and 400 deg. fahr. Thus $1800 \times 0.361 - 400 \times 0.230 = 558$ B.t.u. gained per pound of coke, which is equivalent to approximately 1,120,000 B.t.u. per ton of coke.

These calculations show that steam is generated by utilizing the sensible heat of the hot coke and not by burning the coke as fuel.

Fig. 3 gives the specific heat and heat content in B.t.u. per pound at various temperatures, and has been made up from the data available and found very useful. It will be noted from this chart that the heat content in coke of an average analysis (using curve 2) at 1800 deg. fahr. is 640 B.t.u. per lb. As experience has shown that the most advantageous temperature for discharging the dry quenched coke is 700 deg. fahr., it will be found from the chart that at this temperature there is left in the coke 194 B.t.u. per lb., or a heat available for useful recovery of 446 B.t.u. per lb.

However, it has been found that there is a certain additional amount of heat secured, from combustion of H_2 yielded by green ends and incompletely distilled coke, often amounting to more than 60 B.t.u. per lb. It is therefore conservative to add this to the heat recoverable, which gives a total heat available for recovery amounting to 506 B.t.u. per lb. of coke dry-quenched.

Determination of the mean specific heat (C_m) of coke at temperature (t) from proximate analysis:

$$C_{tM} = KC_{tK} + AC_{tA} + G/SC_{tG}$$

C^t = sp. ht. at given temperature of element
K = per cent fixed carbon
A = per cent ash
G = per cent volatile matter—gas
S = sp. gr. of gas about 0.45.

VALUE OF DRY COKE

The greater efficiency of a fuel free from moisture is becoming more and more appreciated. If a coke contains 10 per cent of water, this water has to be evaporated before it can be ignited. The coke is thus not only inferior because of the smaller percentage of carbon, but its heat is absorbed in evaporating the water and raising the vapor to the temperature of the waste gases.

For instance, if the coke is used to heat retorts and the products leave the regenerator at 600 deg. fahr., we obtain the following calculated results per kilogram of coke containing 15 per cent of ash on the dry sample:[11]

	Dry coke	Wet coke
Carbon, per cent	85	76.5
Ash, per cent	15	13.5
Water, per cent	..	10.0
	100	100.0
Heat of combustion of carbon, kg-cal. per kg	6868	6181
Less to evaporate water from 60 deg. fahr.	..	62
Less to raise vapor to 600 deg. fahr.	..	16
Available heat, kg-cal. per kg	6868	6103

This shows a depreciation of 11 per cent due to the presence of the water.

It may therefore be roughly stated that the heating value of coke increases about 10 per cent more than the percentage of moisture removed, or in other words, that the moisture-free coke provides 11 per cent more available heat than coke containing 10 per cent of moisture.

[11] John P. Leather, M. Inst. C. E., in *Gas Journal*, June, 1927.

Coke in Blast Furnaces

Dry-quenched coke being of more uniform size and devoid of moisture, carries with it less fines and breeze.

Experience shows that fine coke and dust reduce the capacity of the blast furnace, since more resistance is offered to the blast. Further inconvenience arises from the formation of dust whirls and dust pockets. The steel works of the Compagnie des Forges et Aciéries de la Marine et d'Homécourt, in Homécourt, France, reported that by the use of dry-cooled coke more regular and improved action of the furnace was evident, and that trouble caused by hanging of the load in the furnace was greatly reduced. The saving of coke in this furnace after the introduction of dry-cooled coke was 4.17 per cent.[12,13] The dry-cooled coke is of more uniform size. The large pieces, already split on account of the contraction which takes place during the process of distillation, break up to a certain extent when passing through the container. The remaining pieces are of somewhat smaller size, but very much stronger and stand further handling better than wet-quenched coke. Therefore, in going down the cupola of the blast furnace, dry-quenched coke does not break up under the heavy load of the charge as is the case with wet-quenched coke. The formation of dust and breeze pockets in the blast furnace is thus prevented, and a more regular distribution of the blast through the charge is secured.

It is well known that blast-furnace gas contains a considerable quantity of fine dust, both of ore and fuel, which must be removed by expensive gas-cleaning machinery for most needs; and as dry-quenched coke carries less dust and fines, a considerable reduction in the dust content of the gas produced can be expected.

Long-period tests on blast furnaces have been made in German steel works with coke that was purposely subjected to mechanical handling and then was screened. The best results were obtained with coke of medium and uniform size.

Edgar C. Evans[14] in a lecture in England before the National Federation of Iron and Steel Manufacturers, showed that after the elimination of 6 per cent of small coke and dust, the capacity of the furnace increased by 20 per cent. This fact is now well known, and the relation between the percentage of fines and furnace capacity has been established.

The advantages of dry coke for this work are evident, as dry-quenched coke, being devoid of all water, shows a higher thermal value; therefore the use of dry-quenched coke is equivalent to a saving of fuel.

In blast-furnace operation a considerable amount of cooling water is required for the condensation of steam in the blast gases, which under certain conditions must be filtered and recooled. As the water content of the blast gases reduces the heating effect, due to lowering the flame temperature, it should be eliminated, although sometimes water is added for special ores.

It is also a well-known fact that variations in the percentage of moisture of wet-quenched coke cause difficulties in the blast furnace, or in any other type of furnace where coke is used in steady operation. As dry-quenched coke is free of moisture, there is no variation in the quality of the fuel.

The water contained in the wet-quenched coke effects a precooling of the hot blast gas. This difficulty has not been observed at any furnace where dry-quenched coke is used. If a special condition be encountered where the absence of the water should cause faulty conditions, it can easily be remedied by sprinkling the coke with water according to requirements at the place where it is used.

It is becoming more and more important to have the accurate weight of coke charged to blast furnace, and dry quenching eliminates the inaccuracies caused by variation in moisture content so common to wet-quenched coke, and therefore makes possible the accurate records desired.

Sulphur Content of Coke

The question of sulphur content has been explicitly answered by analyzing coke at the mines of Mathias Stinnes, Germany.[12,13] The average of ten samples of coke showed a sulphur content of 0.914 per cent for dry-quenched coke and 0.857 per cent for water-quenched coke, a difference of 0.057 per cent. With water quenching, a desulphurizing action amounting to 6.4 per cent was obtained.

This difference is negligible in the practical use of coke, as it is noticeable in the second decimal only. It may be added that only a portion of the sulphur content of the coke is absorbed by the charges—for instance, only 30 per cent in the foundry and only 50 per cent to 60 per cent in the blast furnaces, which further proves the actual insignificance of this small difference. It was further shown in tests at the Stinnes Mines that only that part of sulphur was extracted which exists in the coke in the form of sulphides and which after quenching evaporates as sulphureted hydrogen or during combustion as sulphurous acid. It is, however, a well-known fact that in the course of time the vapors from wet quenching have a marked destructive effect on iron and concrete, aside from the decided hygienic disadvantage and inconveniences which they cause.

Capacity for Reaction

The capacity for reaction (combustibility) of dry-quenched as compared with water-quenched coke has also been carefully tested. The results showed, it is true, that the combustibility of dry-quenched coke was somewhat less than that of wet-quenched coke; this difference was noticeable, however, only in the finer granulations (up to $^1/_{16}$ in.) of both kinds of coke, and became less and less apparent with the increasing size of the granules. Since the difference diminished with the increased size of granulation, it may be assumed that in practice this difference will be negligible and that it will have no bearing on combustibility, whether the coke be dry- or wet-quenched.

In the laboratory tests both the influence of granulations and temperatures were examined, but for a final judgment of the capacity for reaction, the influences of the kind of furnace, air velocity, chemical composition, porosity, etc., will have to be investigated. The solution of the problem of combustibility by laboratory tests only cannot be expected. It is significant that no difficulty in this respect has been experienced by furnaces using dry-quenched coke.

Coke Fines

In general, the coke fines are used as boiler-plant fuel by burning on Coxe or other similar-type specially built stokers.

Very little successful work has been done along the lines of burning the wet-quenched coke fines for other purposes, owing to the difficulty of packing and choking, although some success has been attained by using small coke in gas producers, but this has not proved very commercial due to the necessity of using only sizes over a $^5/_8$-in. screen.

However, the dry-quenched coke fines have proved a very satisfactory fuel in gas producers and are being substituted for high-grade bituminous gas coal or larger sizes of salable coke.

A comparison of bituminous-coal producer gas and dry-quenched coke fines gas gives the following.

---

[12] Dr. Mueller, "Comparative Investigation of Dry- and Wet-Quenched Coke."

[13] *Glückauf*, 1926, no. 35.

[14] *The Gas World*, June, 2, 1926.

From the report of many different tests, the following bituminous-coal gas analysis may be quoted:

	Combustible				Non-combustible			
	CO	CH_4	C_2H_4	H_2	CO_2	O_2	N_2	B.t.u. per cu. ft.
Max.	30.00	4.20	1.00	14.70	6.20	0.40	58.00	177.30
Min.	23.80	1.90	0.60	11.30	3.50	0.00	48.10	157.30
Avg.	27.50	3.40	0.80	12.70	4.60	0.24	50.80	167.10

Another investigator[15] found that his particular plants secured the best results from gas having the following analysis:

	CO	CH_4	C_2H_4	H_2	CO_2	O_2	N_2	B.t.u. per cu. ft.
Per cent	24.30	3.50	0.70	12.90	4.90	0.00	53.70	168.81

The following results are being obtained with dry-coke fines having the following analysis:

	Volatile	Fixed carbon	Ash	Sulphur	B.t.u. per lb.
Per cent.....	2.80	83.40	13.80	0.73	12,200

(NOTE: Sulphur separately determined.)

The gas delivered from producers using this coke has the following analysis:

	Combustible				Non-combustible			
	CO	CH_4	C_2H_4	H_2	CO_2	O_2	N_2	B.t.u. per cu. ft.
Per cent	26.40	0.70	0.00	12.60	6.30	0.10	53.90	134

The gas delivered from each pound of coke has 10,334 B.t.u., thus indicating a cold-gas efficiency of 84 per cent.

From an examination of these two fuels, it will be found that the coke-fines gas is devoid of the illuminant C_2H_4 (ethylene) and gives the very mellow, soft flame desired in heating processes.

The production of a gas devoid of C_2H_4 permits the use of less excess air, thus giving a better and wider range in flame control.

For the open-hearth and melting processes requiring an illuminating flame this gas should be ideal as it permits the addition of illuminants, such as tar or oil, in the correct quantity under separate control by parallel firing directly at the furnace.

Bituminous-coal producer gas for most processes contains too high a percentage of illuminants, thereby necessitating the use of too much excess air.

The C_2H_4 in such gas usually contains 5 to 6 per cent of the total heat units, while there is hardly any process requiring more than 2.8 to 3 per cent.

This excess C_2H_4 also has a destructive effect on brickwork, causing high refractory maintenance, which can be greatly reduced by substituting the dry coke fines for bituminous coal.

ADVANTAGES OF DRY QUENCHING

The advantages of dry quenching of coke are notable, and experience has shown the following very definitely:

1 Using of the sensible heat in the coke to produce approximately 1000 lb. of steam (from and at 212 deg. fahr.) at the gage pressure required, including superheat where necessary. This means the production of this steam without any additional fuel.

2 Improvement in the quality of the coke. Since dry-quenched coke was first introduced, many efforts have been made to compare the characteristics of dry-quenched with water-quenched coke. These have all shown that the dry quenching produces coke of a more uniform size with greater strength, and when the water-quenched coke has been handled to the same extent as the dry-quenched, the difference in size of the larger pieces is negligible. This is shown clearly in tests that have been run.

It is evident that when the glowing coke at a temperature of about 1800 deg. fahr. is suddenly chilled with water, the structure must be affected. Even though the expansion of coke by heat be small, certain stresses must follow this sudden change of temperature. These stresses, due to the brittleness of the material, form cracks and splits, which, with the sudden developing of steam, cause the breaking apart of the coke. Dry-quenched coke is not subject to these stresses, and is only reduced in size by handling.

The mechanical strength and friability of coke are factors of definite interest, as the formation of coke fines or breeze represents a loss regardless of whether the crumbling occurs in the loading or unloading, by shaking during transit, or in the furnace proper under the weight of the charge. Many investigations of the percentage of dust and coke breeze have determined the superiority of dry-quenched coke.

3 Dry quenching produces a coke devoid of moisture, which insures cleaner coke—that is, less fines and dust adhering to the large pieces. Better screening and preparation of coke is insured by dry quenching, and this is a very important difference in its favor. When coke is to be transported, a reduction in the moisture content of only 5 per cent means frequently a saving in freight of 50 cents per ton of coke delivered. Dry-quenched coke permits the accurate weighing of coke burden in metallurgical-furnace operations, as well as insuring cleaner and more uniform operation.

4 Dry quenching insures a higher sale value for the coke fines, as they form a very satisfactory substitute for bituminous coal in producer-gas plants. This is especially true at coke plants operating in connection with open-hearth and steel plants, as well as for gas producers in connection with the by-product coke ovens, as the dry-coke-fines producer gas takes the place of by-product coke-oven gas in firing the ovens.

5 Dry quenching eliminates the pumping of water necessary for all wet-quenching stations, as well as the dust-laden vapor clouds from wet-quencher stacks which are so destructive to surroundings and unpleasant for the plant personnel. Reduction in maintenance as well as increased life of steel structures are other valuable items to be given consideration.

6 Reduction in labor cost, as frequently one car can, depending on plant layout, do the work with a dry-quencher installation that required two cars for wet quenching.

7 Reduction in cost of conveyor operation, as the elimination of water due to dry quenching insures more continuous operation and lower maintenance cost.

ECONOMIES AND SAVINGS TO BE EXPECTED FROM THE INSTALLATION OF A DRY-QUENCHING PLANT

		Per net ton of coke cooled
1	Production of approximately 1000 lb. of steam (from and at 212 deg. fahr.) per net ton of coke cooled at a saving of 20 cents per 1000 lb. of steam.....	$0.20
2	Reduction in labor operating car and wharf...	0.01
3	Reduction in coke-car and plant maintenance..	0.02
4	Elimination of water pumped to wet-quencher installation.....	0.03
	Total direct savings per net ton.....	$0.26
On basis of a 1500-ton-per-day plant, or, say, 525,000 net tons of coke cooled per year the savings are.....		$136,500
Assuming that this coke plant is operating in connection with a steel plant where there are blast furnaces as well as producer-gas-fired heating furnaces. Then		

[15] F. E. Leahy, Assoc. I.&S.E.E. Convention, June, 1929.

5	Blast furnace assumed as now using 486,720 tons of wet-quenched coke will require with dry quenched coke, say, 467,250 tons, or a saving of 19,470 tons. The value of the coke saved at $4 per ton is	$77,880
6	As the quantity of dry-quenched coke fines available will only be approximately 11 per cent, or 57,750 net tons per year, this can be successfully used in the producer-gas plant in place of high-priced bituminous coal, with the following saving:	
	Coal per net ton delivered	$4.00
	Coke fines per net ton delivered	$2.50
	Gasification charge in each case	$0.50
	57,750 net tons of coke fines per year, cost	$144,375
	As the heat content in gas delivered from each net ton of coke fines is	20,668,000 B.t.u.
	and from each net ton of 14,000 B.t.u. bituminous coal is	19,600,000 B.t.u.
	the quantity of bituminous coal required to deliver the same heat units in the gas as produced from 57,750 net tons of coke fines will be approximately	60,890 net tons
	Value of this gasified	$274,005
	Value of coke fines gasified	$144,375
	Savings per year	$129,630
	At the value given, a dry-quencher installation cooling 1500 net tons of coke per day should conservatively show the following yearly saving:	
1	Direct savings in operation of plant	$136,500
2	Blast-furnace fuel	77,880
3	Dry coke fines in gas producer	129,630
	Total	$344,010

In the foregoing savings report such matters as interest on investment, profit, and amortization of plant have not been

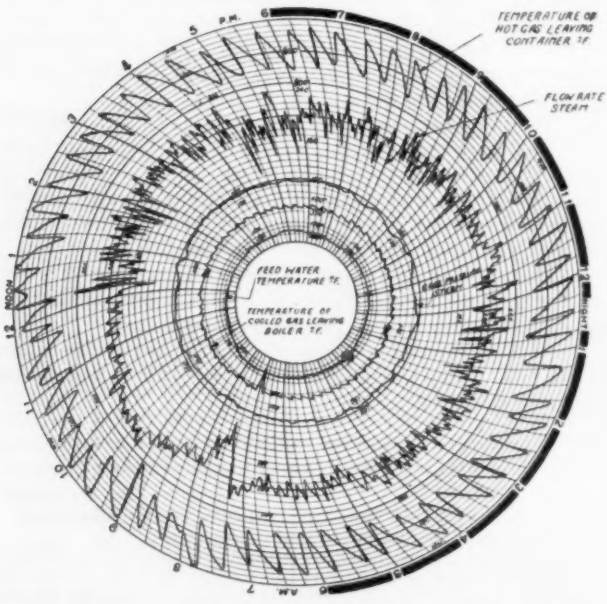

FIG. 4 COMPOSITE CHART GIVING STEAM AND GAS DATA FOR PLANT OPERATING 24 HOURS A DAY

worked out, as the installation assumed shows a complete return of the investment in less than one year.

However, there are many plants not so favorably situated as the one in question and where only the direct steam saving can be counted on plus the increased sales value of coke fines which amounts to from $1.50 to $2.00 per net ton, depending on plant location.

On the basis of figures given by A. M. Beebee in his paper read before the American Blast Furnace & Coke Association, November 26, 1929, the entire installation cost of a 1500-ton-per-day plant should not exceed $300,000.

In this same paper the following statement is made referring to the wet-quenching installation; "We have always had it and have grown to accept it as a necessary evil," and referring to dry-quenching installations such as theirs, where they cannot count on other savings: "It is easy to see that such a plant can earn yearly from 30 to 70 per cent on the investment, depending on the sales price of the steam."

DESCRIPTION OF DRY-QUENCHER INSTALLATION AT THE COURT STREET STATION OF CONSUMERS POWER CO., FLINT, MICH.

This plant has recently been put in operation, and as it differs considerably from installations at other plants, a description following the normal course of operation, with technical data, should prove of interest.

The hot coke is pushed from the coke ovens into a hot car of the usual type (except that it is much shorter, to suit the elevator cage), which is moved by the locomotive car on to a cage hoist where the locomotive is uncoupled and the hot car locked to the cage rails and hoisted up by means of an electrically driven entirely automatically controlled hoisting engine. As the load is hoisted the container charging door automatically opens, and when the cage reaches the top position the car discharge doors, electrically operated, automatically open and permit the coke to flow through the charging chute and door into the container. A time-limit switch then starts the empty car down, and in due time closes the charging door.

When the car again reaches the lower or ground position, the electrical equipment cuts out and the operator couples on the locomotive, releases the car locks, and pulls the car back to the battery in position to receive another charge when the oven is ready.

However, before another load of hot coke is put into the container, the operator withdraws an equivalent amount of cooled coke from the bottom of the container, loading it on to the coke wharf, whence it is taken by a wharf conveyor and transported to the screening station.

The dry quenching or cooling of the coke takes place in the firebrick-lined container which holds about seven loads of hot coke.

A circulating fan drives an automatically formed inert gas into the bottom of the container through a gas distributor and up through the bed of coke, which gas absorbs heat in cooling the coke and passes out near the top of the container through a superheater chamber and into a fire-tube boiler of the vertically inclined type. The gas passing through the boiler gives up heat and generates steam.

Dust carried over with the circulating gas is either precipitated in the superheater chamber or caught by the dust collector at the bottom of the boiler.

The cooled gas is drawn from the boiler into the suction side of the circulating fan and is discharged and driven into the bottom part of the container.

This process is continuous, and the inert gas is used over continuously as the entire system operates on a closed cycle.

To maintain this closed cycle, not more than one point in the gas-circulation system should be open at a time.

The charging door and discharging doors are only opened alternately so as to maintain the closed cycle.

The coke container is provided with a manually operated coke-level indicator so that the operator can readily determine the quantity of coke in the container and also gage the quantity discharged each time.

The coke-discharging device consists of a coke rake, operated

from the outside of chute, and gastight shut-off doors with latching devices to prevent infiltration of air.

The container, superheater chamber, and boiler are lagged and insulated to reduce radiation losses.

The boiler is provided with a Copes feedwater regulator and Reliance water column.

The hoisting machine and motor are placed in a separate brick

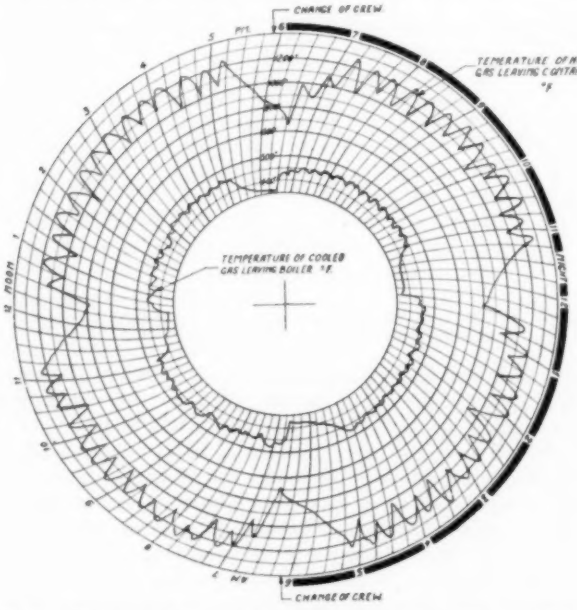

FIG. 5 COMPOSITE CHART GIVING GAS TEMPERATURES FOR PLANT OPERATING TWO TEN-HOUR TURNS IN EACH 24-HR. DAY

building with the operating controls and switch panels placed in a separate room.

MAIN TECHNICAL DATA OF FLINT, MICH., DRY-QUENCHER INSTALLATION

Number of coke ovens	29
Type of ovens	Horizontal by-product
Coke produced per charge	9000 lb.
Plant operates	Two (2) 10-hour turns per day
Capacity of dry quencher per 20-hour day	280 net tons
Capacity of dry quencher per hour	14 net tons
Temperature of glowing coke, approx.	1800 deg. fahr.
Temperature of cooled coke, approx.	700 deg. fahr.
Steam pressure	250 lb. gage
Steam superheat	100 deg. fahr.
Total temperature of steam	506 deg. fahr.
Feedwater temperature (about)	200 deg. fahr.
Time interval between loads (approximately)	19 min.
Mean gas temperature leaving container	1150 deg. fahr.
Outlet gas temperature (assumed)	450 deg. fahr.
Expected steam production per net ton of coke cooled from and at 212 deg. fahr.	1000 lb.
Expected steam production per hour from and at 212 deg. fahr. (approx.)	14,000 lb.

The steam produced is used in steam turbines and as process steam in the by-product plant.

COMPOSITE CHARTS OF PLANT OPERATION

Fig. 4 is the composite chart of a plant operating 24 hours per day. The diagram between the 800 and 1400-deg. lines shows the temperature of the gases leaving the coke container, from which the effect on temperature of each hot charge can be readily seen.

When a load of hot coke is put in the container the temperature rise is almost instantaneous, and then as the coke cools this temperature slowly drops until the next load is put in.

The diagram between the 160 and 240 lines shows the rate of steam flow and is a composite of steam production and demand. In general the fluctuations follow the hot-gas temperature line.

The next diagram shows the steam gage pressure in pounds per square inch, and this is succeeded by one showing the temperature of the cooled gases after passing through the boiler, ducts, and fan; in other words, the temperature of the gas going to the container. This latter diagram shows plainly the effect of each hot load and indicates that the discharging of cooled coke has very little effect on the gas temperature in this installation.

The innermost diagram shows the temperature of the feedwater in degrees fahrenheit.

This composite chart is not a record of test conditions, but was made up from actual operation charts of a plant operating 24 hours per day.

Fig. 5 shows diagrams of the hot and cooled gas temperatures in a plant operating on two 10-hour turns in each 24-hour day. The four delay periods of approximately one hour each show clearly that there is sufficient reserve heat in the stored coke to keep producing steam and quickly pick up the operating load when the hot-coke supply restarts.

In this plant the steam is produced at 250 lb. per sq. in. gage

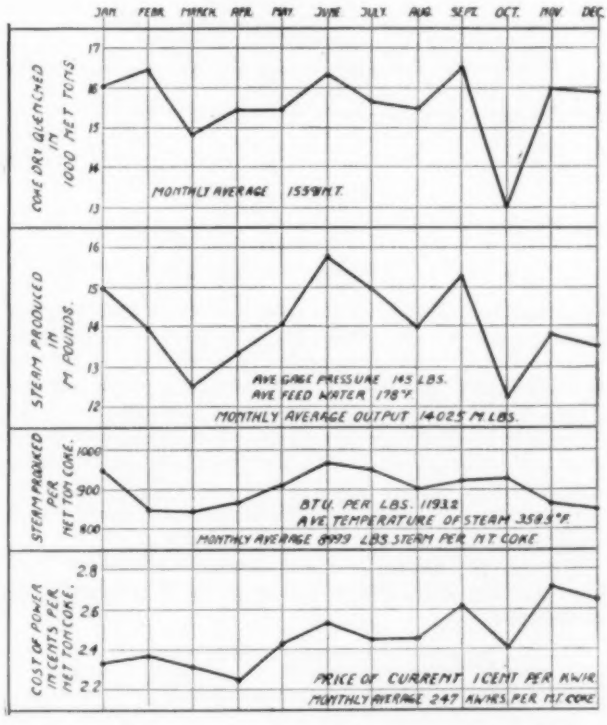

FIG. 6 OPERATING RECORD, BY MONTHS, FOR YEAR 1929

pressure and delivered with 100 deg. fahr. superheat, making a total steam temperature of 506 deg. fahr.

Fig. 6 gives the operating record of one plant for the year 1929. It shows:

1 The quantity of coke dry quenched per month and the monthly average for the year
2 The quantity of steam produced per month and the monthly average for the year
3 The quantity of steam produced per net ton of coke quenched for each month and the average for the year. The steam quantities are given in actual output at the pressure produced

4 The cost of power for the entire dry-quencher installation, including circulating gas fans and hoist.

All of the data given in Fig. 6 are taken from actual operation and are not test figures.

Cooling Gas

In the operation of a dry-quencher plant it has been found that sometimes hydrogen is formed, and in the early plants it was burned off at the opening of the charging doors. These latter were small, and therefore created a restriction which required the use of a small pilot flame.

However, improvements in later installations seem to have

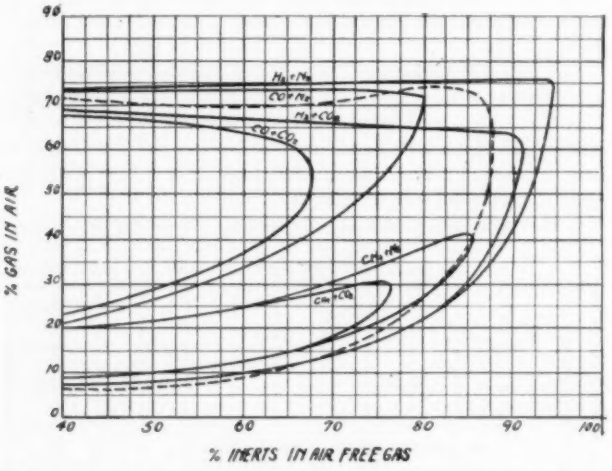

Fig. 7 Showing Composition of Various Mixed Gases in Relation to Dry-Quencher Cooling Gas
(From data by J. W. Jones in *Ind. & Eng. Chem.*, vol. 20, 1928.)

eliminated this difficulty, at the same time giving some additional heat recovery from the burning of the small amount of hydrogen.

As previously mentioned, a mixture of CO and CO_2 is formed in the apparatus at the very start of operation. To this mixture is sometimes added a certain amount of hydrogen, which may increase to about 20 per cent if the cooling chamber is charged with badly distilled coke. The suggestion has been made that such a mixture of gases might lead to explosions. An analysis of the conditions, together with the experience of actual installations, proves that these fears are unfounded.[16]

The following table shows percentage gas analyses from the dry-quenching installation at the gas works of Keilehaven, near Rotterdam:

	Time between observations							
	13 min.		20 min.		19 min.		16 min.	
	Sample numbers							
	I	II	III	IV	V	VI	VII	VIII
CO_2	6.5	7.0	8.6	8.8	13.3	12.4	12.5	11.7
O_2	0.2	0.2	0.3	1.0	0.3	0.7	0.3	1.2
CO	6.7	6.6	6.9	6.4	4.5	4.5	7.0	6.5
CH_4	2.6	2.2	2.0	1.1	0.2	0.2	0.2	0.1
H_2	18.4	11.9	11.4	6.7	0.4	1.3	3.8	1.7
N_2	65.6	72.1	70.8	76.0	81.3	80.9	76.3	78.8

The samples numbered I, III, V, and VII were taken shortly after refilling the container, while those numbered II, IV, VI, and VIII were taken shortly before refilling the container with glowing coke.

In investigating the possibility of explosion, 60 gas analyses taken at this coke-quenching plant were considered. It was found that the proportion of carbon monoxide, as well as that of hydrogen, reached at most a maximum of about 20 per cent.

[16] M. C. Sissingh, *Gas und Wasserfach*, no. 51, 1923.

TABLE 3 ANALYSES OF DRY-QUENCHER-GAS SAMPLES

	No. of samples
Less than 10 per cent H_2 and less than 4 per cent CO:	
Due to presence of air in quencher	10
Due to nearly complete combustion	58
Less than 10 per cent H_2 and 4 per cent or more of CO	218
Between 10 per cent and 20 per cent H_2	154
Between 20 per cent and 30 per cent H_2	69
30 per cent H_2 or more	25
Total number of samples	534

TABLE 4 CORRELATION OF GAS-ANALYSIS DATA

No. of samples	Lower limit	Upper limit	CO	H_2	CH_4	Inerts	B.t.u.
10	12	64	6	33	2.5	58	153
3	15	65	8	35	2.3	54	166
8	13	68	10	32	1.4	57	150
4	15	69	13	25	1.3	62	134
1	18	72	12	17	1.6	69	113
5	20	71	8	19	1.2	72	98
9	23	71	6	18	0.9	75	88
2	24	73	14	14	1.0	71	101
7	27	73	8	13	1.0	78	78
11	28	73	6	< 10	...	> 84	< 62
14	30	72	5	< 10	...	> 85	< 50
15	32	72	4	< 10	...	> 86	< 47
6	31	73	4	< 10	...	> 86	< 45
12	31	74	9	< 10	...	> 81	< 61
16	32	74	8	< 10	...	> 82	< 60
13	36	74	8	< 10	...	> 84	< 57
17	None	None	2	< 10	...	> 88	< 39

This would result in a gas consisting of a mixture of 20 per cent of carbon monoxide and carbon dioxide, and 20 per cent of hydrogen diluted with 60 per cent of carbon dioxide and nitrogen.

The explosion limit for a mixture of water gas and air at average temperatures is between 12.5 and 66.6 per cent of water gas. If air is allowed to enter the mixture of cooling gases it serves to dilute the mixture, and the concentration of combustible material is lowered. Laboratory tests and actual experience in plant operation have shown that no apprehension is to be felt for the safe performance of Sulzer System dry-quenching plants.

At one plant 534 samples of dry-quencher gas were analyzed during the year. These analyses were made primarily to indicate the presence of possible leaks in the system and not as another check on operating conditions, and the results are summarized in Table 3 in terms of the main inflammable constituents in the gases.

The analyses were made by an experienced operator and are considered accurate with 0.1 per cent for each constituent. The B.t.u. was calculated at 60 deg. fahr. and 30 in. pressure.

Consideration of the Data

In order to study the composition of dry-quencher gas, it is necessary to correlate the data and bring the essential figures into a more compact form, as in Table 4. The lower limit is taken as a basis for the following classification. Since oxygen and carbon dioxide seem to affect the limits very slightly, if at all, these have been added to the percentage of N_2 or inerts. Carbon dioxide, as is seen, varies, from about 2 per cent to 10 per cent, and generally the higher percentages are found among those analyses having less than 10 per cent H_2, as would be expected. The other figures are rounded off to the nearest unit except in the case of methane.

Fig. 7 shows curves plotted from the data given by J. W. Jones of the Bureau of Mines,[17] for $H_2 + CO_2$, $H_2 + N_2$, $CO + CO_2$, $CO + N_2$, $CH_4 + CO_2$, and for $CH_4 + N_2$.

These curves differ slightly from those given by other authorities as to curve for $H_2 + CO_2$, but the differences can be accounted for by the type of apparatus used. Jones used upward propagation, i.e., his flame started at the bottom and traveled upward, while most others ignited the mixtures in the center, or upper center, by means of a fuse wire.

Upward propagation was used in these tests, and the results obtained compare favorably with the work of Mr. Jones.

[17] *Industrial and Engineering Chemistry*, vol. 20, 1928.

Dry-quencher gas is continually changing, so that it is therefore hard to get an accurate average, and the curve given in Fig. 7 covers but one condition.

The following few analyses of the circulating gas, taken at the latest installation, will give an idea of the composition of this cooling medium, which is found immediately after starting up with air, as the oxygen is quickly consumed when the air circulates through the first load of coke.

CO_2	O_2	CO	
—Per cent—			
13.80	2.20	3.00	After charging
12.40	0.00	5.40	Cooling
9.40	2.20	4.00	After charging
12.50	0.00	4.90	Cooling

An Installation of the Latest Type

Fig. 8 shows a modern-type installation similar to the Flint plant, except that the glowing coke is transferred from the by-product oven by means of a standard hot-coke car and discharged at the dry quencher into a bucket which is hoisted and dumped into the top of the coke container automatically.

The circulating cooling gases are fed to the discharge chute and bottom portion of the container, as well as through the distributor, thus taking advantage of all the space containing coke for cooling purposes.

This installation includes a superheater and vertically inclined fire-tube boiler with simple type of dust collector at the bottom. The dust collected in the superheater chamber is intermittently discharged into the boiler dust collector, from which all dust is drained approximately once in each turn.

Shut-off dampers are provided to shut off boiler units when necessary. Regulating dampers are installed in the ducts leading to the distributor and container hopper so that the distribution of cooling gas can be adjusted as required.

This type of installation discharges the cooled coke back to the hot-coke car, which delivers it to the regular wharf for distribution by belt conveyor to point of storage or use.

It will be seen from the figure that the container, superheater chamber, and boiler head are well insulated, while the boiler is lagged on the outside to reduce loss by radiation to the minimum.

The charging door, discharging coke rakes, and discharge doors are all mechanically operated and provided with push-button controls.

Sizes of Installations

Local conditions, capacity in net tons of coke per day, and oven output affect the dry-quencher-plant designs, and the illustration referred to below should give a fairly good idea of the equipment required.

Fig. 9 shows a plant of small capacity where the time interval between charges is relatively great; it consists primarily of one or more cooling chambers in which the special coke container is stored for the predetermined period needed to bring the coke down to handling temperature.

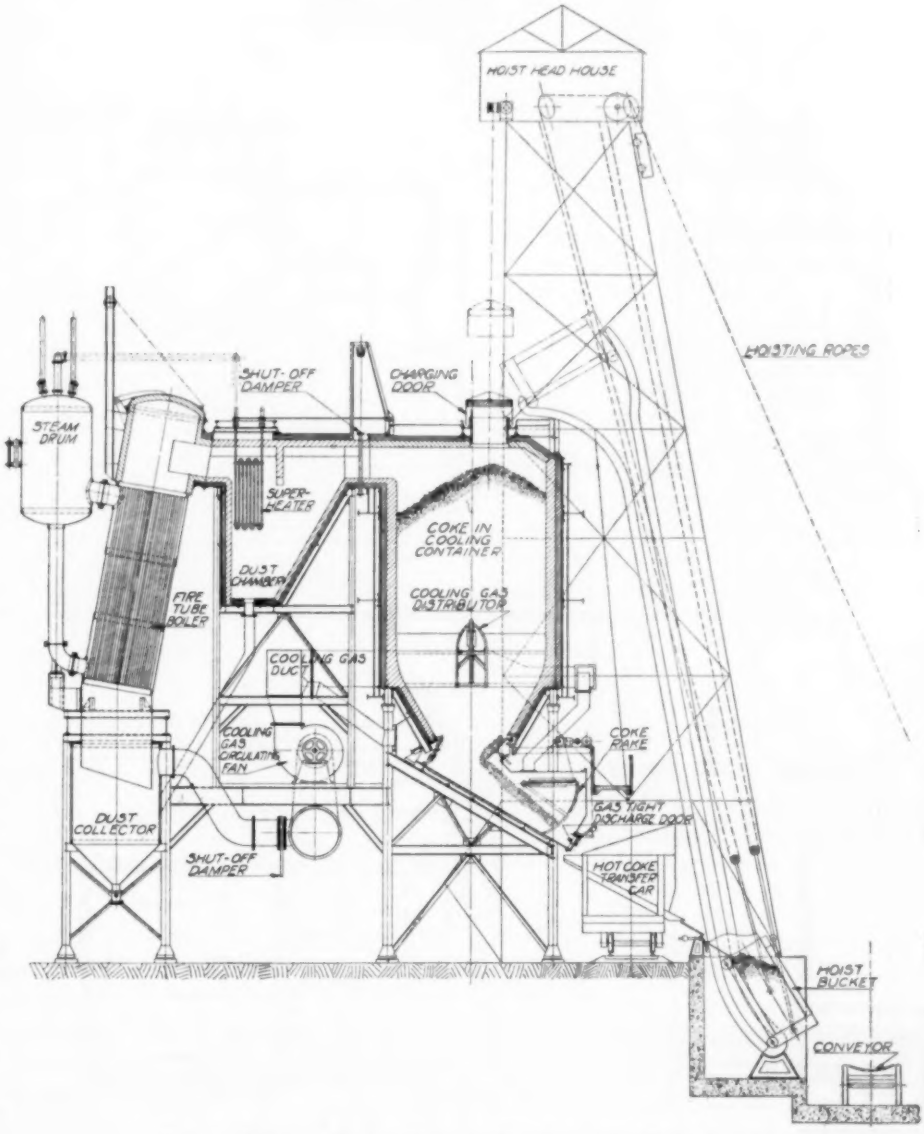

Fig. 8 Showing Latest Type of Dry-Quencher Installation

Fire-tube waste-heat boilers of suitable size are installed in connection with the cooling chambers so that the circulating fan will cause a current of automatically formed inert gas to pass through the coke, into and through the boiler, thence back to fan, ad lib., in a similar manner to that previously described for the process.

The quantity of steam produced by such a plant is usually slightly less than with a larger installation.

Fig. 10 shows a slightly different type of small-capacity installation where the boiler, of the water-tube type, forms the cooling chamber and the coke charge in a special container is stored inside what is practically a water-wall-cooled furnace. The cooling

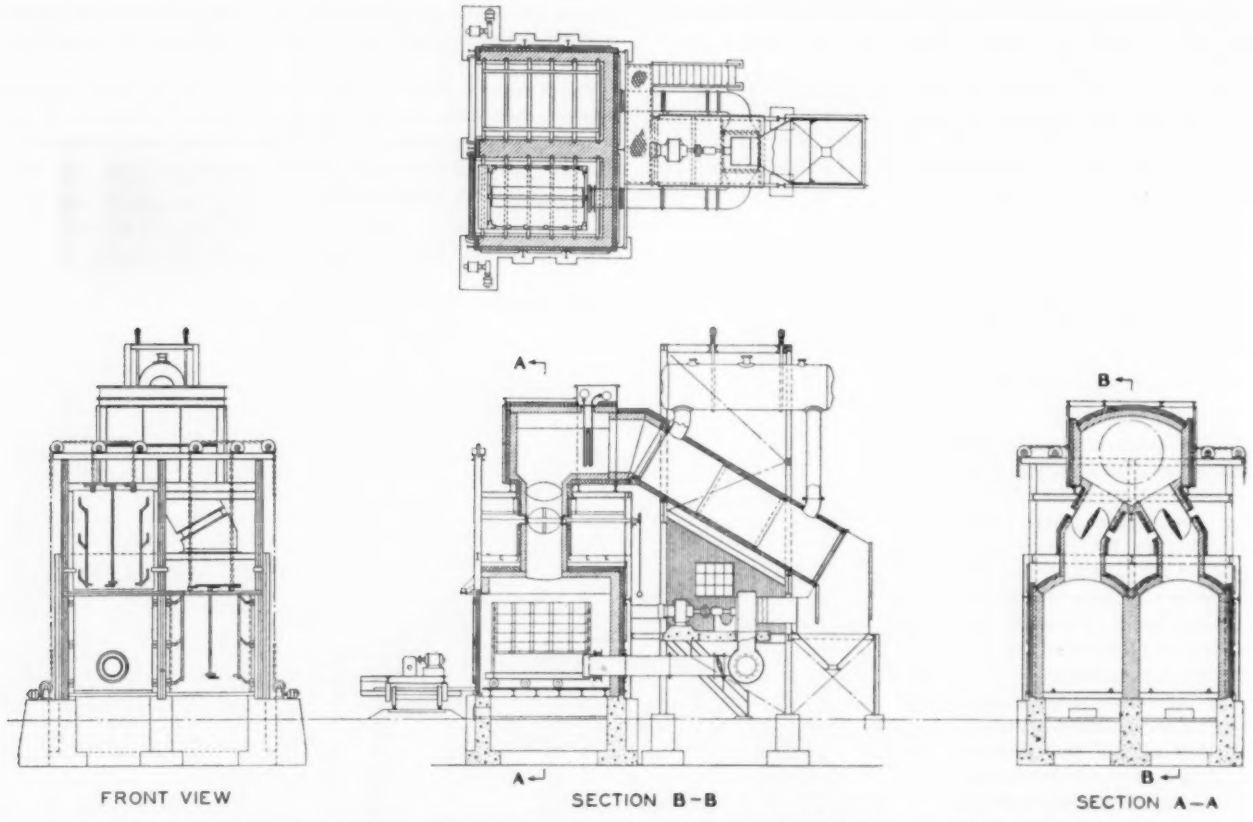

FIG. 9 SHOWING SINGLE-CHARGE COOLING-CHAMBER-TYPE INSTALLATION WITH INCLINED FIRE-TUBE BOILER

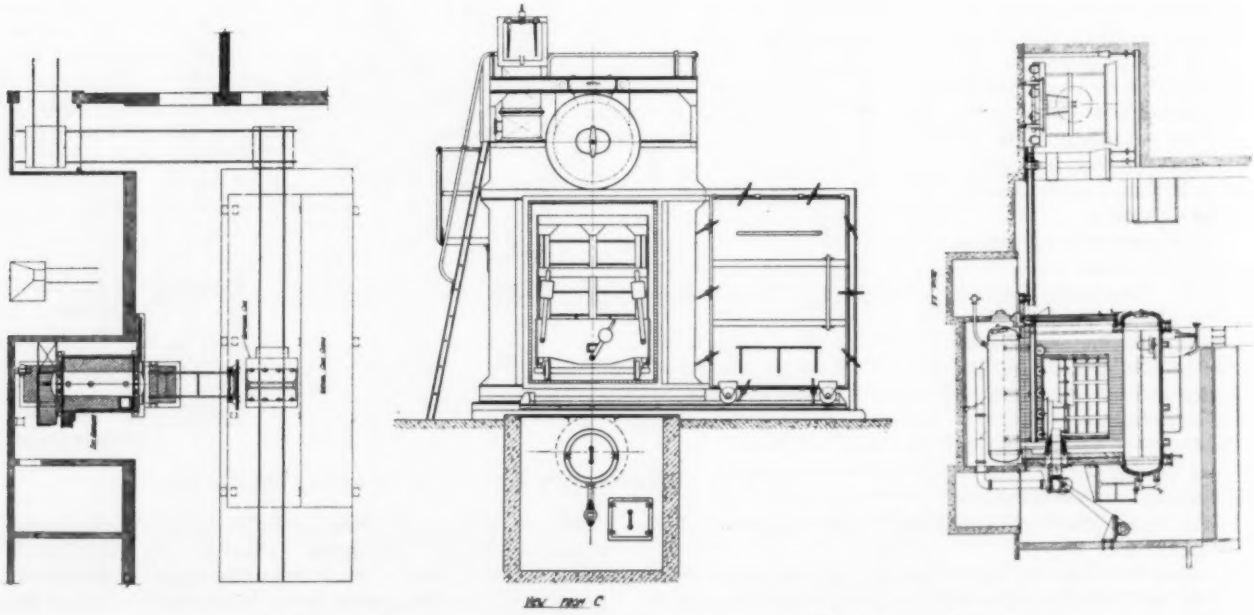

FIG. 10 SHOWING ARRANGEMENT OF SMALL-CAPACITY INSTALLATION WITH WATER-TUBE BOILER

gases pass up through the coke, then down through the boiler-tube interstices, and out at the bottom to the circulating fan. Reproduction of photographs of a plant of this type are given in Figs. 16 to 23.

Fig. 11 shows a plant similar to the installation shown in Fig. 8, but having a hoist tower and bucket to receive the coke from the hot-coke car, and then elevate and discharge it into the top of the coke container. The capacity of the plant is 530 net tons of coke per day, a charge of hot coke being received approximately

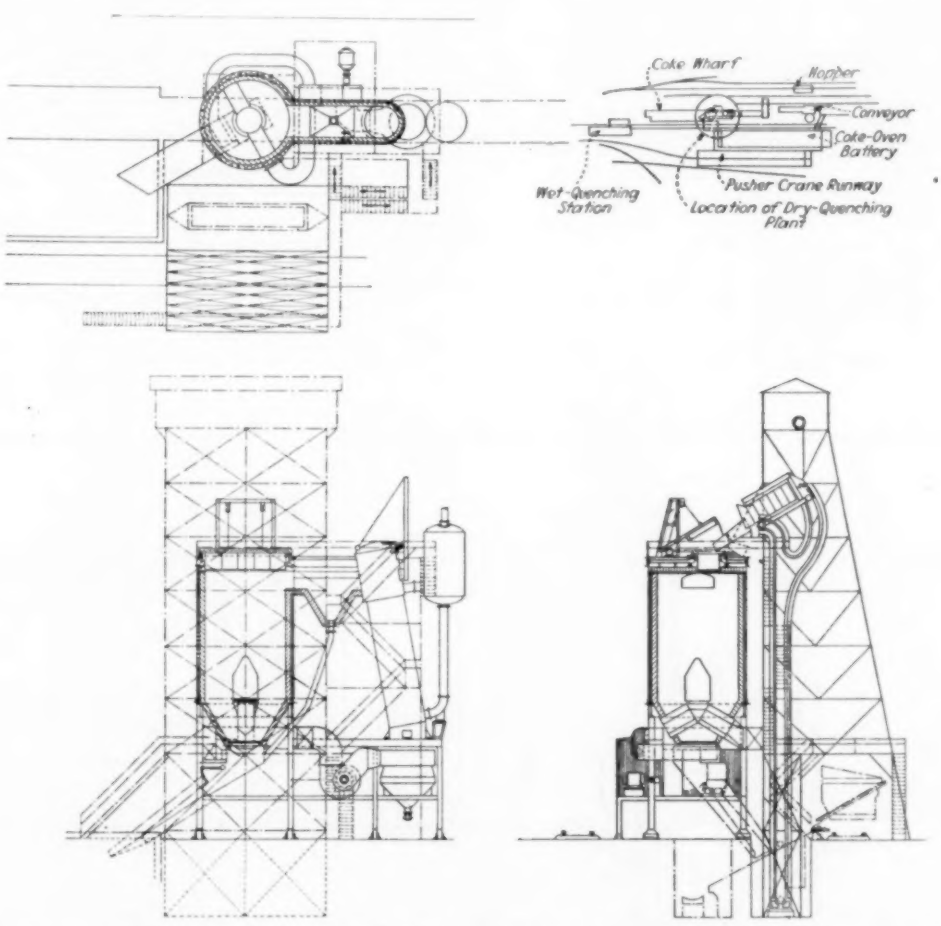

FIG. 11 SHOWING INSTALLATION OF 530 NET TONS PER DAY CAPACITY WITH SINGLE CONTAINER UNIT AND SINGLE VERTICALLY INCLINED FIRE-TUBE BOILER

every 20 min. Fig. 12 shows a similar plant having a capacity of 1000 net tons of coke per day, receiving a charge of hot coke approximately every 15 min. These two installations are arranged to discharge directly on to existing coke wharfs.

Fig. 13 shows a plant of 2200 net tons daily capacity which has a rectangular coke container and three boilers so arranged that any one may be taken out of service when required. This installation discharges the cooled coke into the hot-coke transfer car, which in turn delivers it on the existing wharf, the machinery being designed to handle a charge of coke approximately every 7 min.

Fig. 14 shows a plant designed to handle 3800 tons of coke per day, located over a screening station and built in two units, each equipped with a hoist tower, bucket, and three boilers. It is arranged to discharge the cooled coke on to an intermediate dust-settling wharf, from which it is fed through chain feeders uniformly to belt conveyors.

This system releases the hot-coke car immediately after it has discharged a load of glowing coke into the hoist bucket, which permits one car to do the work where ordinary wet quenching would require two hot-coke cars. It also provides gas burners for use in auxiliary firing of boilers in the event that the coke output runs below that required to produce all the steam required to operate turbines, etc. The time interval between charges for this plant is approximately 5 min.

Fig. 15 shows the 1000-ton-per-day installation at Homécourt, France, which has been in successful operation for some years. This, being one of the early installations, is equipped with water-tube boilers and was designed on the basis of a four-hour cooling time; later experience in this country, however, has demonstrated that only two hours' cooling time is all that is economically needed.

Figs. 16–23 are reproduced from photographs of a 15-ton-per-day plant that has been in successful operation for the past two years. This installation showing sectional elevation in Fig. 10 is at a plant fitted with vertical retort ovens, each oven being of 1.5 net tons coke capacity.

The cooling period in this installation is approximately $1^1/_2$ hours and the steam production is about 800 lb. at 200 lb. gage pressure, the power consumption being approximately 2.5 kw-hr. per net ton of coke cooled.

From an inspection of these views it will be seen that the hot-coke container is moved into and out of the boiler chamber

mainly by means of a hand winch. This of course can be done by power where necessary.

The glowing coke comes to the boiler chamber at an average temperature of 1800 deg. fahr., and the cooled coke is discharged at approximately 450 deg. fahr.

Fig. 24 is a photographic view of the dry-quenching plant at the gas works of the Rochester Gas and Electric Corporation, Rochester, N. Y. This plant was built on the basis of four hours

Coal and Coke Analyses

At both the Rochester and Flint plants high-volatile coals are used, the relative coke and coal analyses being as follows:

Coal Charged to Ovens:

B.t.u. per lb	14,300
Volatile, per cent	36.47
Fixed carbon, per cent	58.97
Ash, per cent (calculated on moisture-free basis)	4.56
Sulphur separately determined, per cent	0.75

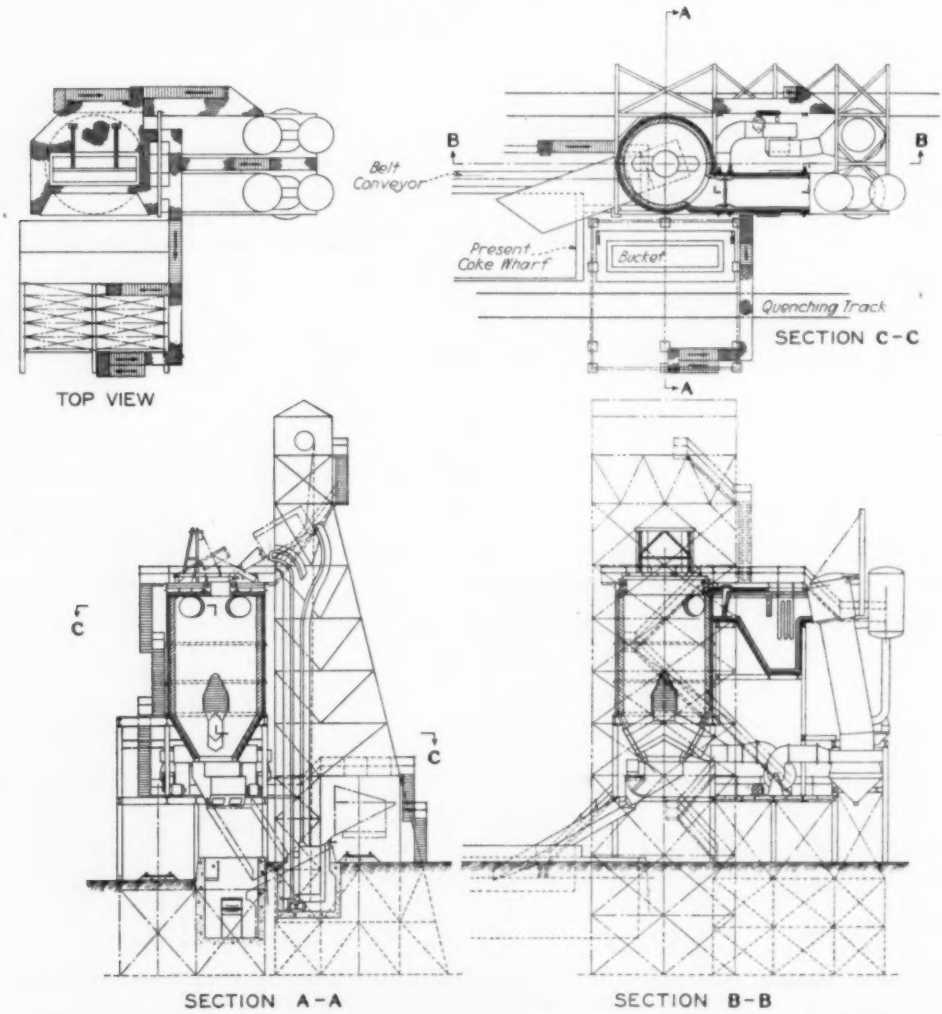

Fig. 12 Showing Installation of 1000 Net Tons per Day Capacity With Single Container Unit and Two Boilers

cooling time for a capacity of 425 net tons of coke cooled in 24 hours. Tests and experiments have demonstrated that two hours cooling time is sufficient, so that new plants designed on this basis will naturally represent a considerably lower investment.

The plant consists of two complete container and boiler units, and over 500 tons per 24 hours have been successfully cooled in one unit on occasions when required. Steam is produced at approximately 140 lb. gage pressure, without superheat.

Fig. 25 shows the dry-coke quenching installation at the Court Street Station of the Consumers Power Company, Flint, Michigan. This installation has a capacity of cooling 280 net tons of coke in 20 hours as the plant operates on two 10-hour shifts in each 24-hour day. Steam is produced at 250 lb. gage pressure with 100 deg. superheat and a total steam temperature of approximately 506 deg. fahr.

Coke Produced, Wet-Quenched:

	Moisture free	As received
B.t.u. per lb	13,039	11,463
Volatile, per cent	1.71	1.49
Fixed carbon, per cent	91.29	79.51
Ash, per cent	7.00	6.10
Moisture in coke as received, per cent		12.90
Sulphur separately determined, per cent		0.75

Coke Produced, Dry-Quenched:

	Moisture free	As received
B.t.u. per lb	13,088	13,023
Volatile, per cent	1.16	1.15
Fixed carbon, per cent	91.48	91.03
Ash, per cent	7.36	7.32
Moisture in coke as received, per cent		0.50
Sulphur separately determined, per cent		0.68

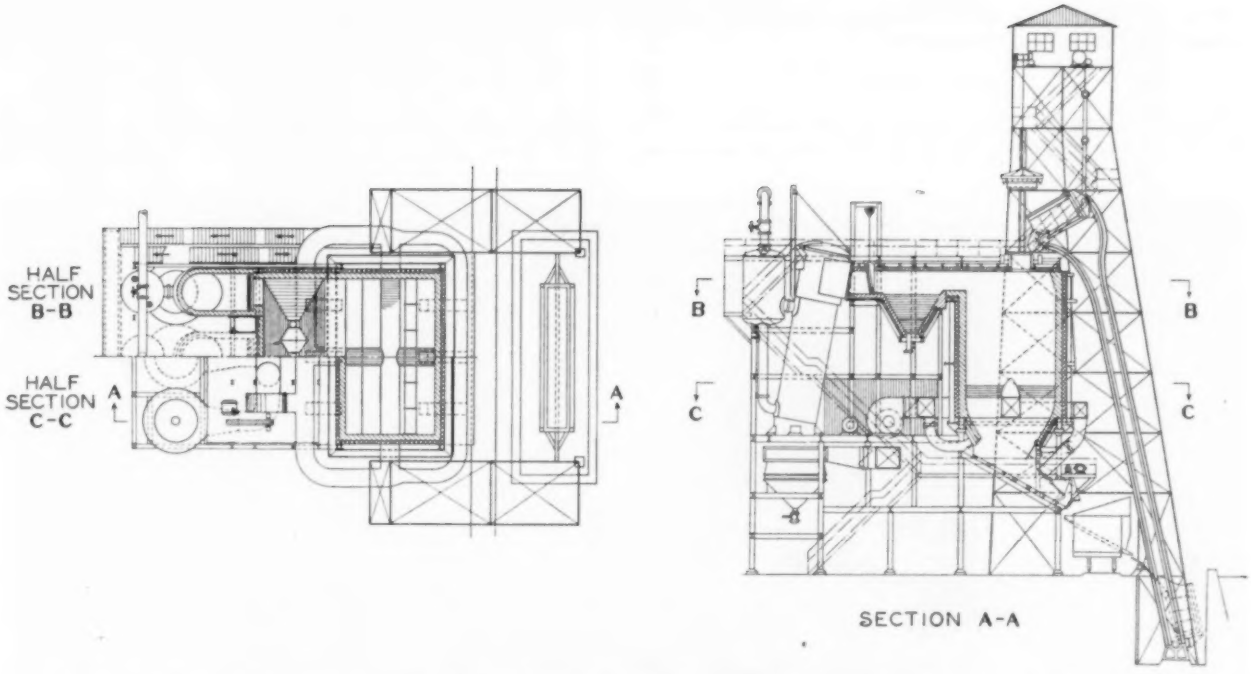

FIG. 13 SHOWING INSTALLATION OF 2200 NET TONS PER DAY CAPACITY WITH SINGLE CONTAINER UNIT AND MULTIPLE BOILERS

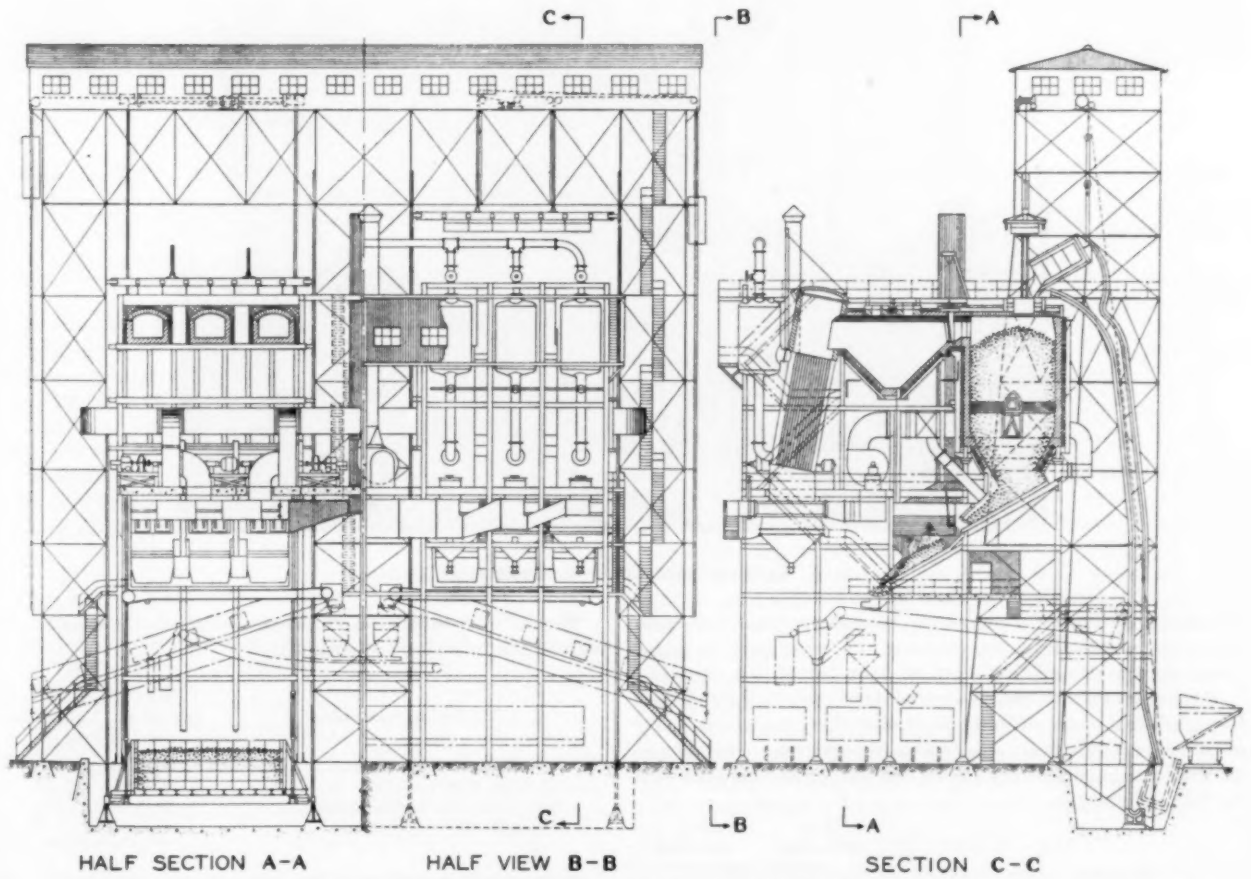

FIG. 14 SHOWING INSTALLATION OF 3800 NET TONS PER DAY CAPACITY WITH TWO CONTAINERS AND MULTIPLE BOILERS

From the foregoing it will be seen that dry-quenched coke has a higher heat value than wet-quenched.

Screen Tests

One of the items of special interest to coke manufacturers is the size of coke produced, and as the Rochester dry-quenching installation apparently handled the coke more roughly than do the usual water-quenching methods, improvements in plant design were developed that seem to have helped the situation.

While plants of new design have not been operating a sufficient length of time to get definite, conclusive data, the results so far obtained seem to indicate a noticeable improvement. Some comparable tests have been run on wet- and dry-quenched coke with the following results:

	Wet-quenched	Dry-quenched
	—Per cent—	
Over 2 3/4-in. × 2-in. screen	63.6	55.3
Through above screen	11.5	15.5
Over 2-in. × 2-in. screen	11.5	11.5
Through above screen	19.4	25.6
Over 3/4-in. × 3/4-in. screen	19.4	25.6
Through above screen	5.5	3.6

From this it will be seen that the quantity of fines through 3/4-in. screen is less in dry-quenched than in water-quenched coke.

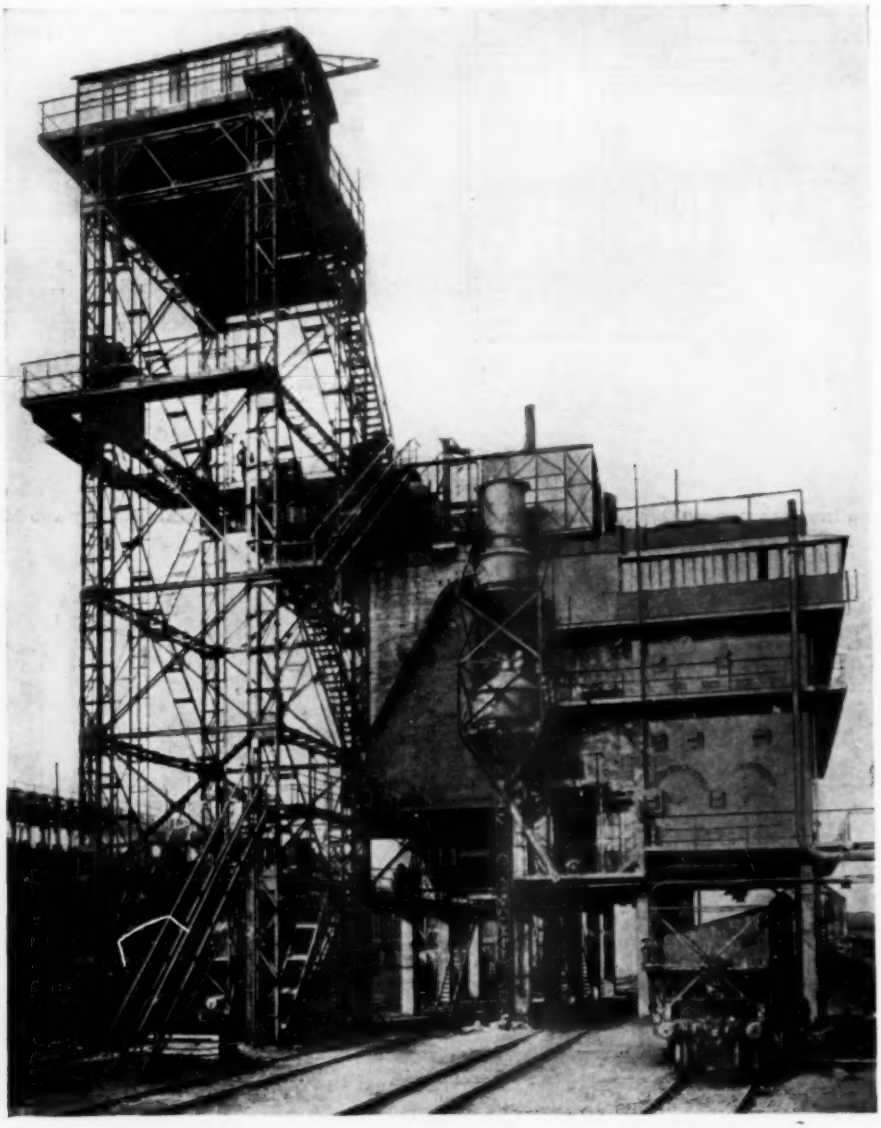

Fig. 15 View of Installation at Homécourt, France

Shatter tests carried on at the same time as the screen tests showed the following comparison:

Method of quenching	Wet-quenched	Dry-quenched
	—Per cent—	
Over 2-in. × 2-in. screen	50.0	66
Through above screen	39.5	26
Over 3/4-in. × 3/4-in. screen	39.5	26
Through above screen	10.5	8

From this it would seem that dry-quenched coke is stronger on 2-inch screen than water-quenched.

This bears out the results of tests run by C. C. Russell[18] in 1927 at Rochester, as we find it stated in his report that—

Dry-quenched coke (through 3-in. on 2-in. screen) when subjected to the standard shatter test (four 6-ft. drops) still contains 63 per cent of coke on a 2-in. screen, whereas wet-quenched coke of the same original size contains 50.1 per cent on a 2-in. screen after the same treatment.

	Per cent		
Over 2¾-in. × 2-in. screen	62.04	60.71	38.79
On 1½-in. × 1-in. screen	25.05	21.17	43.77
On 1-in. × ½-in. screen	2.35	2.50	4.98
On ½-in. × ½-in. screen	3.47	2.86	6.86
Through above screen	7.09	12.76	5.60
Total	100.00	100.00	100.00

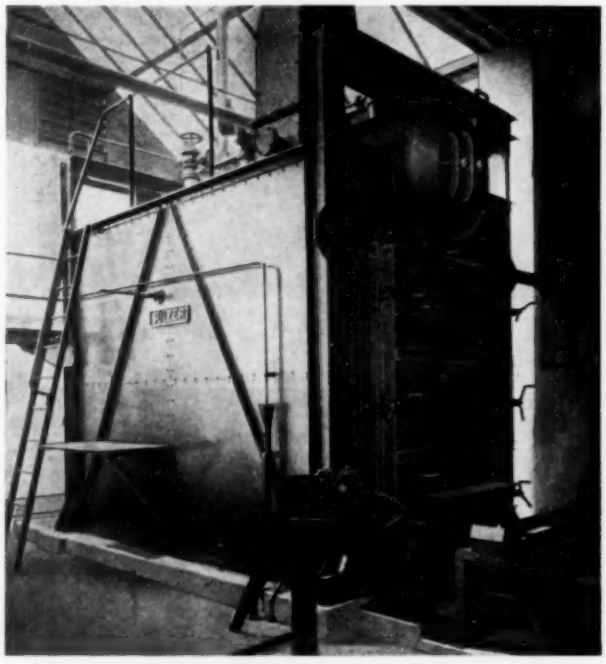

Fig. 16

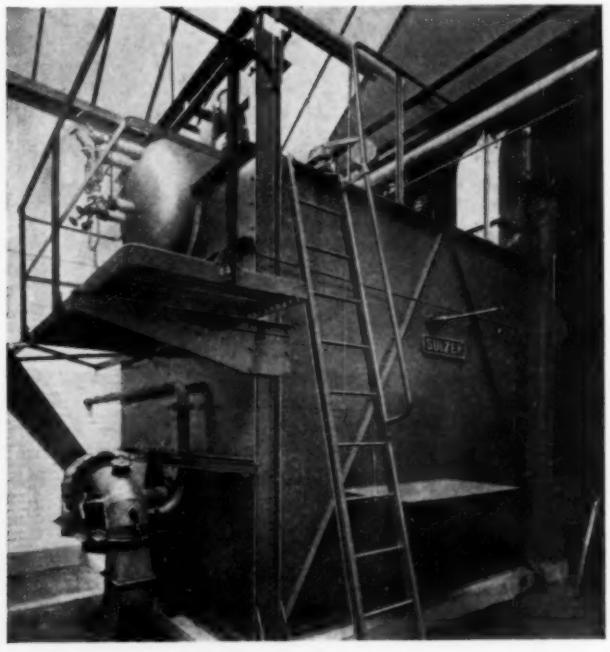

Fig. 17

FIGS. 16 AND 17 VIEWS OF SELF-CONTAINED UNIT INSTALLATION AT SCHAFFHAUSEN, SWITZERLAND

Repeated shatter tests on the same samples of dry- and wet-quenched coke show that any given size of dry-quenched coke resists breakage better than the same size of wet-quenched coke, no matter how much rough handling they are given.

In every case, then, the dry-quenched coke is stronger than the wet-quenched coke of the same size.

At the Flint plant it was observed that the water-quenched and dry-quenched coke as delivered to the wharf differed somewhat in appearance, although some lumps as large as 8 and 10 in. were discerned coming from dry quencher.

Additional samples were then taken and comparable screen tests run as follows. The first column gives the results from a wet-quenched sample taken from wharf; the second gives results from the same sample dried to a moisture-free condition; and the third, similar data from a dry-quenched sample.

	Weight in pounds		
Weight of sample	310	280	281
Weight over 2¾-in. × 2-in. screen	192½	170	109
Weight through above screen	117½	110	171½
Weight over 1½-in. × 1-in. screen	77½	59¼	123
Weight through above screen	40	50¾	49½
Weight over 1-in. × ½-in. screen	7¼	7	14
Weight through above screen	32¾	43¾	35
Weight over ½-in. × ½-in. screen	10¾	8	19¼
Weight through above screen	22	35¾	15¾

Reducing these data to a percentage basis, the following comparison is secured:

[18] Koppers Co., "A Comparative Study of Coke at the Plant of Rochester Gas and Electric Corporation Made December, 1926."

A further test was run to determine, if possible, the amount of fines adhering to the coarse in wet-quenched coke, as no doubt the fines so adhering would be released in furnace, or stock bins, as the moisture evaporated.

A sample of 730 lb. of wet-quenched coke was therefore screened, the moisture partially eliminated through air drying, and again screened, with the following results:

		After drying
Coarse, over ½-in. screen, lb	730	589
Fines through ½-in. screen, lb	73	88
Fines through ½-in. screen, per cent	10	15
Moisture in fines, per cent	23	5

This showed clearly that dry coke is much cleaner than the usual run of moisture-laden coke, and that there is actually more fines with the wet-quenched than the dry-quenched, although the usual screening method does not show it.

It should be noted that the difference in weight of sample cannot be construed as all moisture, because a portion of the fine coke was lost in handling so that the weights given represent the actual quantity put on the screen, and the figures giving the amount of fines after air drying are therefore conservative.

From the foregoing it will be noted that the fines are very much greater in the wet-quenched coke after drying than in the dry-quenched coke. This simply indicates the condition that arises when the water-quenched coke is put in a furnace, and proves that the dry-quenched coke is cleaner and more desirable.

HEATING VALUE OF COKE

Most wet-quenched coke contains a large percentage of moisture, while dry-quenched coke is moisture-free when it leaves

Fig. 18

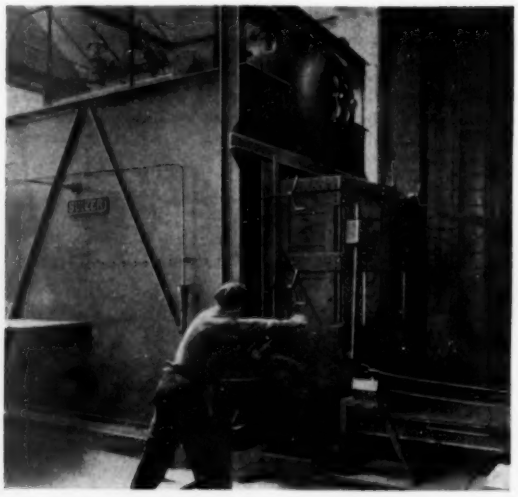

Fig. 21

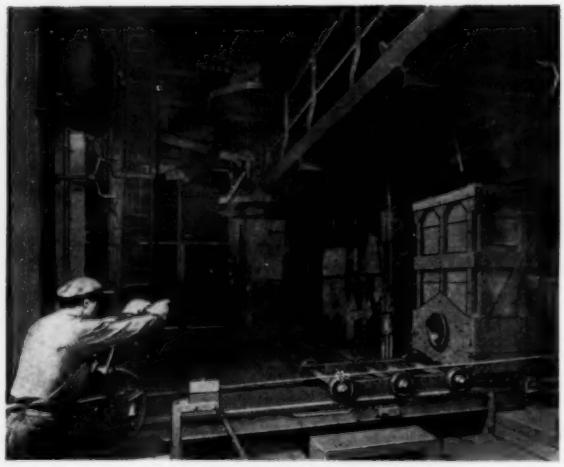

Fig. 19

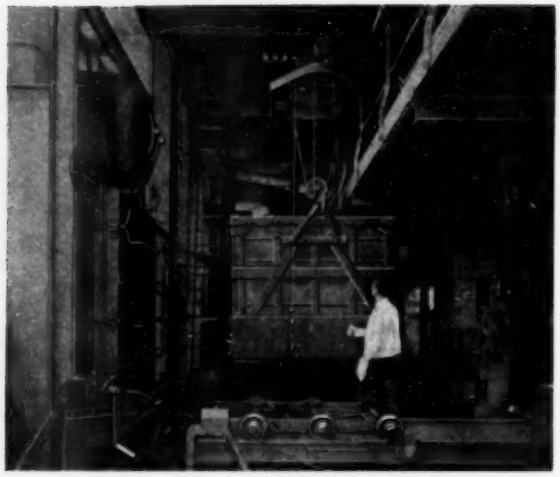

Fig. 22

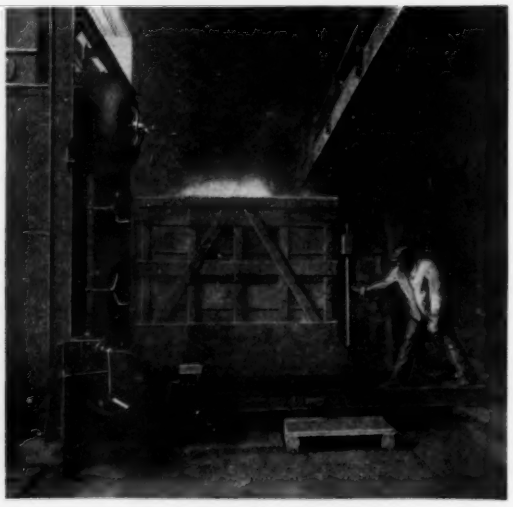

Fig. 20

Fig. 23

FIGS. 18-23 VIEWS OF SELF-CONTAINED UNIT INSTALLATION AT SCHAFFHAUSEN, SWITZERLAND

the quenching unit; sometimes, however, it is sprayed or absorbs moisture from the air, which, it has been found, amounts to from four-tenths to sixth-tenths of 1 per cent.

The actual heating value per pound of coke as received is naturally affected by this moisture content, so the following comparisons will no doubt be of interest.

Tests of wet-quenched coke as received by consumer show 8.10, 11.65, 14.20, and 19.79 per cent moisture. Dry-quenched-coke tests show 0.41, 0.50, and 0.60 per cent, so an average of 0.50 per cent is conservative.

The comparative heating value of water-quenched and dry-quenched coke, assuming an average of 8.10 per cent moisture for the former, is therefore as follows:

	B.t.u. per lb. as received
Water-quenched coke	11,983
Dry-quenched coke	13,023
Actual increase in heating value	1,040

or, on a percentage basis, the consumer receives 10.87 per cent more heat units per pound of dry-quenched coke than per pound of water-quenched coke.

In the case of coke fines it seems that the moisture is concentrated, and it has been found that wet-quenched coke fines through a $^3/_4$-in. screen contained from 20 to 30 per cent of moisture, while the dry-quenched maximum was but 0.8 per cent. Assuming, therefore, an average for wet-quenched of 23 per cent and for dry-quenched a maximum of 0.8 per cent, the following comparison is conservative:

	B.t.u. per lb. as received
Water-quenched coke	10,525
Dry-quenched coke	12,974
Actual increase in heating value	2,449

or on a percentage basis, the consumer receives $23^1/_4$ per cent

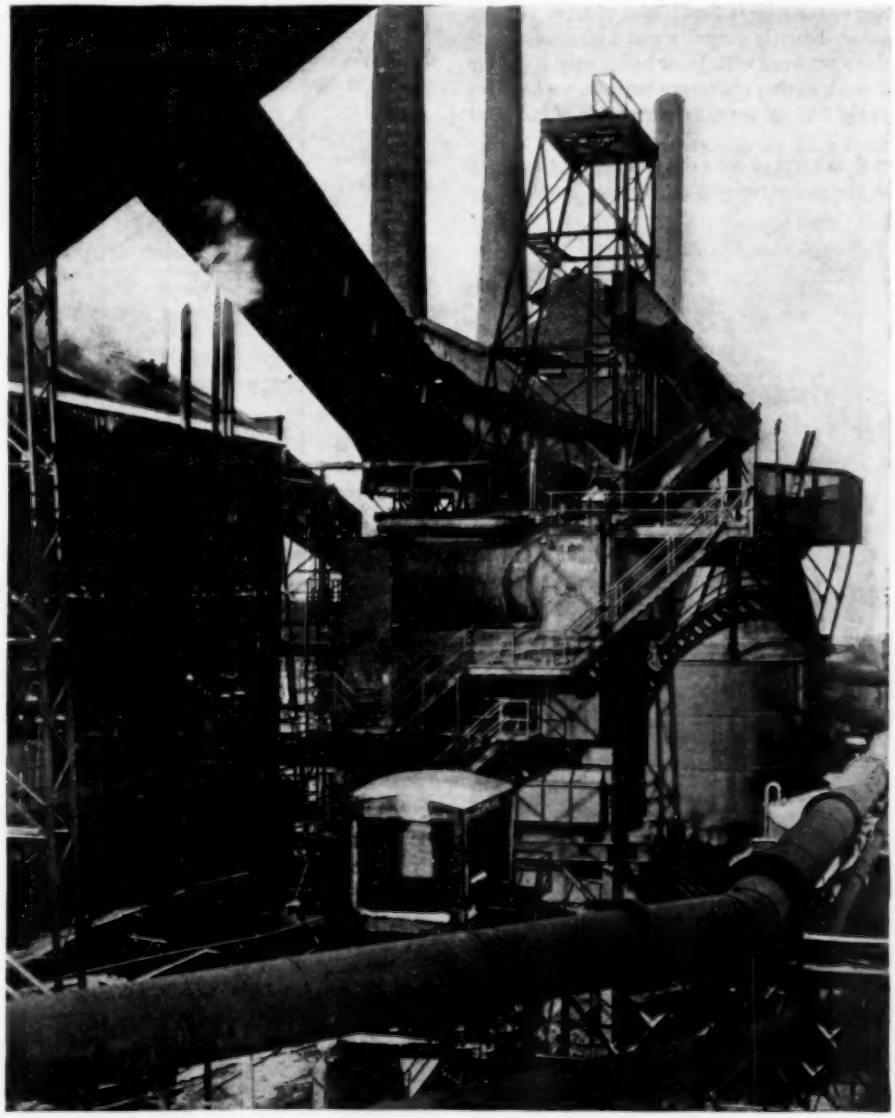

FIG. 24 VIEW OF INSTALLATION OF PLANT OF ROCHESTER GAS & ELECTRIC CORPORATION, ROCHESTER, NEW YORK

more heat units per pound of dry-quenched coke fines than per pound of wet-quenched coke fines.

These figures indicate that the consumer should insist on dry-quenched coke wherever it can be used.

Fig. 26 shows the relative heat units in dry-quenched and wet-quenched coke as received by consumer at various moisture contents.

Return on Investment

Assuming an average overall investment cost of $240 per net ton of installed dry-quencher daily capacity and a steam-producing operation of 350 days per year with labor being paid 365 days per year due to repair work during shutdown periods, we have an average output per year of 350 net tons of coke per ton of installed quencher capacity.

From the heat in each net ton of coke dry quenched, there will be produced steam at the pressures and superheats required by

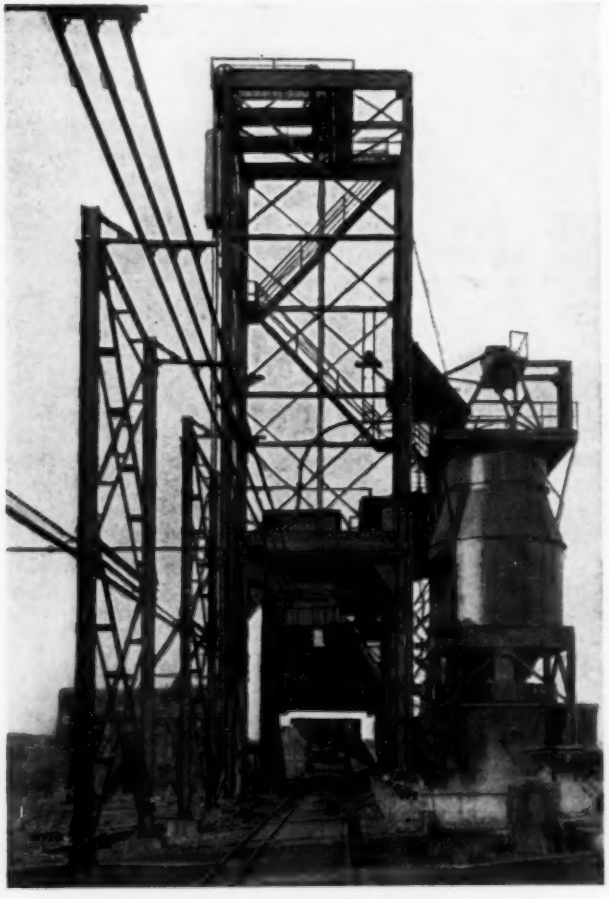

Fig. 25 View of Installation at Consumers Power Company, Court Street Station, Flint, Michigan

different plants in varying amounts, and the chart in Fig. 27 has been made up on the following basis:

1 Steam produced from and at 212 deg. fahr. at rates of 800, 900, and 1000 lb. per net ton of coke cooled
2 Steam values of 20 to 60 cents per 1000 lb. from and at 212 deg. fahr.
3 Return on the investment in dollars per year per net ton of coke installed daily quencher capacity, for each of the steam outputs at money values per 1000 lb.

This latter figure is made up as follows:

1 Value of steam produced
2 Less cost of steam, including fixed charges amounting to 16 per cent on the investment cost

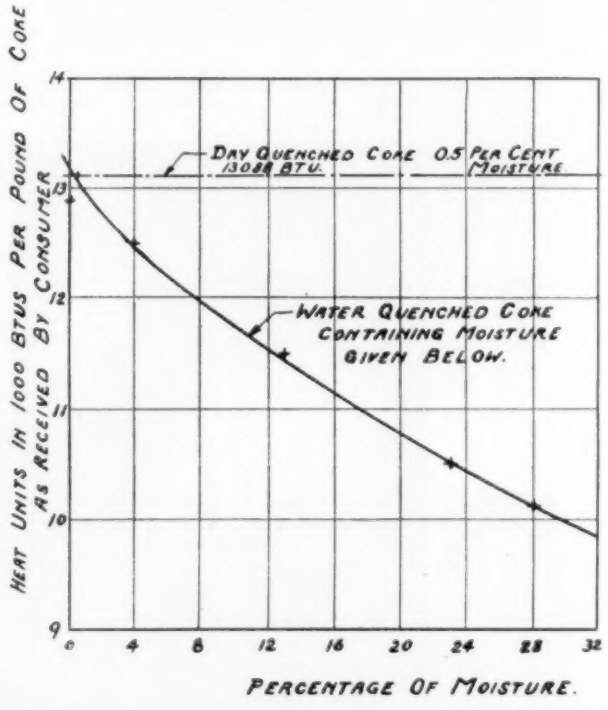

Fig. 26 Chart Showing Relative Heating Value of Dry-Quenched and Wet-Quenched Coke

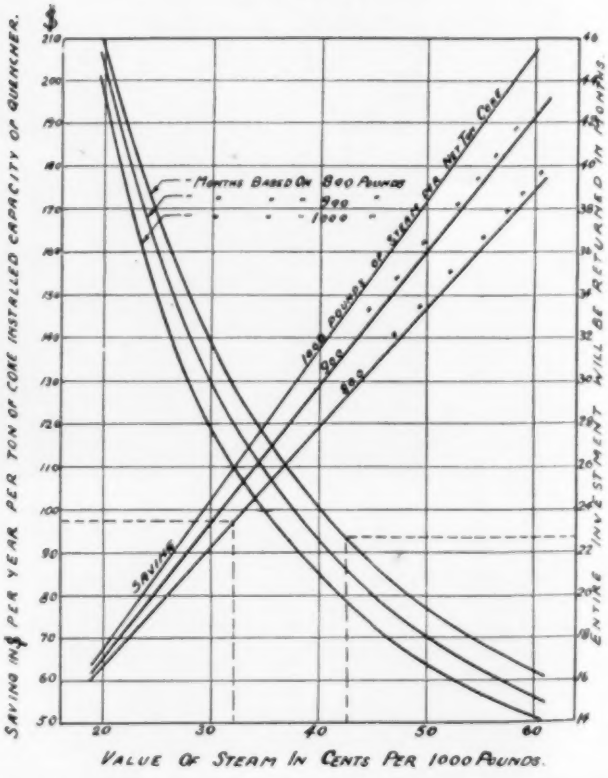

Fig. 27 Chart Showing Savings and Return on Investment Obtainable With a Dry-Quencher Installation

3 Less cost of pumping water in existing wet-quenching plant—assumed at 2 cents per net ton of coke
4 Less an allowance for reduced maintenance due to elimination of corrosive action of wet quenching—assumed at 1 cent per net ton of coke
5 Less increased sales value of dry coke fines, assumed at $1 per net ton, on basis of this being 11 per cent of the total coke cooled.

From the chart it will be noted that an installation producing 1000 lb. of steam from and at 212 deg. fahr. per net ton of coke cooled with a steam value of 60 cents per 1000 lb., shows a saving of $206.50, at which rate it will equal the investment cost in less than 15 months.

Correspondingly, a plant producing but 800 lb. of steam at a value of 20 cents, will show savings of only $52.50 and will require approximately 4½ years to amortize the investment cost.

Conclusion

With our present need for fuels conservation, it would seem that the waste and discomfort caused by water quenching of coke are economically indefensible.

As the savings to be secured and advantages to be gained by dry quenching are so notable, there should be no doubt as to its desirability, and the author hopes the facts he has presented will be of assistance in furthering this economic improvement.

Discussion

R. J. Bender.[19] The writer would ask whether the necessity of using some kind of a steam accumulator has been proved in connection with these dry-quenching plants so as to control the steam output, which is apparently irregular; or are the boilers of sufficient volume to store enough steam?

H. P. Reid.[20] This paper gives an interesting detailed discussion on a simple but novel method of reclaiming heat in the form of steam as a by-product of a large-scale commercial operation, viz., coke production. One interested in conservation of by-products cannot but be impressed by the seemingly extravagant methods of removing heat from coke by the wet-quenching method; likewise, the cooling of other high-temperature products by water spraying.

While the data given in the paper cover the operation from both the coke-cooling and steam-generation angles, it is lacking in some other data which would be interesting. To enumerate, could the author answer the following:

(1) What is the total static pressure drop across the system as indicated by pressures at the inlet and the outlet of the fan? Of course this pressure drop would increase greatly with the increase in percentages of smaller sizes of coke. Are there any data available on these pressure drops with higher percentages of these smaller sizes present in the coke? If so, what are they?

(2) What is the time period required for coke to pass the system?

(3) Have any plants been operated long enough to determine the abrasive effect of the coke dust on (*a*) the superheater elements, (*b*) the boiler tubes, (*c*) the dust collector, and (*d*) the fan blades and housing? If so, what is the life or service period of each of these items?

(4) What average gas velocities are used across the superheaters elements and through the boiler tubes?

(5) The flow of material downward through a hopper or bin such as the coke container of this installation is rather difficult to control so that the flow shall be uniform across any horizontal cross-section of the container. For best boiler efficiency and effective cooling it is evident that this flow should be uniform. Has this system been so designed as to give such uniformity; and if so, how?

(6) Is it possible to admit a constant stream of hot-material charge by a conveyor of some type, rather than by batches, granting that such hot material could be obtained in stream flow rather than by batch, without infiltration of cold air to the system?

R. W. Parkinson.[21] The author shows savings due to the use of the dry-quenching process which will pay the cost of the installation in from one to two years' time. It is quite probable that such large savings can be effected only in more or less ideal cases where there is a continuous demand for moderate pressure steam which will be equal to or in excess of the rated steam output of the proposed dry-quenching plant.

It would of course be possible in the case of an isolated coking plant where there is only a small demand for steam to dry-quench only a portion of the product and thus make only such steam as is required. In most cases, however, this would result in a very small installation, and the economies effected would be small. It would seem that one of the broadest fields for the application of the dry-quenching process would be in large coking plants owned and operated by steel companies when these plants are located on or adjacent to the mill properties. In such cases there is generally a large demand for medium-pressure steam to be used for process and for heating purposes throughout the mills. Ordinarily such a dry-quenching plant would be called upon only to furnish a portion of the steam required, so that the entire output could be used to advantage in this case, and the deficiency in steam could be made up from other sources perhaps in fuel-burning boiler plants using coke breeze. When applied to steel mills, the dry-quenching process must necessarily compete with other sources of waste heat, such as the heat in the exit gases from the open-hearth furnaces and blast-furnace gas from the blast furnaces. In one case comparisons of various methods of producing steam from waste heat have shown that all the heat for the moderate-pressure steam required could be recovered to at least equal advantage by utilizing other waste-heat sources. It is quite clear that in such a case, if the dry-quenching plant can be justified at all, the justification must be based mainly on other advantages claimed by the author, such as the superiority of the dry coke and the lower percentage of coke breeze produced. The author states that the dry coke will have a heating value approximately 1000 B.t.u. per lb. higher than that of wet-quenched coke. This of course will result in higher efficiencies due to the lower moisture losses when burning the dry fuel. This will be a net saving, although the total B.t.u. value of the coke produced per ton of hot coke quenched will of course be little in excess of that for the wet-quenched coke.

With regard to the sizing of the coke, it appears that the coke made by the dry-quenching process runs somewhat smaller in size than the wet-quenched product, and this is considered to be a disadvantage by the majority of blast-furnace operators. From an inspection of drawings presented with the paper, it would appear that this objection could be largely overcome by the manufacturer by means of improvements in the design of the conveying equipment which dumps the hot coke into the top of the dry quencher. This could probably be arranged so that the coke would slide in smoothly and would not have to be

[19] Whiting Corporation, Harvey, Ill. Mem. A.S.M.E.
[20] Special Engineer, Universal Atlas Cement Company, Chicago, Ill.
[21] Allied Engineers, Inc., Jackson, Mich. Jun. A.S.M.E.

dumped twice, first into the skip bucket and then into the coke container through the charging doors. If the rough handling of the coke were eliminated, there is no apparent reason why the dry-quench coke should not be equal in size to the wet-quenched product.

While it is believed that the author is a little optimistic in his expectation that the savings to be realized with a dry-quenching plant will ordinarily pay for the installation in a period of one or two years, it is no doubt true that there are very material savings to be made with the use of this process, and all should feel very much indebted to the author for the detailed account of the progress being made along these lines.

G. R. Strimbeck.[22] Our installation has been in operation only a short time, and any comments must be viewed in the light of that fact. Our experience to date using a mixture of Kentucky King coal from Lisle, Ky., and Wharton coal from Wharton, W. Va., does not show any increase in strength of the coke that would clearly point to a gain inherent to the process of dry quenching. Our shatter tests show only a slight increase, which could be explained by the extra handling the coke receives in our plant due to use of the dry-quenching unit. We find no difference in the sulphur content and very little change in amount of fines produced. The coke does have a better appearance since the volatile matter in any "black" ends is burned out and the silvery appearance is retained due to dry-quenching.

Our biggest problem and one that will be encountered by all users of this process is the matter of dust. When the container is charged, some dust blows over the yard, and a large cloud of dust rises when the container is dumped. Due to the temperature of the coke leaving the unit, it is difficult to eliminate this by any spraying system, and we are trying a dust-collector arrangement. Due to peculiarities of our layout, this dust causes some trouble in our screening system. The writer feels that where new units are installed this trouble could be overcome by allowing time for the coke to cool after leaving the container and then treating with calcium-chloride solution before screening. We expect to try out dust collectors over our screens with final spraying of coke with calcium chloride before it enters trucks or cars for our customers.

In the paper a statement is made that a saving on labor operating car and wharf will result. This is difficult to understand as the hot-car operator would be retained and the man formerly on the wharf would run the dry-quenching unit. That is our arrangement.

The statement is also made that some steam is produced during the four one-hour layover periods. Our experience indicates that this is negligible and that we must keep our regular plant boiler under fire to take care of these drops in steam production. On continuous operation of the battery the steam production fluctuates some, and the writer doubts very much if it would be possible to operate on a dry-quencher boiler only, without some means of controlling the variations in pressure and steam production. At Flint we run our regular boiler, which is equipped with automatic controls, in connection with the dry-quencher boiler and obtain very good charts at the point of steam consumption. To obtain a load sufficient to secure good operation of our regular boiler we have added enough steam-using units to increase our steam consumption by about 15 per cent over last year. These units replace electrically driven ones.

The other data given on the Flint plant are correct. We have not been able to find any hydrogen in our recirculating gases, and we have obtained a steam production which meets the guarantees.

The difficulties we have had in operating the unit are those to be expected from any new equipment, and our costs cannot yet be taken as indicative of long-time operation results. Our power costs are considerably higher than those quoted on the seventh page, due to the fact that we are hoisting the entire hot car. We will undoubtedly save in maintenance of the hot car and the steel work in the vicinity of the quenching station due to the elimination of wet-quenching, but it is difficult to state this saving in dollars.

[22] Superintendent, Consumers Power Company, Flint, Mich.

Author's Closure

In regard to Mr. R. J. Bender's question, the direct answer is "No," as we have not so far felt the need of an accumulator, as the boilers are generally of sufficient size to store steam.

In the smaller-sized plants the steam-generating unit is made oversize and the steam is generated at a fluctuating pressure generally higher than the pressure at which steam is to be used. A regulating valve being installed on the steam outlet permits the steam to flow only at the pressure required. In plants having boilers of the type installed at Flint the steam drum is made of sufficient size to generally act as an accumulator.

Fluctuation in steam pressure is generally affected by the charging, or coke-oven pushing, interval, and the boiler-steam space or reservoir is designed to suit each particular installation. For instance, in a plant having a 25-min. charging interval, the total steam temperatures fluctuation is approximately 8 per cent, while in a plant having a 7-min. charging interval, the fluctuation is approximately $6^1/_2$ per cent.

Answering the questions of Mr. H. P. Reid: (1) The total static pressure drop across the system is approximately 7 in., of water as this has been found to be economic from a fan-operating standpoint. Unless accurate data are available on the percentage of voids in the coke, the calculations are based on an average of 50 per cent voids with not more than 10 per cent breeze or fines through $^1/_2$-in. screen. Data on pressure drops for other conditions are being collected and will be available later.

(2) For such plants as that installed at Flint, the cooling time is 2 hours; that is, the coke container has effective volume to hold 2 hours' production of coke.

(3) Plants have been in successful operation for some years and the question can be answered in detail as follows: (*a*) The superheater elements have so far shown no signs of abrasion or wear due to the abrasive effect of the coke. (*b*) In installations having horizontal fire-tube boilers no wear has been noted in one plant after more than four years of operation. In the vertically inclined type of boiler, as installed at Flint, no wear has so far been noted. (*c*) The dust collectors have so far shown no sign of wear or cutting. (*d*) The fan blades at the Rochester plant are renewed at the time of the yearly plant overhauling, although at other plants the fan blades have run two years. The fan housing has not been replaced at Rochester, and it is in the fifth year of operation.

(4) In general the mean gas velocities through the superheater space and boiler tubes are 60 to 80 ft. per sec. Each installation is calculated separately.

(5) The cooling-gas distributor and the container-discharge opening are designed with a certain amount of adjustment to cause a fairly uniform flow of the coke through the container.

(6) Yes, in special cases by using a rotary or other type of sealing discharge mechanism. One plant is now under development to receive the hot coke from a conveyor. Cold air does not enter the system; there are never two points open to atmosphere at the same time.

In answer to the question of Mr. R. W. Parkinson, the author would say that there are many factors entering into the savings to be effected by dry-quenching of coke, not the least of which is the reduction in plant upkeep due to the elimination of the wet-quenching, very frequently phenol-laden, vapor that is being found very destructive of steel work as well as of the neighbors' property.

Referring to Mr. Parkinson's comment on the sizing of the coke, it will be well to bring out the fact that dry-quenched coke has noticeably less cross-fracture and is stronger size for size than the wet-quenched coke. Uniformity of usable sizes rather than more large pieces is really what the blast-furnace operators want; in fact, crushing and screening to uniform size is now being very extensively demanded by the blast-furnace men. One plant visited by the author is arranging to screen all blast-furnace coke in 3 sizes through $3^1/_2$ in. on $2^1/_2$ in., through $2^1/_2$ in. on $1^3/_4$ in., and through $1^3/_4$ in. in $1^1/_4$ in., charging these different sizes separately.

In conclusion, the author desires to thank the gentlemen who discussed this paper, and to add here that the brick lining of the coke container in one plant is now in its fifth year of operation without one cent of repair or expense and at another plant the steam produced has been more than 1050 lb., F. & A. 212 deg., per net ton of coke cooled.

FSP-53-8

The Performance Rating of Steam-Generating Equipment

By H. L. SOLBERG,[1] LAFAYETTE, IND.

The demands for high capacity, high efficiency, and flexibility have resulted in the development of modern stokers and pulverized-coal burners, adequate furnaces with steam- and water-cooled walls, air heaters, steel-tube economizers, etc., and have completely changed the equipment which was used for steam generation ten years ago. Consequently the author believes it is time that the methods of expressing the performance of such equipment should be revised to conform with new conditions. Considering the problem of steam generation from the viewpoint of the functional purpose of the equipment, it appears to the author that the logical method of expressing the performance of such equipment should be on the basis of the total heat absorbed by all water- and steam-cooled surfaces per unit of time, such a method being general and applicable to all types of steam-generating equipment, and expressing the performance, not in terms of arbitrary dimensions, but of actual results produced.

THE output of steam-generating equipment is generally expressed in terms of boiler horsepower or pounds of steam produced per hour. The second term is indeterminate and unscientific inasmuch as feedwater temperatures, steam pressures, and steam temperatures vary so widely that there may be a difference of 25 per cent in the quantity of heat required to produce a pound of steam in two neighboring plants operating under entirely different conditions. Consequently the term "pounds of steam produced per hour" should be avoided.

The term "boiler horsepower" is unfortunate in that no power is developed in the boiler, nor is there any relationship between boiler horsepower and the power obtainable from the steam in a prime mover. The term originated in 1876 when the Committee of Judges of Steam Boiler Trials at the Centennial Exhibition in Philadelphia defined a boiler horsepower as the evaporation of 30 lb. of water per hour at 100 deg. fahr. into steam at 70 lb. gage, 30 lb. being the average water rate of engines in use at that time. The term was introduced into the A.S.M.E. boiler test code of 1884, and was finally redefined as the evaporation of 34.5 lb. of water per hour at 212 deg. fahr. into steam at 212 deg. fahr. As thus defined, a boiler horsepower is equivalent to the absorption of 33,479 B.t.u. per hr. The term is a misnomer, and the only justification for its continued use is the fact that it has a definite numerical value and is in common use.

Rated Capacity and Per Cent of Rating

The performance curves of steam-generating equipment are ordinarily plotted on a common abscissa of "per cent of rating" or "pounds of steam evaporated per hour." As previously mentioned, the second term is dependent upon several variables and should be avoided. "Per cent of rating," since it is based on an arbitrary "rated capacity," is equally unsatisfactory.

In the A.S.M.E. boiler test code of 1899, the rated capacity of a boiler was defined as follows:

> A boiler rated at any stated capacity should develop that capacity when using the best coal ordinarily sold in the market where the boiler is located, when fired by an ordinary fireman, without forcing the fire, while exhibiting good economy; and further, the boiler should develop at least one-third more than the stated capacity when using the same fuel and operated by the same fireman, the full draft being employed and the fires being crowded; the available draft in the flue just beyond the boiler, unless otherwise understood, being not less than one-half inch water column.[2]

On the basis of this extremely vague definition, boilers were rated at from 8 to 16 sq. ft. per boiler horsepower. The custom gradually developed of rating water-tube boilers on the basis of 10 sq. ft. per boiler horsepower. Consequently, a water-tube boiler, not equipped with a superheater, is operating at 100 per cent of rating when the mean rate of heat transfer is 3348 B.t.u. per sq. ft. per hour. If a boiler is operated at 200 per cent of rating, it does not mean that the boiler is overloaded or subject to excessive thermal strains, but merely that the mean rate of heat absorption is 6696 B.t.u. per sq. ft. per hour. As heat absorption rates in excess of 100,000 B.t.u. per sq. ft. per hour (approximately 3000 per cent of rating) are encountered under favorable conditions in certain parts of boilers, the rated boiler horsepower is not a measure of the maximum capacity of the unit in the same sense that the rating of a turbo-generator is a measure of the power which it can produce continuously. In fact, when units can be run continuously at five times rated capacity and there is no relation between rated capacity and maximum capacity, then the term "rated capacity" is little else than an arbitrary and meaningless one. However, the term "per cent of rating," when applied to boilers not equipped with superheaters, does express in a definite though clumsy way the mean rate of heat transfer, and gives some indication of the conditions under which the boiler is being operated.

Superheaters and Per Cent of Rating

In the case of an installation composed of boiler and superheater, the developed boiler horsepower is based on the total heat absorbed in both the boiler and superheater and may be calculated as follows:

Developed boiler horsepower = (total heat absorbed per hour in boiler plus total heat absorbed per hour in superheater) ÷ 33,479.

The rated horsepower is based on the boiler surface *only*, although the superheater surface is obviously additional heat-absorbing surface. Consequently the per cent of rating does *not* indicate the mean rate of heat transfer in a boiler when a superheater is included in the setting.

Economizers

Curve *A* of Fig. 1 represents the temperature gradient through the water-cooled surfaces of a conventional boiler. It will be noticed that 50 per cent of the heat is absorbed in less than 25 per cent of the surface, and that the last 50 per cent of boiler surface

[1] Associate Professor of Mechanical Engineering, Purdue University. Assoc-Mem. A.S.M.E. The author received his degree of Bachelor of Science in Mechanical Engineering from Purdue University in 1921 and the Master's degree in 1923. Since graduation in 1921, he has been connected with that university.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] Trans. A.S.M.E., vol. 21 (1900), p. 37.

is relatively ineffective. If the last 40 per cent of boiler surface is replaced by economizer surface as shown by curve *B*, Fig. 1, then the rated capacity of unit *B* is only 60 per cent of that of unit *A*. Nevertheless, with the same stoker and furnace, the steam-generating capacity of the two units would be approximately the same. However, the boiler horsepower developed at identical steaming rates would not be the same, since, according to the A.S.M.E. boiler test code, the heat absorbed in the economizer is not considered in figuring the developed boiler horsepower. Why should the economizer be left out

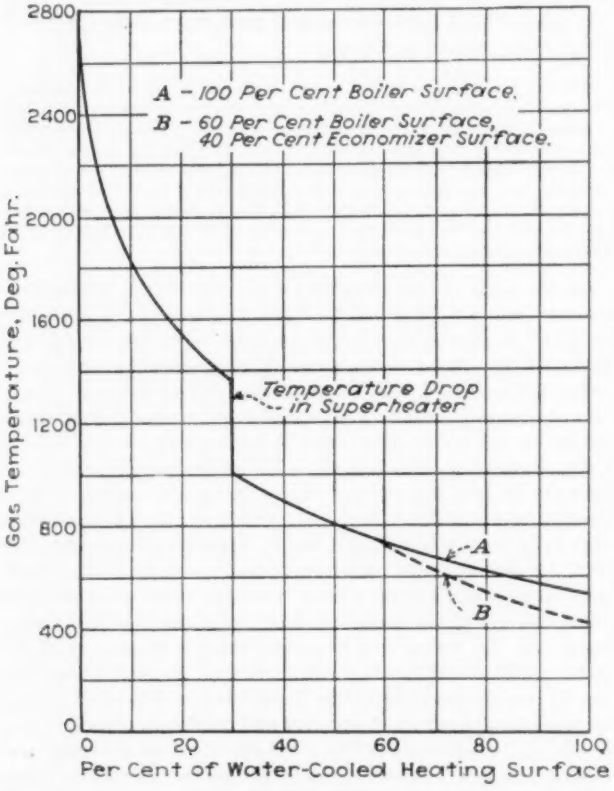

FIG. 1 RELATION OF GAS TEMPERATURES TO PER CENT OF WATER-COOLED HEATING SURFACE PASSED OVER
(Based on Fig. 27, Prime Movers Committee Report No. 25–82.)

of consideration when it is an essential part of unit *B* and one square foot of economizer surface is more effective as a heat absorber than the same amount of surface which it replaces in the conventional boiler? For the same steaming rates, with unit *B* rated at 60 per cent of the capacity of unit *A*, the boiler and superheater are developing about 85 per cent of the boiler horsepower developed in unit *A* and are being operated at a percentage of rating which is about 1.4 times that of unit *A*. The higher "per cent of rating" developed in unit *B* does not indicate that it is being forced more than unit *A*, since for the same steaming rate the mean rate of heat absorption in the boiler of unit *B* is the same as that in the first 60 per cent of unit *A*. The higher percentage of rating in case *B* is obtained merely by replacing relatively ineffective boiler surface by economizer surface. Consequently, the term "per cent of rating" is no indication whatever of the rate of forcing a boiler unless complete data are at hand concerning the arrangement of the heat-absorbing surfaces.

Fig. 2 shows a cross-section of the 11,400-sq. ft. boiler at the 59th Street Station of the Interborough Rapid Transit Company. If this boiler, which is 24 tubes high, were replaced by a 14-high boiler and an economizer of sufficient size to result in about the same flue-gas temperatures as are obtained with the 24-high boiler (assuming that feedwater temperatures will permit this to be done), the unit would be rated at 684 hp. instead of 1140 hp., but could produce the same amount of steam if set over the same furnace and stoker. The larger boiler would be operating at 300 per cent of rating, and the smaller at about 450 per cent when producing the same amount of steam, with identical combustion rates on the stokers and in the furnaces, and with the same heat-transfer rates in the first 6800 sq. ft. of boiler surface. "Per cent of rating" ceases to mean anything under such circumstances unless the entire arrangement of heat-absorbing surfaces is specified.

WATER- AND STEAM-COOLED FURNACE WALLS AND AIR HEATERS

The development of steam- and water-cooled furnaces has resulted in a large increase in capacity brought about by the addition of a relatively small amount of surface. This is especially true in cases where air heaters are employed to maintain the furnace temperature and permit of the absorption of a maximum amount of radiant heat. Fig. 3 shows the remodeled boiler in the Fordson plant of the Ford Motor Company. By doubling the number of pulverized-coal burners and adding air heaters and water-cooled surfaces equal in area to 12 per cent of the original boiler surface, the capacity of the unit was practically doubled. Yet the per cent of rating upon which the performance curves are plotted in Fig. 4 is based upon the original surface of the boiler. In determining the rated capacity of this unit, why is the additional saturated-steam-making surface in the furnace walls not included when it is the most effective surface in the boiler? If it is included, should the rated capacity be figured on the basis of 10 sq. ft. per boiler hp. when the rate of heat absorption is often over five times that of the mean heat-transfer rate of the convection boiler? As yet there is no accepted method of determining the number of square feet of heating surface in the furnace walls and screens. Under such circumstances the rated capacity can be figured in several different ways to give different results which change the "per cent of rating" developed by corresponding amounts. What is the value of "per cent of rating" and "rated capacity" when the unit is operated continuously at five times its rated capacity?

In determining the per cent of rating of a unit such as the Calumet boiler shown in Fig. 5, what is the rated capacity? If based on the boiler surface only, it is 594 hp.; if the furnace surface is included, it is 840 hp. Why should the economizer surface be ignored when it is practically as extensive as the combined furnace and boiler surface? If the economizer were replaced by equivalent boiler surface, then at the same steaming rate the "per cent of rating" would be much lower, although the heat release per cubic foot of furnace volume and the heat transfer per square foot of radiant-heat-absorbing surface remained the same. What is the value of the term "per cent of rating" when applied to units of this type where most of the boiler surface is exposed to radiant heat?

Fig. 6 shows a cross-section of reheat boiler No. 1 on unit No. 3 at the Crawford Avenue Station of the Commonwealth Edison Company. What is the rated capacity of this unit? How is the per cent of rating to be determined? The rating of such units as this on the basis of conventional boiler surface is not only worthless but misleading.

Fig. 7 shows a set of performance curves which was recently published by a prominent stoker manufacturer. In examining these curves, two things are very noticeable: (1) the increase in maximum efficiency of the newer installations, due to better stokers and furnaces and improved arrangements for absorbing the heat, and (2) the higher ratings at which the newer units are

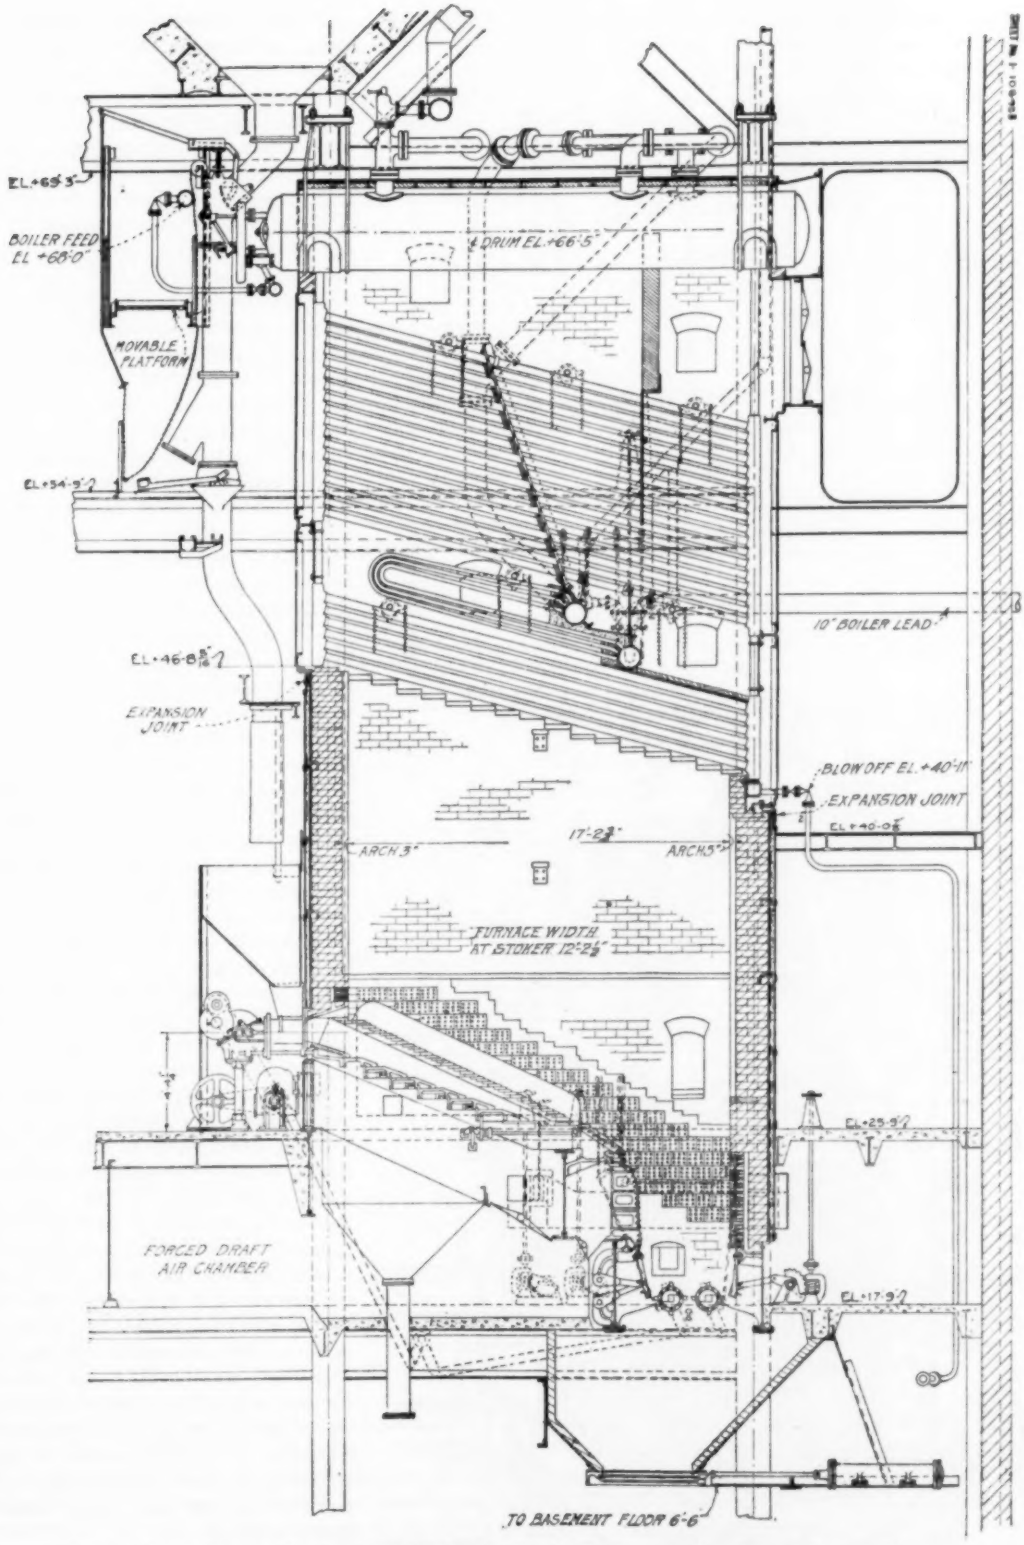

FIG. 2 CROSS-SECTION THROUGH 11,400-SQ. FT. B. & W. BOILER, 59TH STREET POWER STATION, INTERBOROUGH RAPID TRANSIT COMPANY

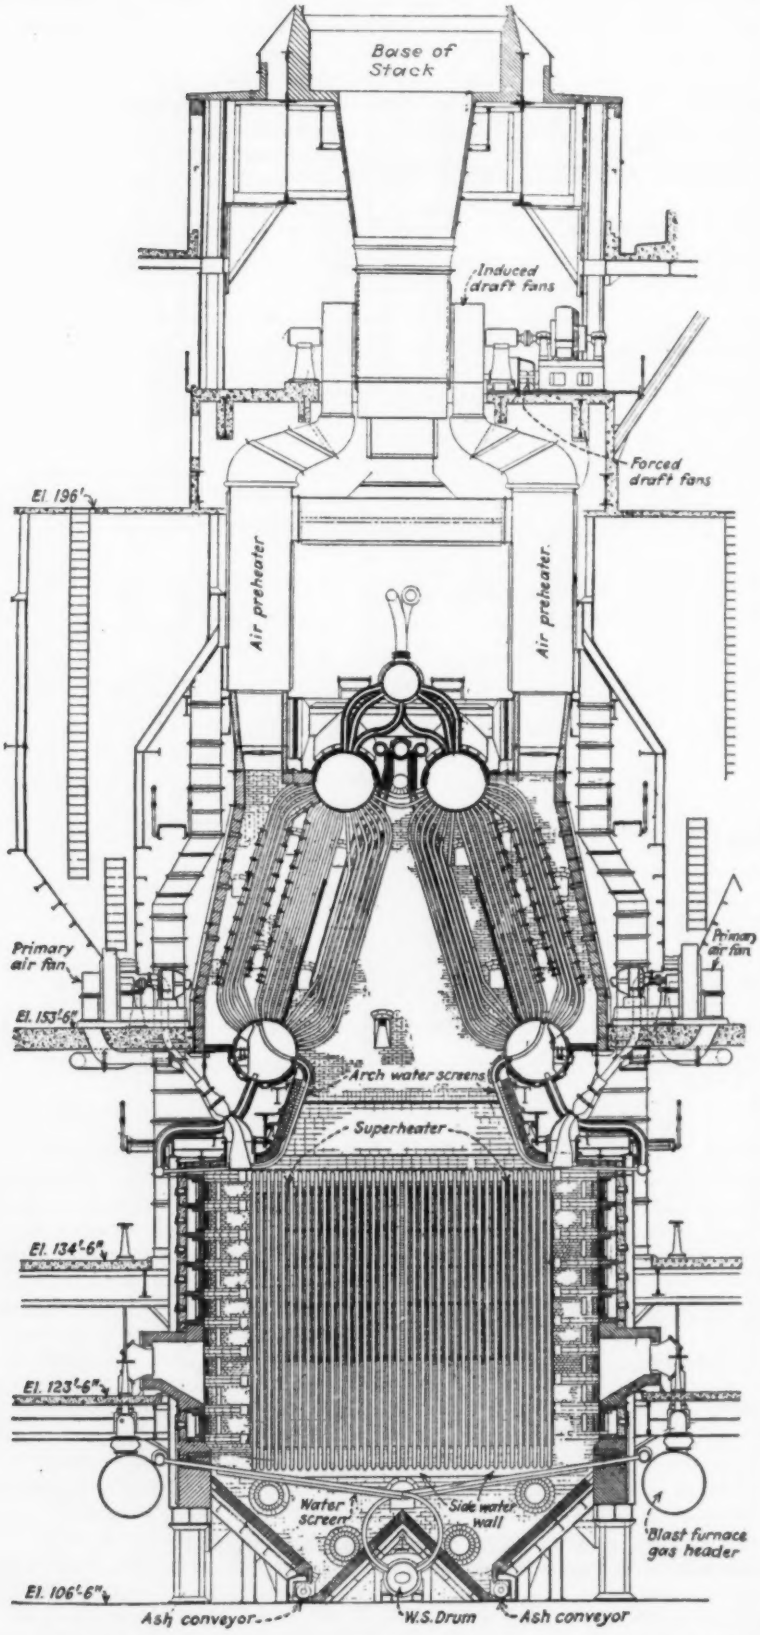

FIG. 3 CROSS-SECTION OF SIDE ELEVATION OF THE REMODELED STEAM-GENERATING UNITS OF THE FORDSON PLANT, FORD MOTOR COMPANY

operating. However, the abscissa upon which these curves are plotted is meaningless. The coal burned per square foot of grate, the heat release per cubic foot of furnace volume, and the maximum rate of heat transfer are no greater in some installations operating at 500 per cent of rating than in others when operating at half of this figure. These high ratings are obtained by eliminating ineffective boiler surface, placing a maximum amount of boiler surface where it is exposed to direct radiation from the fuel bed and flame, and utilizing air heaters and economizers to maintain a high gas temperature throughout the saturated steam-making surfaces. In other words, with adequate fuel-burning capacity, the per cent of rating is a function of the type and arrangement of heat-absorbing surfaces, and curves such as those in Fig. 7, which do not take into account this factor, are misleading.

To summarize, the present system of expressing the performance of steam-generating equipment is open to the following serious objections:

1 The "rated capacity" bears no relation to the maximum capacity and is arbitrarily based on the extent of heat-absorbing surface of one type only without regard to the position of this surface, its effectiveness per unit area as a heat absorber, or the influence of heat-absorbing surfaces of other types.

2 The output, expressed in terms of equivalent evaporation or developed horsepower, as defined in the boiler test code, does not include the heat absorbed in the economizer, although economizer surface serves the same general purpose as boiler surface and is more effective per unit area than the boiler surface which it replaces.

3 "Per cent of rating" is not an indication of the mean rate of heat absorption in a boiler where superheaters are used. Nor does a high mean rate of heat transfer indicate that a boiler is being forced, since it is generally obtained by replacing relatively ineffective boiler surface by other types of heat-absorbing surface.

Modern steam-generating equipment is composed of several different types of heat-absorbing surfaces, combined in so many ways and proportions that the performance can no longer be based upon boiler surface alone. The boiler, superheater, economizer, and reheater are designed and operated as a unit, and must be so considered in determining the performance of steam-generating equipment. The function of the boiler, superheater, and economizer is to absorb heat from the products of combustion in order to generate steam. The function of the air heater is to return to the furnace as much as possible of the heat not absorbed by the steam- and water-cooled surfaces. Therefore, the logical method of expressing the performance of steam-generating equipment is in terms of total heat absorbed by water- and steam-cooled surfaces.

THE UNIT OF CAPACITY

There are three units of capacity used in the A.S.M.E. boiler test code: (1) the unit of evaporation; (2) equivalent evaporation from and at 212 deg. fahr.; and (3) boiler horsepower. The

unit of evaporation is the absorption of 1000 B.t.u. per hour; the unit of equivalent evaporation is the absorption of 970.4 B.t.u. per hour, based on Marks and Davis steam tables; the unit of boiler horsepower is the absorption of 33,479 B.t.u. per hour. Of the three, the unit of evaporation is the simplest, easiest to calculate and understand.

The output of steam-generating equipment can be most easily expressed as follows:

$$\text{Units of evaporation developed} = \frac{\text{Weight of water evaporated per hour} \times \text{total heat absorbed per lb. in economizer, boiler, superheater, and reheater}}{1000}$$

This differs from the present test-code method in that the output is expressed in terms of total heat absorbed in all steam- and water-cooled surfaces. The output could be expressed in boiler horsepower by dividing the numerator by 33,479 instead of 1000. However, the name is a misnomer and the unit is clumsy, so that it would be better to eliminate the term entirely. The output could also be expressed in terms of equivalent evaporation by dividing the numerator by the latent heat of steam at standard atmospheric pressure, instead of by 1000. However, this is an unwieldy unit and, as generally computed, requires the calculation of a useless term called "factor of equivalent evaporation." The simplest method of expressing output is in terms of thousands of B.t.u. absorbed per hour by all steam- and water-cooled surfaces.

Rated Capacity

The rated capacity should be based upon the maximum continuous load which a unit can carry. Otherwise the term is arbitrary and meaningless. The maximum capacity of a steam-generating unit supplied with good feedwater is generally limited by the amount of fuel that can be burned rather than by the heat-absorbing capacity. On account of the flexibility of such equipment, the numerous factors which may limit the capacity, and the manner in which characteristics of the fuel and operating conditions affect performance, it is necessary to consider the entire fuel-burning, draft-producing, and heat-absorbing equipment as a unit and rate its capacity on the basis of the quantity of heat that can be transferred to steam- and water-cooled surfaces per hour under conditions of maximum constant-load operation when supplied with the fuel which is normally burned in the plant. In other words, rated capacity should be based upon actual performance and not upon arbitrary, empirical standards which bear no relation to the actual capacity of the unit.

It may be urged that the rated capacity of a unit when figured in this manner depends upon the kind of fuel burned and other operating conditions and cannot be determined very closely until the unit has been placed in operation. However, steam-generating equipment is generally purchased on the basis of the quantity of steam which it can produce per hour when burning coal of known characteristics. This result, expressed in thousands of B.t.u. absorbed per hour in order to eliminate local operating conditions, should constitute the rating of the unit. It might be necessary to revise the rating somewhat after the unit has been placed in operation because of conditions not foreseen by the designer. However, as data continue to accumulate on the performance of modern steam-generating equipment, it should be possible to estimate in advance, with reasonable accuracy the maximum continuous capacity of a unit. A rating so determined is certainly more satisfactory and indicative of the actual capacity of a steam-generating unit than a rating determined by present arbitrary methods which gives results which are often not within 500 per cent of the actual capacity of the unit.

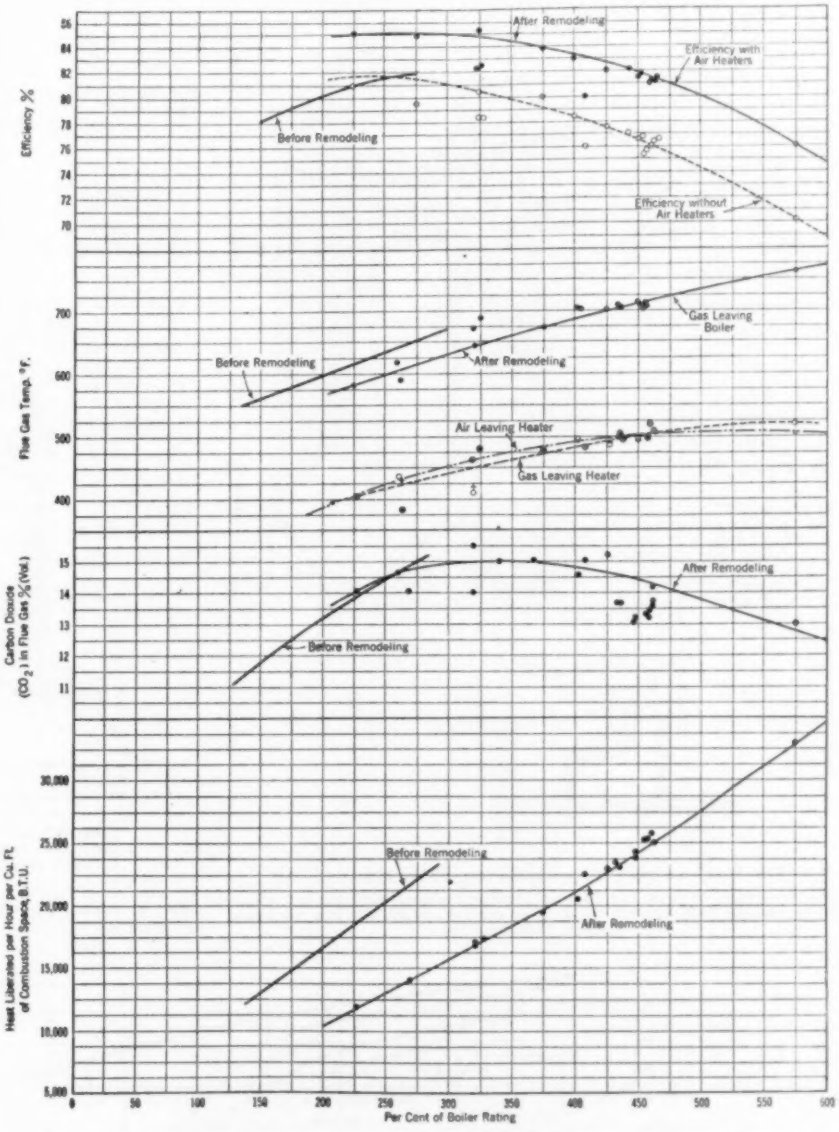

FIG. 4 COMPARATIVE PERFORMANCE OF NO. 2 UNIT OF FORDSON PLANT BEFORE AND AFTER REMODELING

(From publication 1 C-2 of Combustion Engineering Corporation; 500,000 lb. of steam per hour from one unit.)

Performance Curves

Performance curves should be plotted on a common abscissa

which has a definite numerical value, is readily understood, and leaves no opportunity for misinterpretation or false comparisons. The objections to "per cent of rating" and "steam produced per hour" have been considered. Fig. 8 includes a set of performance curves plotted on a common abscissa of "total heat absorbed per hour in thousands of B.t.u. by water- and steam-cooled surfaces." Other data such as draft losses, gas temperatures, heat absorbed in various parts of the system, etc., can be plotted on the same abscissa. The essential advantage of a set of curves plotted in this manner over the conventional curves plotted on per cent of rating is that the abscissa has a definite numerical value and

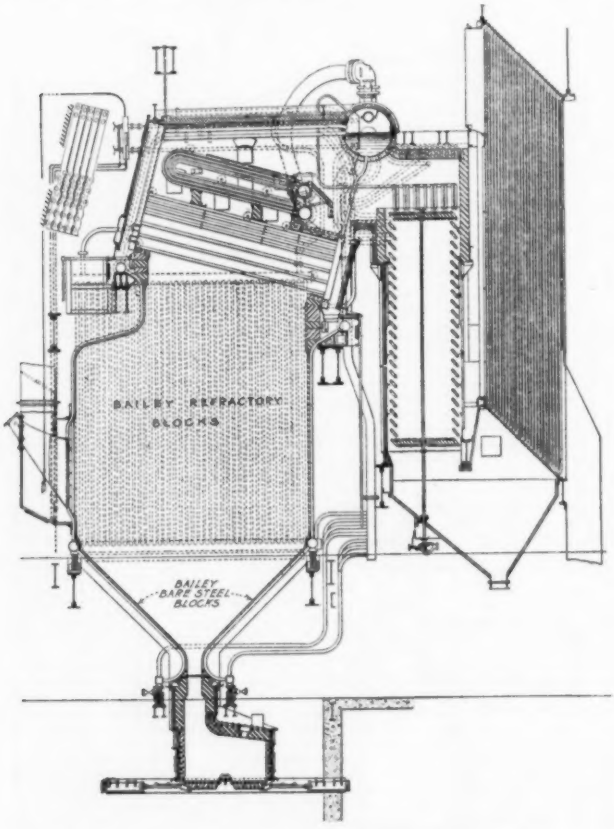

FIG. 5 CALUMET PULVERIZED-FUEL-FIRED BOILER UNIT
(Boiler surface, 5938 sq. ft.; furnace heating surface, 2460 sq. ft.; economizer surface, 8365 sq. ft.; total water surface, 16,763 sq. ft.; air-heater surface, 41,700 sq. ft.)

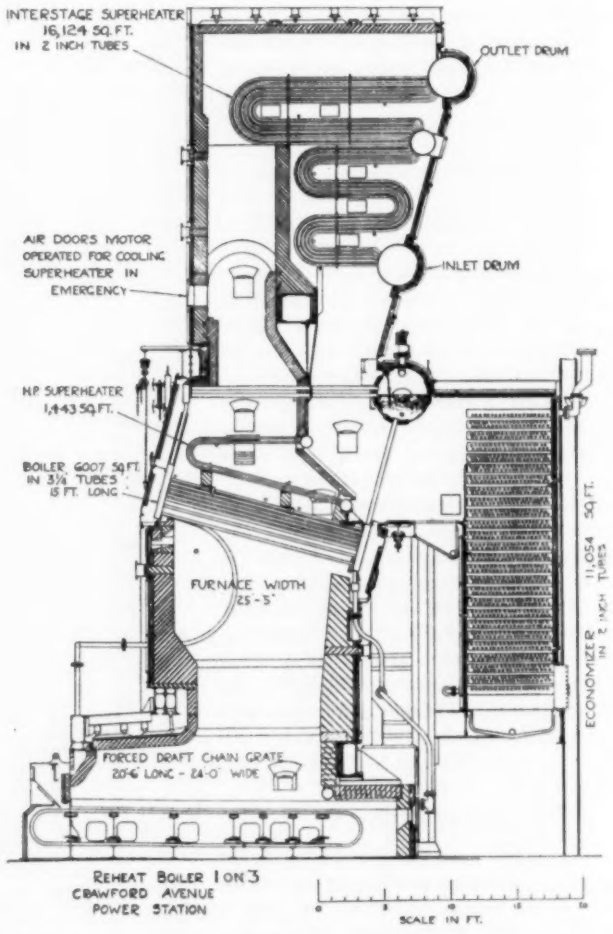

FIG. 6 CROSS-SECTION OF REHEAT BOILER NO. 1 ON UNIT NO. 3, CRAWFORD AVENUE STATION, COMMONWEALTH EDISON COMPANY

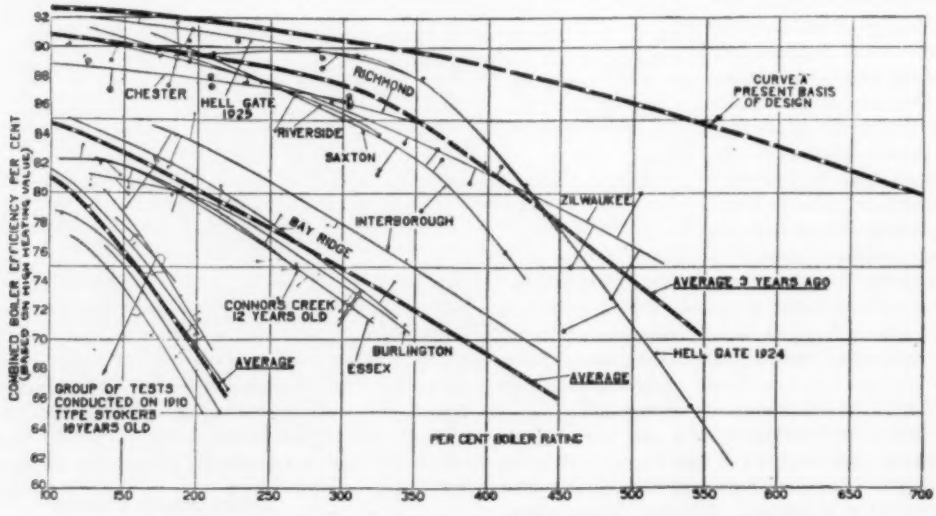

FIG. 7 PERFORMANCE CURVES OF STEAM-GENERATING EQUIPMENT

shows not only the range of capacity but the actual capacity developed.

The curve of mean rate of heat transfer is plotted for the boiler only. It is possible, from this curve, to estimate the extent to which the unit is being forced if the amount and position of each type of heat-absorbing surface is known and a drawing of the setting is available. However, without this supporting information, the curve is of little value as an indication of the rate of forcing of the unit. Similarly, the curve showing the heat release per cubic foot of furnace volume is of questionable value until the kind of coal, particularly its fusing temperature, the excess air supplied for combustion, and the position and extent of all radiant-heat-absorbing surfaces are known.

Few fields of mechanical engineering have witnessed so many progressive changes in the past ten years as have taken place in the field of steam generation. The demands for high capacity, high efficiency, and flexibility have resulted in the development of modern stokers and pulverized-coal burners, adequate furnaces with water- and steam-cooled walls, air heaters, steel-tube economizers, etc., and have completely changed the equipment which was used for steam generation ten years ago. Consequently it is time that the methods of expressing the performance of such equipment, particularly in regard to rated capacity and graphical representation of results, should undergo a revision to bring them into conformity with new conditions. Considering the problem of steam generation from the viewpoint of the functional purpose of the equipment, it appears that the logical method of expressing the performance of such equipment should be on the basis of the total heat absorbed by all water- and steam-cooled surfaces per unit of time. Such a method is general and applicable to all types of steam-generating equipment, and expresses the performance, not in terms of arbitrary dimensions but of actual results produced.

Flow Characteristics of Special Fe-Ni-Cr Alloys and Some Steels at Elevated Temperatures[1]

By H. J. FRENCH,[2] WILLIAM KAHLBAUM,[3] and A. A. PETERSON[4]

In this paper the authors give the results of "creep" tests at different temperatures for three groups of alloys. The eleven metals in the first group included commercial alloys of nickel, chromium, and iron, both with and without tungsten, and low-chromium steels containing also tungsten, vanadium, or molybdenum. The second group comprised two carbon steels, a 3½ per cent nickel steel, and two low-nickel-chromium steels which were tested only at 700 deg. fahr.; the twelve alloys of the third group were melted in a high-frequency induction furnace and their compositions were selected to show the general trends at 1000 deg. fahr. in the load-carrying ability of castings of the nickel-chromium-iron system. A metallographic study of the creep-test specimens revealed intercrystalline weakness in some of the wrought nickel-chromium-iron alloys, especially at temperatures between 1160 and 1390 deg. fahr. A study was also made of the effect of deformation in the creep tests at different temperatures on the hardness and impact resistance of a chromium-vanadium steel at atmospheric temperatures.

I—INTRODUCTION

CONSIDERABLE attention is now being given in both this country and Europe to "creep" tests (or flow tests) in which the time-deformation relationship is determined for metals subjected to constant loads for long periods at approximately constant temperatures. Previous tests at the Bureau of Standards have related jointly to the development of a testing technique and to the procurement of data intended to assist engineers in the selection of safe working stresses for equipment designed to operate at elevated temperatures. Correlations have also been made between the laborious flow tests and short-time tension tests with the object of finding, if possible, rapid methods of determining approximately the load-carrying ability of metals at different temperatures.

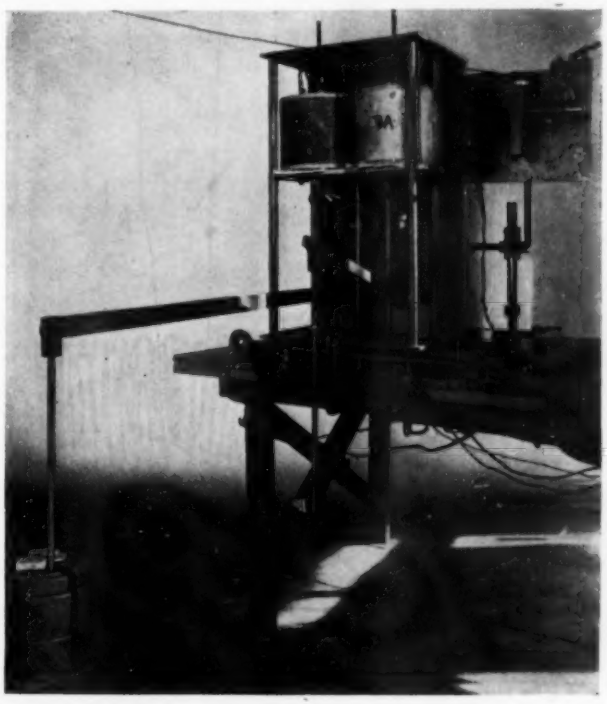

FIG. 1 TWO OF THE VERTICAL TEST UNITS FOR FLOW TESTS AT DIFFERENT TEMPERATURES

(Four vertical and six horizontal test units constituted the testing equipment for the flow tests. The optical micrometer used in making length measurements is shown on the stand at the right.)

So far, data have been published for only five steels, and the purpose of this report is to present the results of additional tests extending over several years so that comparisons can be made of a wider range of metals, based on data secured under comparable conditions in one laboratory. The work simply represents the extension to more materials of the methods of test already described in detail.[5, 6, 7] (See page 2 for footnotes 6 and 7.)

[5] H. J. French and W. A. Tucker, "Flow in a Low-Carbon Steel at Various Temperatures," Technologic Papers of the Bureau of Standards, No. 296 (1925).

Tests were made of three groups of metals; the first, comprising commercial nickel-chromium and nickel-chromium-iron alloys and low-chromium steels containing tungsten, vanadium, or molybdenum, were tested, with one exception, under the research associate plan[5] with a research associate from The Midvale Company, Philadelphia, Pa. The second group consisting of two carbon steels, a $3^1/_2$ per cent nickel steel, and two low-nickel-chromium steels were tested at 700 deg. fahr. to assist the Bethlehem Steel Company, Bethlehem, Pa., and the Combustion Engineering Corporation, New York, N. Y., in the selection of a composition suited for particular requirements of power-plant construction. The metals of the third group were used in a study of the flow characteristics at 1000 deg. fahr. of alloys of the nickel-chromium-iron system.

II—TEST METHODS

The test methods employed were substantially the same as those used previously, but subsequent to the last published de-

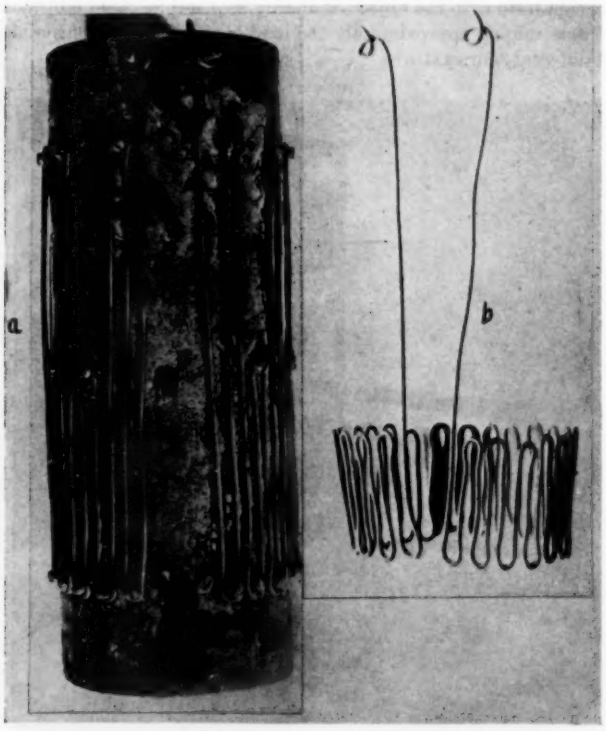

FIG. 2 IMPROVED RESISTORS OF THE HEATING UNITS
a = main resistor on the forming fixture
b = auxiliary resistor placed outside and at the lower end of the main resistor

scriptions a number of modifications were incorporated in the equipment and test procedure. Four of the ten horizontal loading machines were replaced by vertical units (Fig. 1) in which the frictional losses of the mechanical lever system were materially reduced. The new units were therefore better adapted than the old horizontal units for tests at the highest temperatures where the applied loads were the smallest.

[7] H. J. French, H. C. Cross, and A. A. Peterson, "Creep in Five Steels at Different Temperatures," Technologic Papers of the Bureau of Standards, No. 362 (1928).

[8] Described in Circular 296 of the Bureau of Standards.

The temperature fluctuations within the test specimens were reduced by placing the control thermocouples at the furnace windings instead of in the test specimens. Resistors of improved form (Fig. 2) were installed in the furnaces of the vertical test units to reduce the temperature gradients from top to bottom in the test specimens. In order to secure greater accuracy in the length measurements with the metals which oxidized most readily, the practice was followed of using platinum or silver wire (32 B. & S. gage) in small grooves as reference points for length measurements with an optical micrometer instead of the edge of the enlarged end section of the specimen.

Only a limited quantity of some of the metals was available. The desire to secure the maximum information under such conditions led to the adoption of a specimen having two different diameters within the customary 2-in. gage length as is shown in Fig. 3. A given applied load produced different unit stresses in the two halves of the gage length of such a specimen, and this was equivalent to two of the customary specimens. However, the use of the modified test specimen is not advocated under ordinary conditions. It is disadvantageous to reduce the measured length from 2 in. to 1 in., and the abrupt change in section at the center of the 2-in. gage length may introduce stress concentrations and also tend to increase the temperature variations in the test sections. As a result the flow produced by a given stress in the

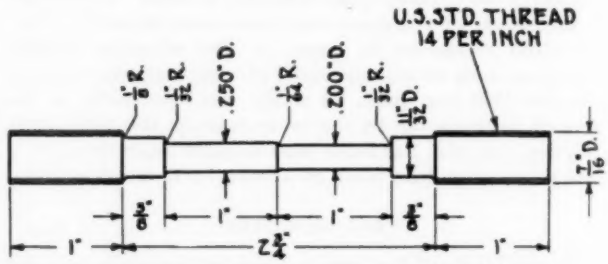

FIG. 3 MODIFIED FLOW-TEST SPECIMEN USED IN SOME OF THE TESTS
(The flow under two different stresses can be followed on the one test specimen. See text for discussion.)

large half was not always as close as could reasonably have been expected to that produced by the same stress in the small half of the gage length. In cases of doubt many of the tests were repeated on test bars having a gage length of uniform diameter.

III—MATERIALS TESTED

The composition and other details of the metals tested are summarized in Table 1. The eleven metals of the first group may be divided into three classes; the first comprised the one alloy, K-4, which was prepared for the Joint Research Committee on Effect of Temperature on the Properties of Metals[9] to represent the alloy 80 nickel, 20 chromium, widely used as resistance wire. Its composition is actually not representative of the bulk of the metal used in such wires, but it should serve to indicate in a general way the flow characteristics of this class of material. The second class in the first group comprised nickel-chromium-iron alloys both with and without appreciable proportions of tungsten, while the third class consisted of low-alloy steels having not more than 4 per cent of alloying elements.

The six nickel-chromium-iron alloys in the first group represent compositions which have been used industrially in the construction of chemical or engineering equipment operating at high temperatures. Alloys E1894 and E1567 were made in this country and the test bars from heat E1894 were taken from the riser of

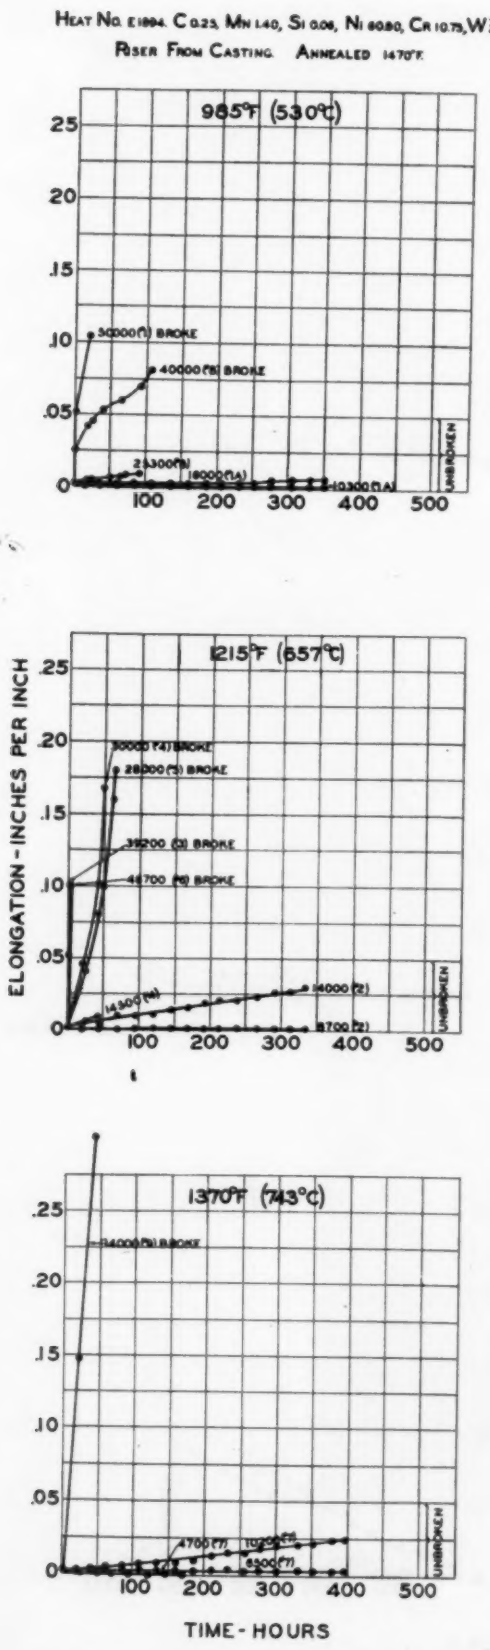

FIG. 6 TIME-ELONGATION CURVES FOR THE NI-CR-FE ALLOY E1894

a casting and did not show the best properties obtainable in this alloy at either room or elevated temperatures (Table 1). The similar alloys marked FS-1 and FS-2 were made abroad.

Alloy E1912 is an austenitic steel of the type of Krupp's V2A and the English corrosion-resistant steel called Stabrite. Since austenitic steels are often said to retain a high proportion of their room-temperature strength at elevated temperatures, this nickel-chromium steel was included for comparison with the high-chromium "stainless" steels previously tested. Alloy EE1114 is similar to alloy E1912, with the exception that it has somewhat higher carbon and silicon and 4.5 per cent of tungsten.

The materials designated as E1894, FS-1, FS-2, and E1567 have been used extensively abroad, and to a lesser degree in this country, the first two chiefly in the form of castings and the latter pair largely as forgings. Alloy EE1114, which has been used both in castings and in forgings, is claimed to be resistant to softening at elevated temperatures and to resist scaling, even in oxidizing and sulphurous atmospheres at temperatures as high as 2000 deg. fahr.

The chromium-vanadium steel, No. 10-518, Table 1, has been used widely for autoclaves, and, especially with a somewhat lower carbon content, for vessels for ammonia synthesis. The treatments to which this steel was subjected before test were intended to produce conditions comparable to those existing in the walls of forgings too large to quench and too thick to harden effectively in the air.

Steels EE1139, E1549, and E1490 are compositions used in cylinders for the extrusion of metals. Such cylinders, or the liners for such cylinders, are subjected to severe service. The material must flow only very slowly under fairly high pressures at temperatures as high as 1200 or 1300 deg. fahr., and at the same time exhibit sufficient toughness to resist cracking.

The two carbon steels and the three low-alloy steels comprising the second group of metals in Table 1 were made in 75-ton basic open-hearth furnaces and cast into large-end-up, hot-top ingots. The ingots were charged hot into the soaking pits, and after being brought to the proper rolling temperatures, rolled to the bloom sizes shown in Table 1. After heat treatment, as indicated, flow-test specimens were cut from the blooms, the long axis being at 90 deg. to the direction of rolling, at points half-way between the center and surface but at an appreciable distance from the ends. The heat treatment and the method of taking the flow-test specimens were selected to represent the metal in large forgings for high-temperature, high-pressure power-plant equipment and the tests at 700 deg. fahr. were made to assist in the selection of a steel to meet special design requirements. The specified heat treatments did not reduce the strengths of the steels at atmospheric temperatures to the desired values in all cases, and it was necessary to repeat the treatments for some of the steels in order to obtain the desired properties.

In view of the fact that some of these steels were heat treated more than once, the structural condition of the material as tested is shown in the micrographs of Fig. 4.

The metals of the third group, Table 1, were melted in a high-frequency induction furnace, the charges being based on a carbon content of about 0.25 per cent, a manganese content of 0.5 per cent, and a silicon content of about 0.5 per cent. As far as was practicable the nickel and chromium contents of the different alloys were selected to conform to those found in typical commercial alloys, but the primary basis of selection was a widespread scattering over the nickel-chromium-iron ternary diagram so that the general trend of effects of composition on the flow characteristics at 1000 deg. fahr. could be determined. The alloys were all tested in the cast condition after being heat treated as shown in Table 1.

The results of tensile tests at atmospheric temperatures or

Brinell hardness tests are given in Table 1 for many of the materials in order to define better the conditions in which the different metals of the several groups were tested. Since the properties of the metals in groups I and II are compared with those of five steels previously reported upon, the chemical compositions and preliminary treatments of the latter have been included for convenience in Table 1.

IV—RESULTS AND DISCUSSION

1—General Relations Between Stress, Temperature, Deformation, and Time

The flow of the metals of Groups I and II, Table 1, when loaded at different temperatures, is shown graphically in Figs. 5 to 17, inclusive. The relations between stress, temperature, deformation, and time are similar to those observed in the steels previously tested, and the time-elongation curves fall into three classes which depend upon the metal and the temperature.

At atmospheric and slightly elevated temperatures, initial changes in dimensions (initial flow) are not necessarily followed by continuous flow, but, due to strain hardening, the rates of flow may decrease with time. In many cases the flow rates subsequent to the initial period (second stage of flow) may be considered to be zero for all practical purposes, and determination of allowable working stresses is therefore a function of the permissible initial deformation.

At temperatures above those at which strain hardening is observed, any appreciable initial flow is followed by further and continuous deformation which may take place at approximately the same rate, a higher or a lower rate, depending upon the conditions of test. At such high temperatures the flow ordinarily increases with time and the allowable working stresses usually become a function of the rate of deformation subsequent to any initial changes in dimensions (secondary flow rates).

At intermediate temperatures, the time-elongation curves may show some of the characteristics of each of the two classes of curves mentioned. In other words, the transition from the relations typical of temperatures at which marked strain hardening is observed to the relations typical of much higher temperatures is most often gradual. The time-elongation curves may show appreciable initial deformation followed by decreases in flow rates, but the flow may be continuous so that fracture occurs in relatively short time.

In ductile materials appreciable elongation eventually results in appreciable contraction in area. This in turn results in stress concentration, and the rates of flow are greatly increased just before fracture (final flow).

Different methods have been used in summarizing the results of flow tests, but probably the most acceptable to engineers are those which show the relations between deformation, stress, temperature, and time, since the selection of allowable working stresses is usually not solely a function of the time for fracture but demands consideration of the allowable deformation during any selected life. The desired life and the maximum allowable deformation will vary with different classes of structures, and the viewpoints of individual designers and are likewise affected by the details of construction and operation. For this reason, the results are summarized in terms of per cent deformation per thousand hours at the different temperatures as is shown in Figs. 30 to 41, inclusive, and in Table 2.

The stresses producing the deformation rates shown in Figs. 30 to 41 were determined from charts giving the relations between the applied load and the initial flow or secondary flow rates, shown in Figs. 18 to 29, inclusive. The methods by which Figs. 30 to 41 were obtained from data in Figs. 18 to 29 and Table 2, and the assumptions involved, have been discussed in detail in reports already referred to.

[1] For details of chemical composition and heat treatment refer to Table 1.
[2] Bracketed values estimated.

Where comparisons are made with the metals of group IV, Table 1, the required flow data for these steels were taken from previously reported tests which were carried out under comparable conditions.[10]

One important point, which has not been given much consideration in the interpretation of flow tests, is that the numerical values obtained on one bar, lot, or melt of a given alloy may not coincide closely with the values obtained on other bars, lots, or melts. Similar variations in the properties of metals at atmospheric temperatures are well recognized and should likewise be given consideration in the application of flow-test data. The extent of these variations is not now accurately known but it has been shown[11] that the differences in load-carrying ability, from heat to heat of steel, may be large. Without additional data, it is not safe to assume that the reported values represent the average, maximum, or minimum of the range characteristic of a given metal, and safety factors must still be employed.

2—The Commercial Nickel-Chromium-Iron Alloys

In Fig. 42, comparisons are given at 700, 1000, 1125, and 1350 deg. fahr. of the metals in Groups I and II, Table 1, and the five steels previously tested, Group IV. The stresses producing 0.1 per cent and 1 per cent initial elongation and also 0.1 and 1 per cent secondary elongation (calculated per 1000 hours) are represented by the lower and upper limits, respectively, of the blocks in the chart and serve as a basis of comparison of the flow characteristics of the different metals. Comparisons can be made at lower temperatures in some cases, and likewise at higher rates of flow, from data given in Figs. 30 to 41, inclusive.

In the relation of stress to total deformation for alloys at certain temperatures, it is necessary to consider both the initial and the secondary flow. These differences can be studied in detail from data given in Figs. 18 to 29 and Table 2.

The data given in Fig. 42 confirm some of the facts developed from practical experience, but in addition show certain features which have not been given much, if any, attention. At temperatures between 1125 and 1350 deg. fahr. the high-nickel-chromium steels were generally superior to the carbon and low-alloy steels, but if the deformation per 1000 hours at the higher temperatures is limited to 1 per cent or less, the maximum allowable stresses drop to low values even for the high-alloy steels.

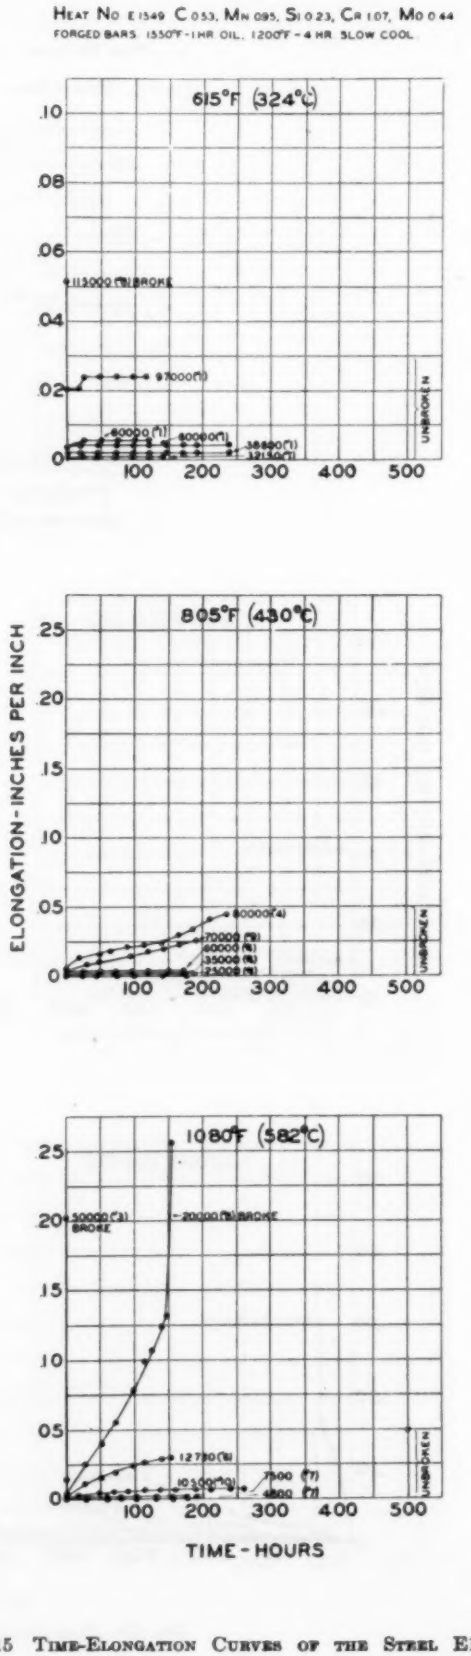

Fig. 15 Time-Elongation Curves of the Steel E1549

The outstanding alloy of the group at temperatures between 1000 and 1350 deg. fahr. was the one containing about 0.3 per cent carbon, 1 per cent silicon, 20 per cent chromium, 8 per cent nickel, and 4.5 per cent tungsten; it showed as high or higher load-carrying ability than any of the other alloys. Its superiority was most marked at 1350 deg. fahr., but tended to decrease with decrease in the permissible rates of flow and with decrease in temperature.

With this one exception, alloys showing superior properties at 1350 deg. fahr. did not necessarily show superiority at lower temperatures. At 1350 deg. fahr. superior load-carrying ability was shown by the alloys, 20 Cr–8 Ni–1 Si–4.5 W; 18 Cr–8 Ni; and 61 Ni–11 Cr–2.8 W; at 1000 deg. superiority was shown by the alloys 20 Cr–8 Ni–1 Si–4.5 W; 38 Ni–11 Cr–1.8 W, and 57 Ni–10 Cr–3 W (FS-1 lot A; as rolled).

These different alloys all represent compositions used industrially for service at different temperatures and it was not practicable to attempt to determine the effects of variations in important elements such as nickel, chromium, and silicon upon their high-temperature-flow characteristics, since in only a few cases were the differences in composition of any two alloys restricted to a single element. For example, the effect of tungsten on the alloy nominally containing 18 per cent chromium and 8 per cent nickel cannot be established from data in Fig. 42 since the alloy with tungsten contains about twice the carbon and five times the silicon in the alloy without tungsten. Such circumstances do not affect the usefulness of the flow-test data, but made it necessary to depend upon the experimental melts, group III, Table 1, to show the general trends in the system, nickel-chromium-iron.

The two lots of alloy E1912, containing about 18 per cent chromium and 8 per cent nickel with 0.15 per cent carbon, offer some interesting comparisons. It was originally intended to test this alloy only in the hot-worked condition as represented by lot A, Table 1. However, more samples were required before the tests were completed, and the bars of the second lot (B) were found to have a higher tensile strength at atmospheric temperatures than bars of lot A, due quite probably to a somewhat lower finishing temperature in rolling. Therefore lot B was softened by water quenching from 1850 deg. fahr. and subsequently tested, although its room-temperature tensile strength was still somewhat higher than that of lot A. Also, the grain size of the quenched samples was smaller than that of the hot-finished samples, as is shown in Figs. 43 and 44.

At 990 deg. fahr. these two lots of alloy E1912 exhibited about the same load-carrying ability, but at 1180 deg. the fine-grained (water-quenched) steel was weaker than the coarse-grained material (Fig. 36). Comparisons of the two lots were not made at higher temperatures, but the evidence available gives interesting confirmation of the view that fine-grained metals, having more intercrystalline material than corresponding coarse-grained metals, should be stronger at atmospheric temperatures but weaker at high temperatures.

There is some evidence, however, that coarsely crystalline metals may be dangerous from other viewpoints. While they flow at lower rates than corresponding fine-grained metals, fracture *may* occur with less total elongation. There is also the possible added disadvantage of weakness in resisting shock at high temperatures as well as at atmospheric temperatures.

In the case of the steel nominally containing 18 per cent chromium and 8 per cent nickel, a marked intercrystalline weakness was observed at temperatures between 1165 and 1380 deg. fahr., and to some extent also at 990 deg. fahr., in both fine-grained and coarse-grained samples, though the latter seemed to show the more marked tendency in this direction. When the specimens were allowed to remain under load at 1165–1195 deg. or 1380 deg. fahr. until fracture occurred, the fracture was intercrystalline and

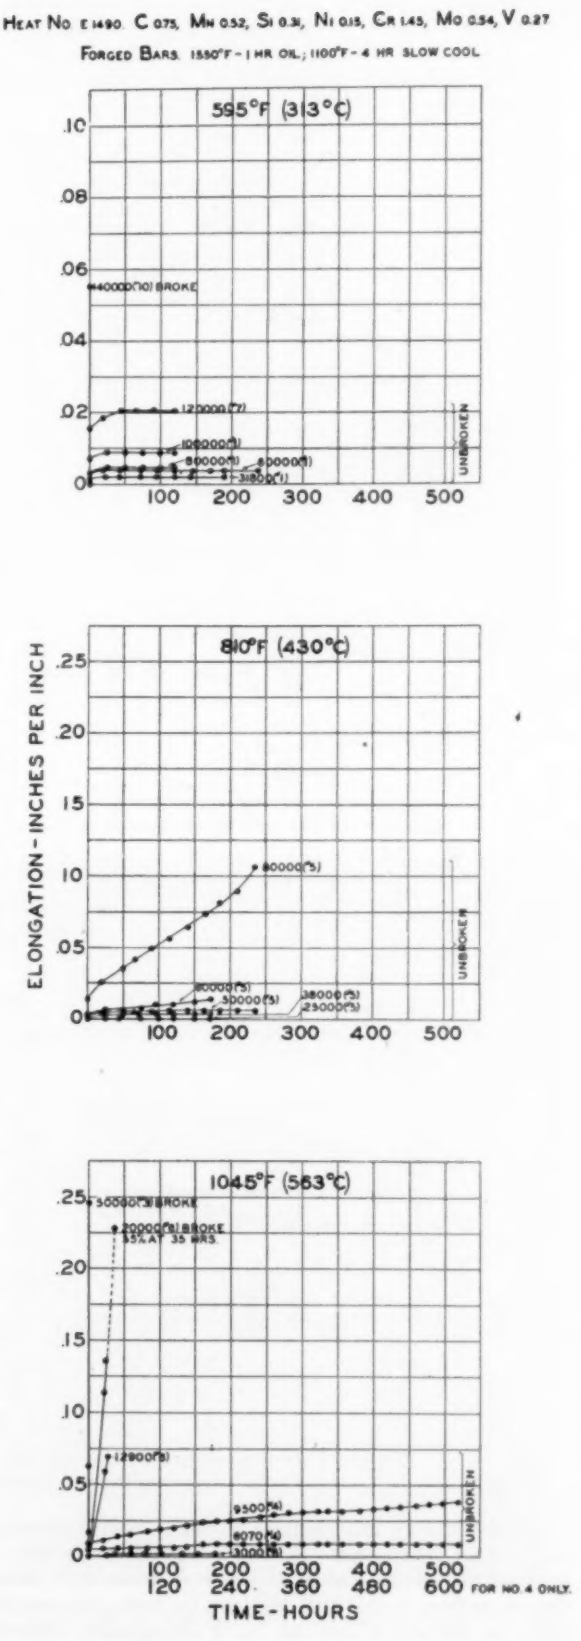

FIG. 13 TIME-ELONGATION CURVES OF THE STEEL E1490

grain separations were to be observed at some distance back of the fractures, especially at the surface. These features are shown in Figs. 43 and 44. There is no clear evidence that this intercrystalline weakness is associated with carbide precipitation at the grain boundaries.

above 990 deg., embrittlement of steels with over 0.07 per cent carbon has been reported to occur and has been attributed to the reprecipitation of carbides at the grain boundaries.

The steel containing about 0.3 per cent carbon, 1 per cent silicon, and 4.5 per cent tungsten, in addition to 20 per cent chro-

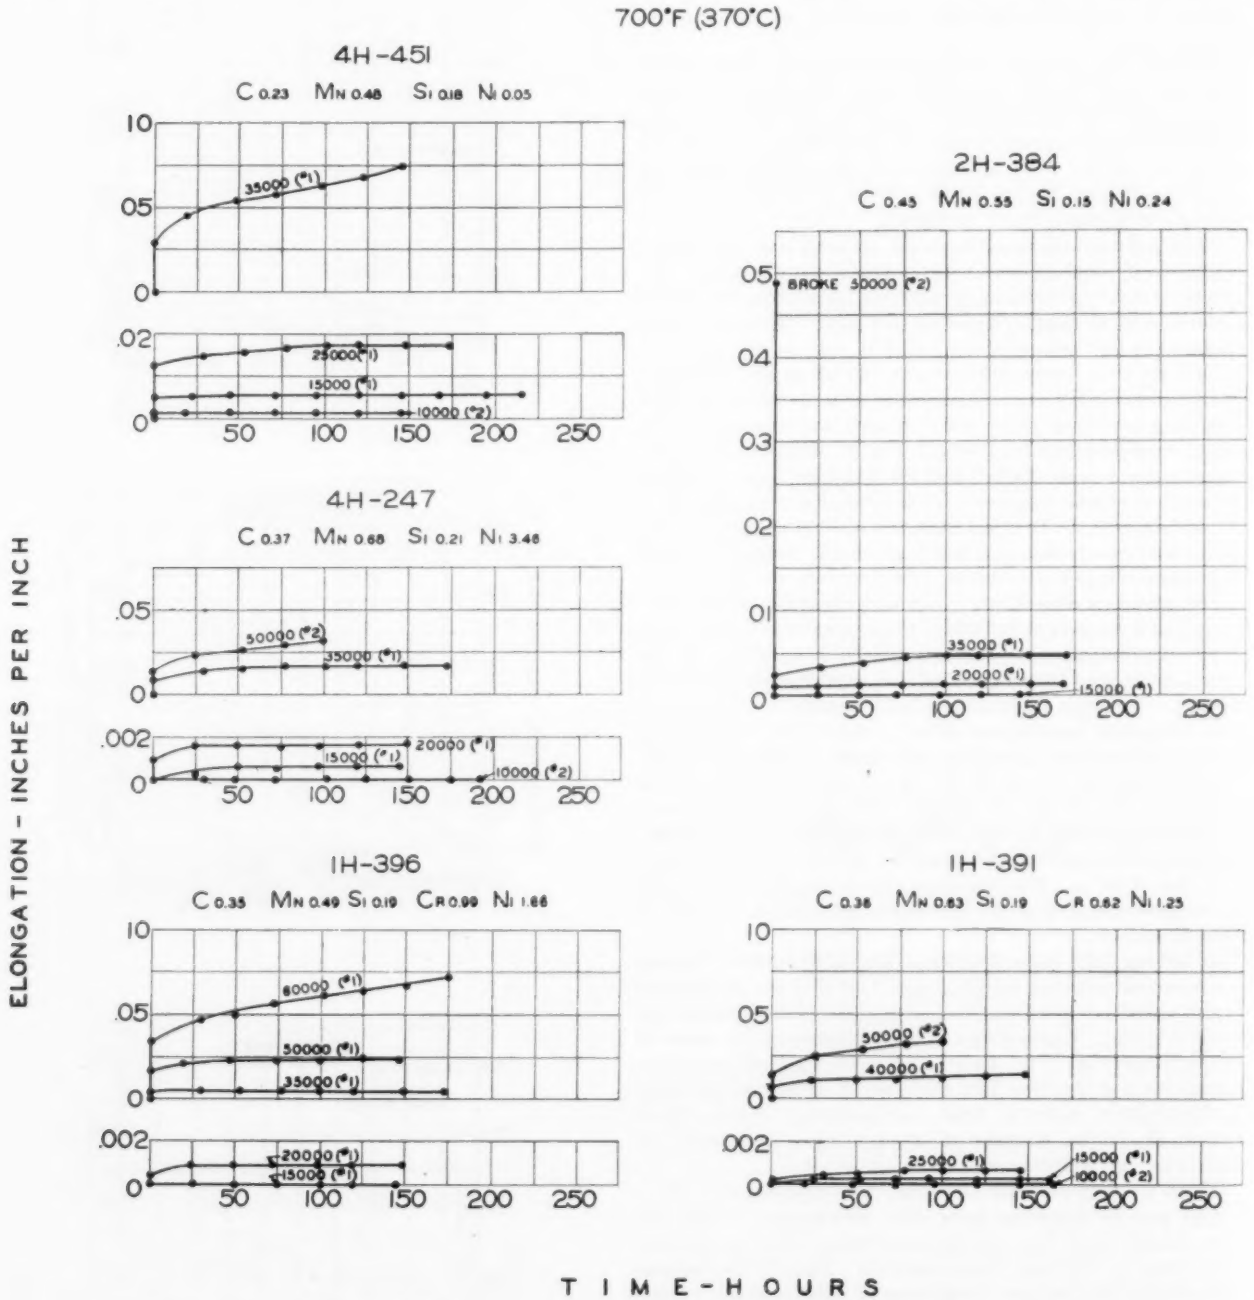

FIG. 17 TIME-ELONGATION CURVES AT 700 DEG. FAHR. OF TWO CARBON AND THREE ALLOY STEELS
(Table 1 contains details of chemical composition and preliminary heat treatments.)

According to one manufacturer,[12] there is decided difference in behavior of this nickel-chromium steel which depends upon whether the carbon content is below or above 0.07 per cent. Quenching from around 2100 deg. fahr. has been recommended to bring the carbides in solution, but if subsequently reheated to

[12] Private communication.

mium and 8 per cent nickel, showed intercrystalline weakness at 1160 and 1390 deg. fahr., but, so far as could be determined from the usual metallographic examination, this was less marked than in the 0.15 per cent carbon steel with 18 per cent chromium, 8 per cent nickel, and no tungsten. (Figs. 43, 44, and 45.)

Intercrystalline weakness, possibly associated in some cases

with grain growth, was observed in two of the samples of the alloy E1567 containing 38 per cent nickel, 11 per cent chromium, and 1.8 per cent tungsten when subjected continuously to stress at 1185 deg. fahr. (Fig. 46). No similar effects were found in the alloy, E1894, containing about 60 per cent nickel, 11 per cent chromium, and 2.8 per cent tungsten which was tested in the cast (annealed) condition. The structure of this latter alloy was exceedingly coarse, as is shown in Fig. 47, and in tests at 1370 deg. there was evidence of either carbide precipitation or the formation of a eutectic at the grain boundaries (*b* and *c*, Fig. 47). Further attention to constitutional changes and intercrystalline weakness of the high-nickel chromium alloys when subjected continuously to stress at high temperatures with comparisons of the alloys nominally containing 18 per cent chromium and 8 per

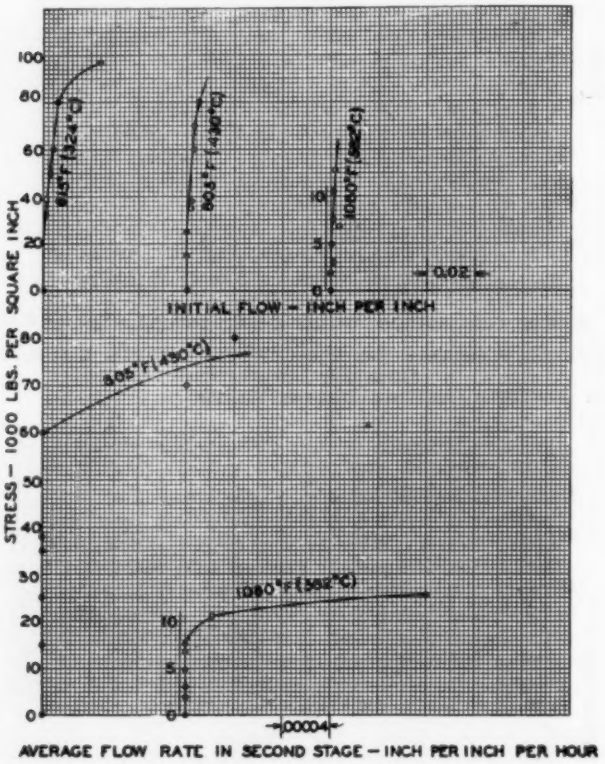

FIG. 28 FLOW DATA FOR THE CR-MO STEEL E1549 AT DIFFERENT TEMPERATURES
(Obtained from Fig. 15.)

cent nickel with both more and less than 0.07 per cent carbon, would seem to be merited.

3—CARBON AND LOW-ALLOY STEELS

If the load-carrying ability is judged by the stresses producing 0.1 to 1 per cent deformation in 1000 hours, as in Fig. 42, the low-alloy steels show promising properties at 700 to 1000 deg. fahr. and even up to 1125 deg.

Fig. 42 shows a number of factors which tend to improve the load-carrying ability of carbon and low-alloy steels. The first is increase in carbon content. The steel with 0.45 per cent carbon showed much better load-carrying ability than that with 0.23 per cent carbon and resisted flow at 700 deg. fahr. about as well as the steel with 0.35 per cent carbon and either $3^1/_2$ per cent nickel or a combination of $1^1/_4$ to $1^3/_4$ per cent nickel and $^1/_2$ to 1 per cent chromium.

A comparison of the stresses producing 0.1 to 1 per cent deformation in 1000 hours for 0.35 per cent carbon steel obtained by interpolation of values for the 0.23 and 0.45 per cent carbon steels with the load-carrying ability of the nickel and nickel-chromium steels of similar carbon content indicates that the addition of $3^1/_2$ per cent of nickel or $1^1/_4$ to $1^3/_4$ per cent nickel and $^1/_2$ to 1 per cent chromium is relatively ineffective in increasing the resistance to flow at 700 deg. fahr. At least the load-carrying ability was no higher than that of a plain carbon steel of some-

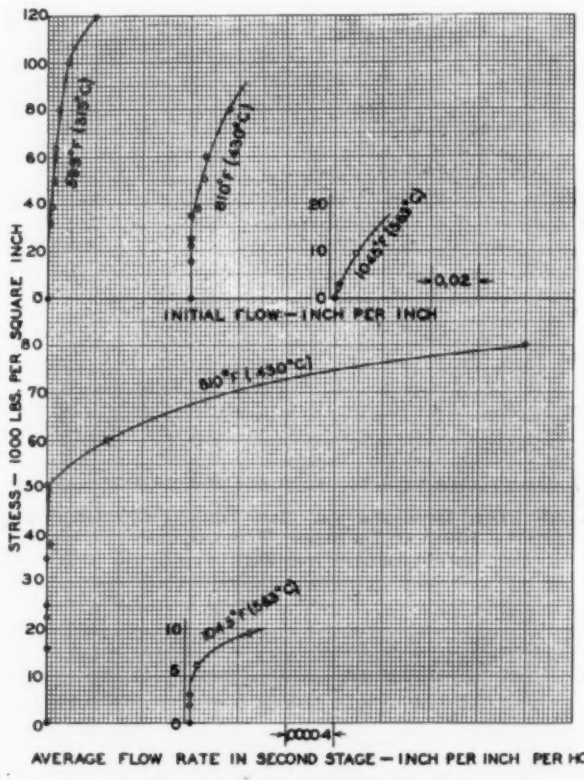

FIG. 29 FLOW DATA FOR THE CR-MO-V STEEL E1490 AT DIFFERENT TEMPERATURES
(Obtained from Fig. 16.)

what higher carbon content (0.45 per cent) when the metal was placed in a "soft" condition corresponding to that in large forgings. However, other characteristics of the alloy steels may give them marked superiority, such, for example, as superior resistance to grain growth on recrystallization which results from deformation and subsequent heating in cyclic temperature operation.

The outstanding feature with respect to the low-alloy steels is the effectiveness of quenching in raising the resistance to flow at temperatures around 700 to 1000 deg. fahr. It may be said, a priori, that quenching should be followed by tempering at temperatures at, or preferably above, those of subsequent operation if stability is to be expected, but it is significant that at 700 and 1000 deg. fahr. (in one case at 1125 deg.), the quenched and tempered steels showed load-carrying ability proportionately much higher than that produced by small additions of any of the alloying elements considered. It is largely for this reason that it was considered impracticable to attempt to develop the magnitude of the effects of tungsten additions to the chromium or other alloy steels (Fig. 42) since the heat treatments were not all comparable.

Another item of interest is to be found in the comparison of the results obtained on the chromium-vanadium steel, No. 10-518, Table I, subjected to two different preliminary heat treatments. At atmospheric and slightly elevated temperatures the

samples with the higher tensile strengths, as determined at room temperature, showed the higher load-carrying ability, but at 1200 deg. fahr., the order of superiority was reversed although the differences between the two sets of samples were not marked. It is probable that this reversal is analogous to that found in the high-chromium-nickel steel, E1912, Table 1, already discussed. Once again evidence has been obtained to indicate that high tensile strength at ordinary temperatures does not necessarily signify high load-carrying ability at high temperatures.

4—Effect of Prolonged Stress at Different Temperatures on Hardness and Impact Resistance at Atmospheric Temperatures

One question which may arise in the practical application of metals at high temperatures is whether prolonged loading will produce appreciable changes in their properties at either atmospheric or elevated temperatures. Aside from precipitation of carbides, claimed to embrittle high-chromium or high-nickel-chromium steels similar to E1912, Table 1, deformation at high temperatures followed by cooling and reheating, which may be encountered in cyclic operation of high-temperature equipment, may result in grain growth and changes in impact resistance or other properties.[13]

Recently, Rosenhain and Hanson[14] reported an appreciable increase in the Brinell hardness of mild-steel strips containing 0.11 per cent carbon when subjected for about 5 years at 570 deg. fahr. to loads equivalent to one-third to two-thirds of their tensile strength determined at ordinary temperatures. This hardening was observed despite the fact that the samples were reported to have undergone only a very small amount of deformation in the specified interval.

No satisfactory explanation was offered for these effects, but if appreciable hardening can take place generally in steels without deformation, when they are subjected to prolonged stresses at high temperatures, this matter must be considered in the interpretation of flow-test data. On this account hardness and notched-bar impact tests were made on samples of the chromium-vanadium steel, No. 10-518, Table 1, after they had been stressed for long periods in the flow tests.

The impact specimens were prepared from the reduced sections of the flow-test specimens, the notch being placed in the center of the gage length. On account of the small size of the specimens used in the flow tests (0.25 in. diameter), a standard impact-test specimen could not be obtained. Instead, specimens were prepared for a low-range Charpy impact-testing machine and had a length of 2.1 in., a thickness of 0.1 in., and widths varying from 0.14 to 0.2 in., depending upon the diameters of the tested flow-test specimens. Whenever possible, specimens having a width of 0.2 in. were used. However, the results were all converted[15] to equivalent values for specimens having a width of 0.2 in.

Rockwell hardness tests were also made on the broken impact specimens, a $^1/_{16}$-in. ball and 100-kg. load (B scale) being used. The results are summarized together with pertinent flow-test data in Tables 3 and 4.

No measurable changes were found in the hardness or impact resistance at atmospheric temperatures so long as no appreciable deformation was produced in the previous flow tests. Deformation at temperatures at which strain hardening occurs in the flow tests was accompanied quite generally by an increase in the hardness and a decrease in the resistance to impact. In all cases, however, the changes were small. At higher temperatures, 1000 to 1200 deg. fahr., no measurable changes were produced in the impact resistance or hardness by deformation in the flow tests. The flow tests were not continued for such long periods as in the tests reported by Rosenhain and Hanson, and a steel of very different composition was studied. The results indicated, however, that no changes occurred other than those which might normally be expected from strain hardening.

5—Trends at 1000 Deg. Fahr. in the System Ni-Cr-Fe

In the tests of the commercial alloys of nickel, chromium, and iron it was impracticable to determine the effects of variations

[15] Since the thickness of the specimens was the same in all cases, the impact values vary directly with the width.

in nickel or chromium on the load-carrying ability of the alloys at high temperatures since the variations in composition were not restricted to these individual metals. It was largely on this account that the twelve metals of group III, Table 1, were prepared. Their approximate locations in the nickel-chromium-iron ternary diagram are shown in Fig. 48.

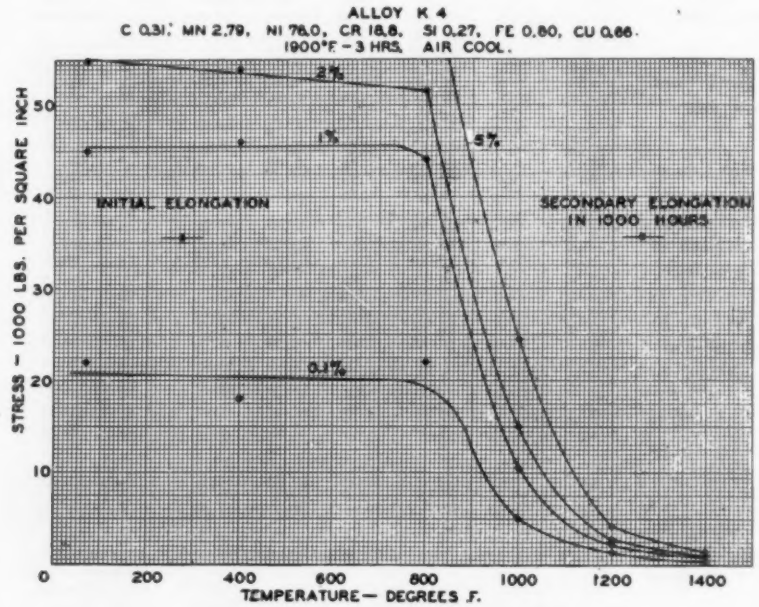

FIG. 30 FLOW CHART FOR ALLOY K-4

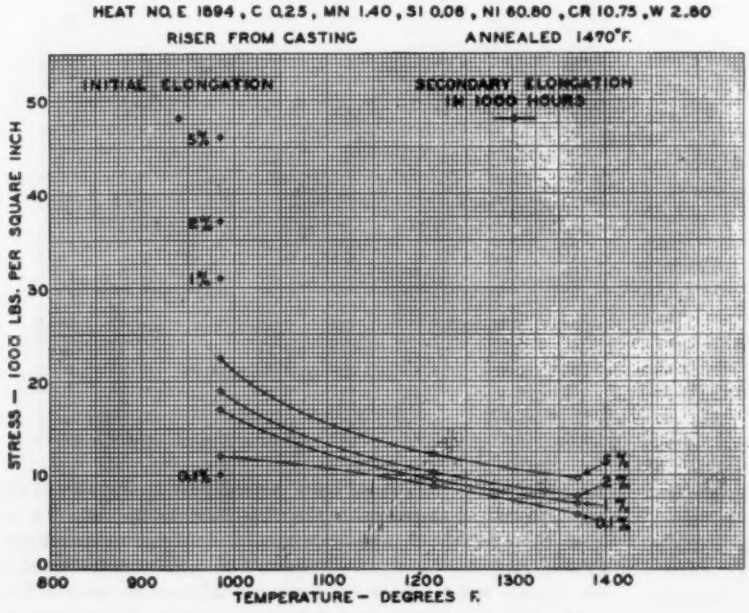

FIG. 31 FLOW CHART FOR ALLOY E1894

The flow tests were not continued for such long periods as those made on the commercial alloys since the principal object was to determine general trends in the system, nickel-chromium-iron, rather than to secure numerical values of the load-carrying ability of the different alloys.

The metals were melted in zirconia crucibles in a high-frequency induction furnace, cast in iron molds (preheated to approximately 390 deg. fahr.), and subsequently heat treated as indicated in Table 1. The heat treatments were selected to produce at least a partial grain refinement, promote diffusion, and leave the alloys in a "softened" condition.

The alloys tested were not pure in the sense that they were free from all elements except nickel, chromium, and iron, since intentional additions were made of carbon, silicon, and manganese. The presence of appreciable proportions of the last three elements probably exerted a pronounced effect upon numerical values of the flow at 1000 deg. fahr., and by acting in different ways in different alloys may have modified somewhat the magnitude of the changes existing in the pure nickel-chromium-iron system. However, it is hardly probable that the general trends were upset by the presence of the carbon, silicon, or manganese, and since most industrial-alloy castings of this general type contain appreciable amounts of these three metals, the results are probably closer to those obtainable in practice than would be the case with pure metals.

Table 1 shows that not all of the alloys contained the desired amounts of carbon, silicon, and manganese. The carbon contents were 0.20 to 0.35 per cent in most cases, but some of the alloys contained as much as 0.50 per cent or as little as 0.11 per cent. The manganese was between 0.6 and 0.9 per cent, but the silicon varied from about 0.5 to 1.1 per cent. These variations probably affected the numerical values of the flow appreciably, but in general may be disregarded since only the major trends in the nickel-chromium-iron system are to be considered.

The specimens for the flow tests were cut from the castings at points midway between the outside and the center in the direction of the long axis. The Brinell hardness values subsequent to the recorded heat treatments are given in Table 1, and have been used as the basis of the three-dimension model in Fig. 49 to give a better picture of the conditions in which the metals were tested. The time-elongation curves from the flow tests at 1000 deg. fahr. are given in Fig. 50, while the relations between the flow and the applied loads are summarized in Fig. 51.

As in the case of the alloys of groups I and II, Table 1, the load-carrying ability may be represented by the stresses producing 1 per cent elongation in the first 1000 hours, and a comparison of the metals on this basis is given in the three-dimension ternary model in Fig. 52. Fig. 52 shows that the addition of nickel to the iron, containing about 0.2 per cent carbon, etc. (Table 1) resulted in no marked changes in the stresses producing 1 per cent elongation in the first 1000 hours.

The addition of chromium to iron containing about 0.2 per cent carbon, etc. (Table 1), did not improve the load-carrying ability at 1000 deg. fahr. appreciably until the chromium content was in the neighborhood of 50 per cent. In fact, the iron alloy with 30 per cent chromium showed the lowest resistance to flow of all of the alloys tested and that with 14 per cent chromium, representing the composition of "stainless steel," was about on a par with steel containing no chromium.

On the other hand, the addition of a little chromium to the

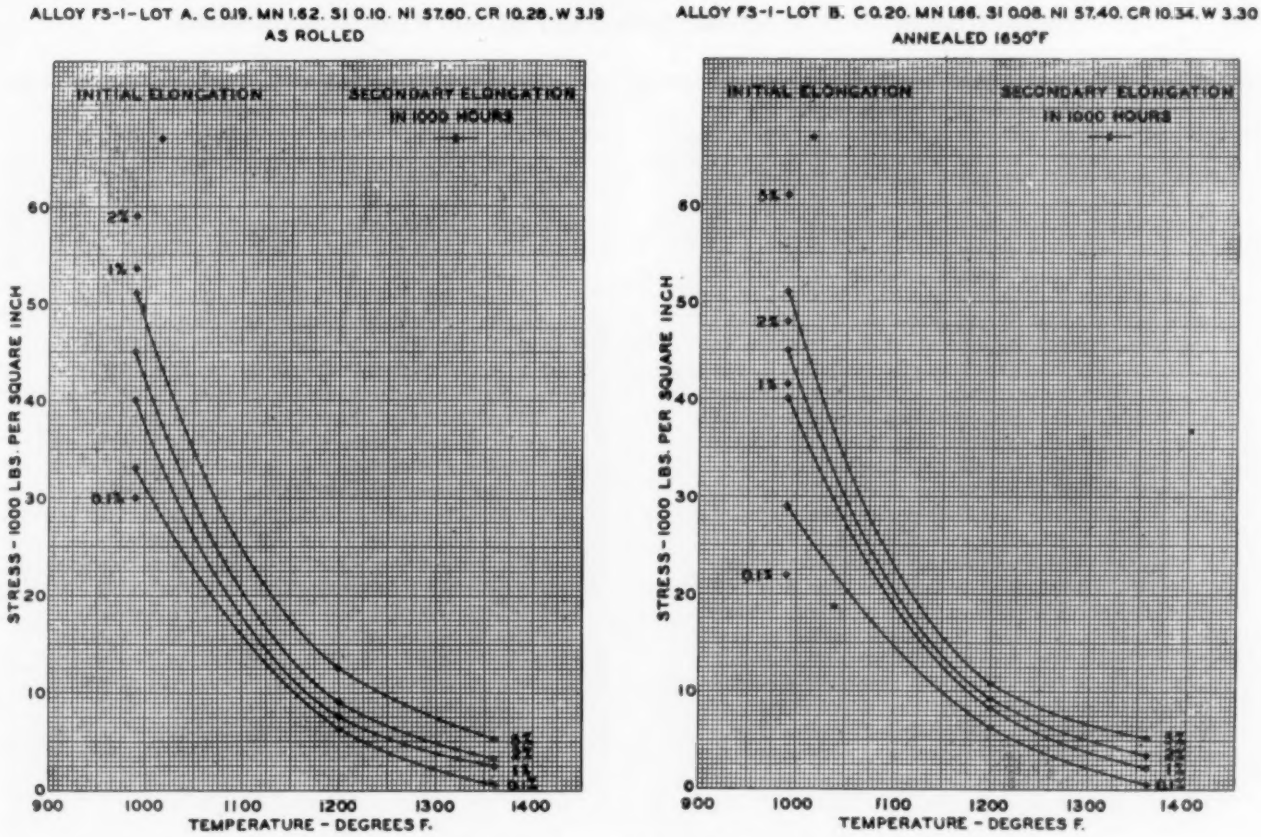

FIG. 32 FLOW DATA FOR ALLOY FS-1, LOTS A AND B

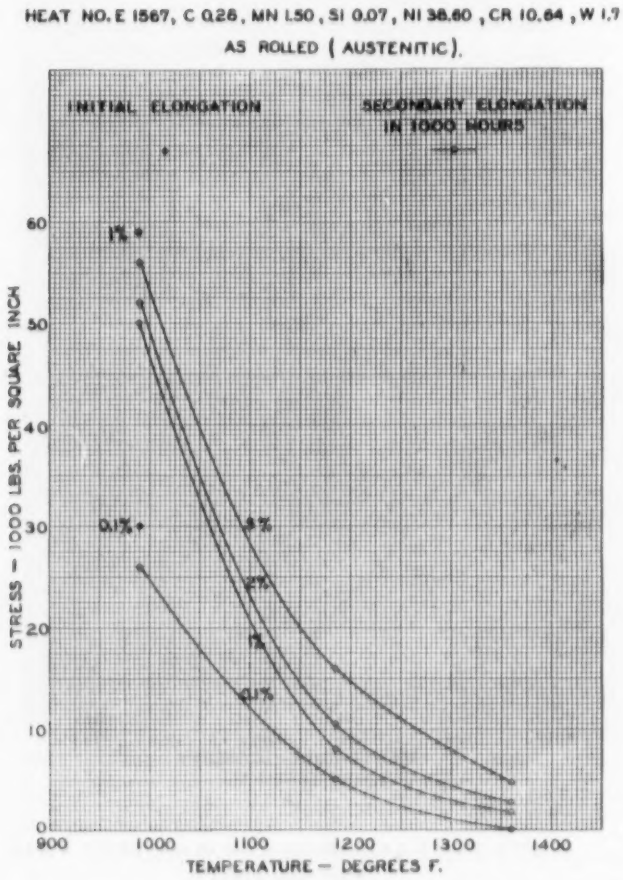

Fig. 34 Flow Chart for Alloy E1567

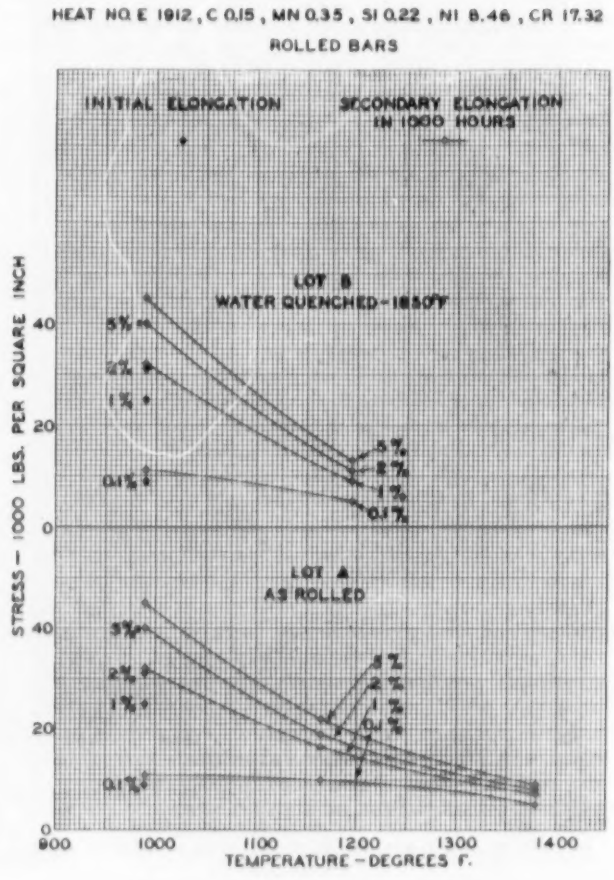

Fig. 36 Flow Chart for Steel E1912

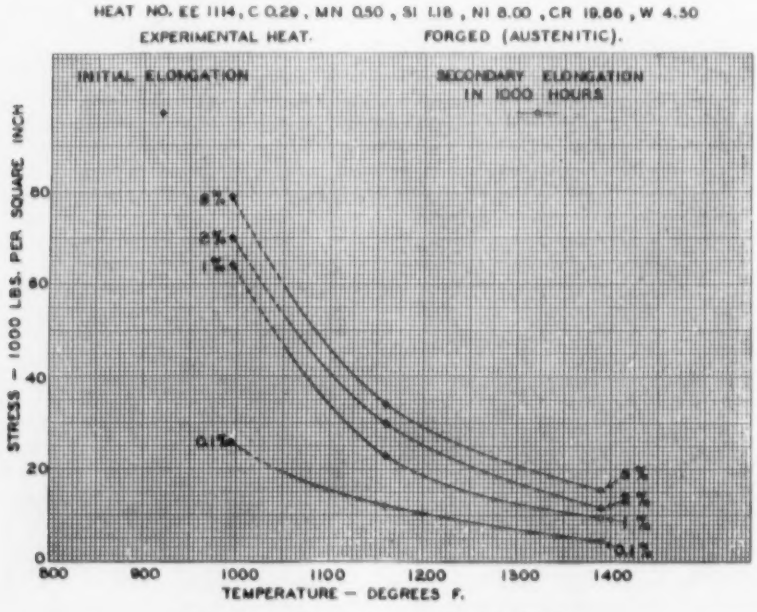

Fig. 35 Flow Chart for Steel EE1114

iron alloys with 40 per cent or more of nickel, produced a marked increase in the load-carrying ability. The most effective proportions of chromium were between 5 and 20 per cent; higher proportions produced further increases but not in the same degree.

These results explain in part the popularity of the commercial iron-nickel-chromium casting alloys containing about 60 to 65 per cent of nickel and 10 to 20 per cent of chromium. This composition is in the range of high load-carrying ability, although it does not have the best resistance to flow.

The strongest of the alloys at 1000 deg. fahr. were those with little or no iron, 50 to 80 per cent nickel, and 50 to 20 per cent chromium. The highest load-carrying ability was obtained in the castings containing about 50 per cent each of nickel and chromium (alloy 1008, Table 1) but this alloy would be expected to offer difficulties in the foundry and had the serious disadvantage of fracturing with low elongation (Fig. 50). The remedy for this latter condition may be in decrease in the impurities, but foundry difficulties would be expected to persist under such conditions. A more practical solution of the problem of securing higher resistance to flow at high temperatures would probably be in additions of other elements to the alloys containing 60 to 65 per cent of nickel and 10 to 20 per cent of chromium. Tungsten is one of the additions used industrially for this purpose, as is shown by the composition of the commercial alloys of group I, Table 1.

In the alloys containing 50 per cent or more of nickel and 10 to 20 per cent of chromium, it would seem to be advisable to keep the chromium close to 20 per cent, since a decrease to 15 per cent or less brings the metal into a range of rapidly decreasing load-carrying ability, as is shown in Fig. 52. This means that the composition variations ordinarily encountered in commercial production would result in wider variations in properties in the nickel-iron alloys with 5 to 15 per cent chromium than in those with 15 to 20 per cent. Furthermore, lowering the chromium should also tend to lower the oxidation resistance of the metal.

It is of interest to note that the iron-nickel-chromium alloy having the nominal composition of 18 per cent chromium and 8 per cent nickel, which is now so widely used in the wrought condition, is in the field of low load-carrying ability at 1000 deg. fahr. It cannot compete with some of the other alloys in castings for service requiring high resistance to flow, but is attractive on account of excellent resistance to oxidation and because it can be formed either hot or cold.

While this and some of the other alloys in the nickel-chromium-iron system were found to have relatively low resistance to flow at 1000 deg. fahr. it should be recognized that improvement may be obtained through modifications in treatment or by varying the proportions of elements such as carbon, silicon, etc. An example is found in the iron alloy containing 14 per cent chromium. Tests on two different ingots containing, respectively, 0.24 and 0.37 per cent carbon showed (Fig. 51) that the alloy with 0.37 per cent carbon had a much better resistance to flow at 1000 deg. fahr. than alloy with 0.24 per cent.

It should be recognized that variations in the general structure (cast or wrought metal), in heat treatment, or in the proportions of elements such as carbon and silicon, may affect the load-carrying ability to a greater degree than appreciable variations in the proportions of nickel, chromium, or iron at least in some parts of the system (Fig. 52).

V—SUMMARY

Flow tests were made at different temperatures on three groups of alloys. The eleven metals of the first group comprised one nickel-chromium alloy, six nickel-chromium-iron alloys, with or without tungsten, and four low-chromium steels containing also vanadium, tungsten, or molybdenum. The flow characteristics of these metals are summarized in charts given in the report.

Two carbon steels, two low-nickel-chromium steels, and a 3½ per cent nickel steel comprised the second group of metals which were tested at 700 deg. fahr. When annealed so as to

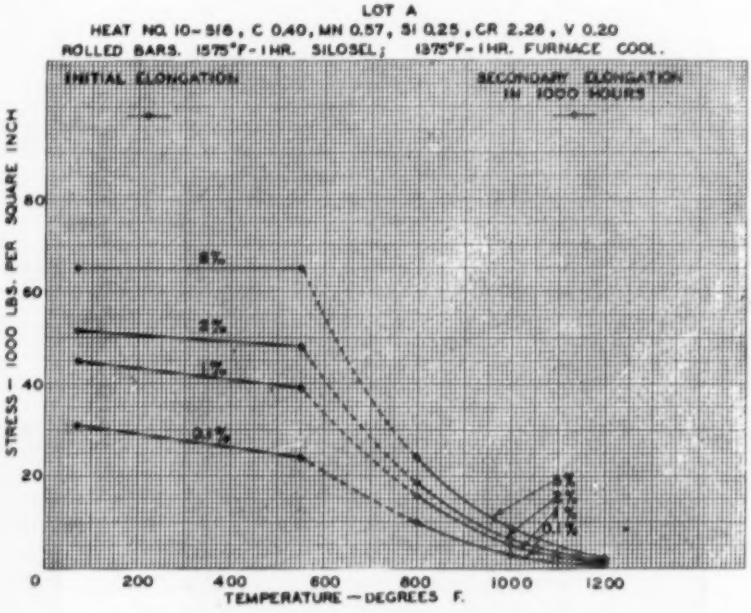

FIG. 37 FLOW CHART FOR STEEL 10-518, LOT A

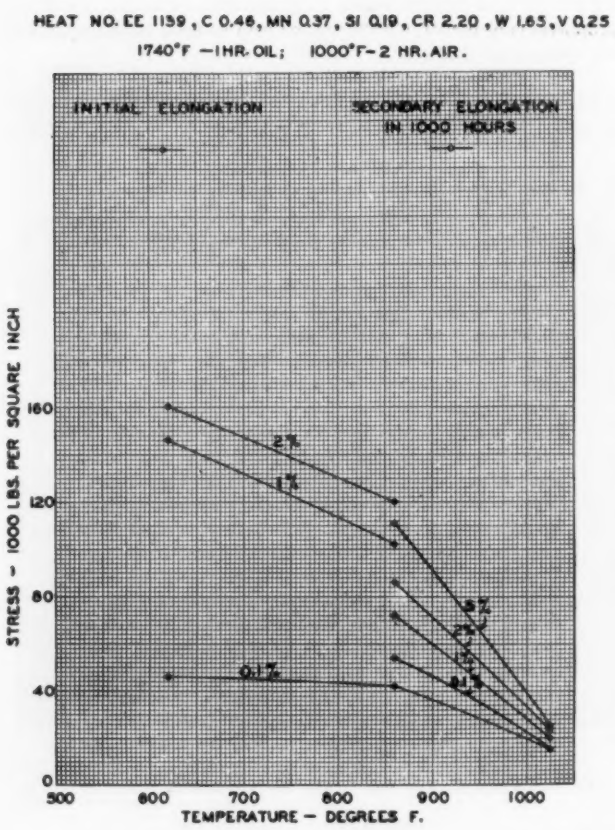

FIG. 39 FLOW CHART FOR STEEL EE1139

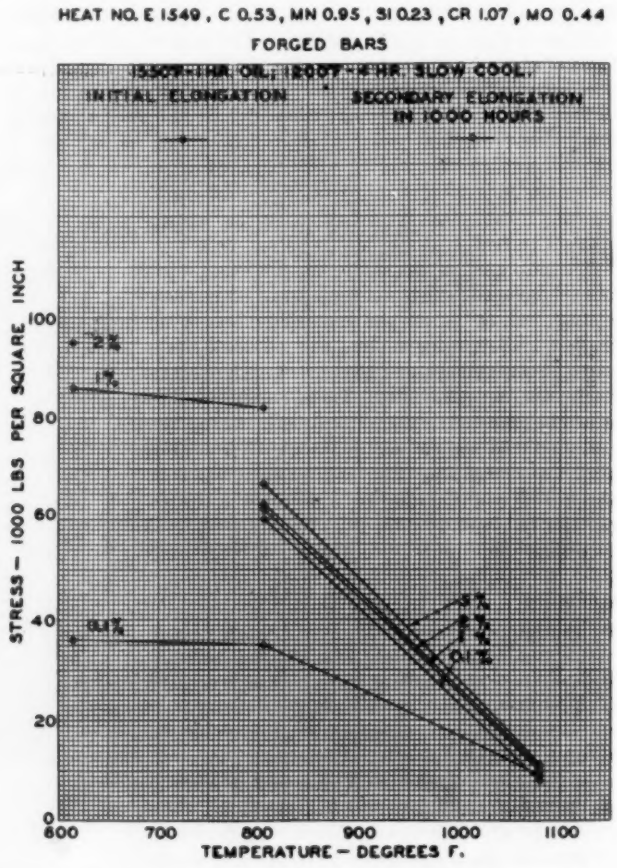

FIG. 40 FLOW CHART FOR STEEL E1549

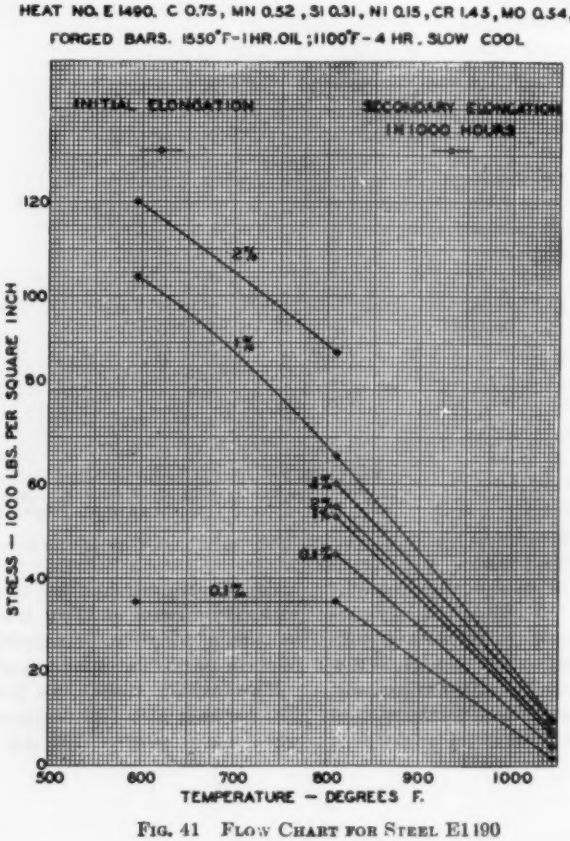

FIG. 41 FLOW CHART FOR STEEL E1190

reproduce the conditions existing in large forgings the plain carbon steel containing 0.45 per cent carbon showed better load-carrying ability than that with 0.23 per cent carbon, and resisted flow at 700 deg. fahr. about as well as the steels with 0.35 per cent carbon and either $3^1/_2$ per cent nickel or a combination of $1^1/_4$ to $1^3/_4$ per cent nickel and $^1/_2$ to 1 per cent chromium. However, other characteristics of the alloy steels may give them marked superiority, The addition of chromium to the iron did not greatly improve its load-carrying ability until the chromium content reached about 50 per cent. In fact, the iron alloy with 30 per cent chromium showed the lowest resistance to flow of all of the alloys tested at 1000 deg. fahr., and the one with 14 per cent chromium, representing the composition of "stainless steel," was about on a par with steel containing no chromium.

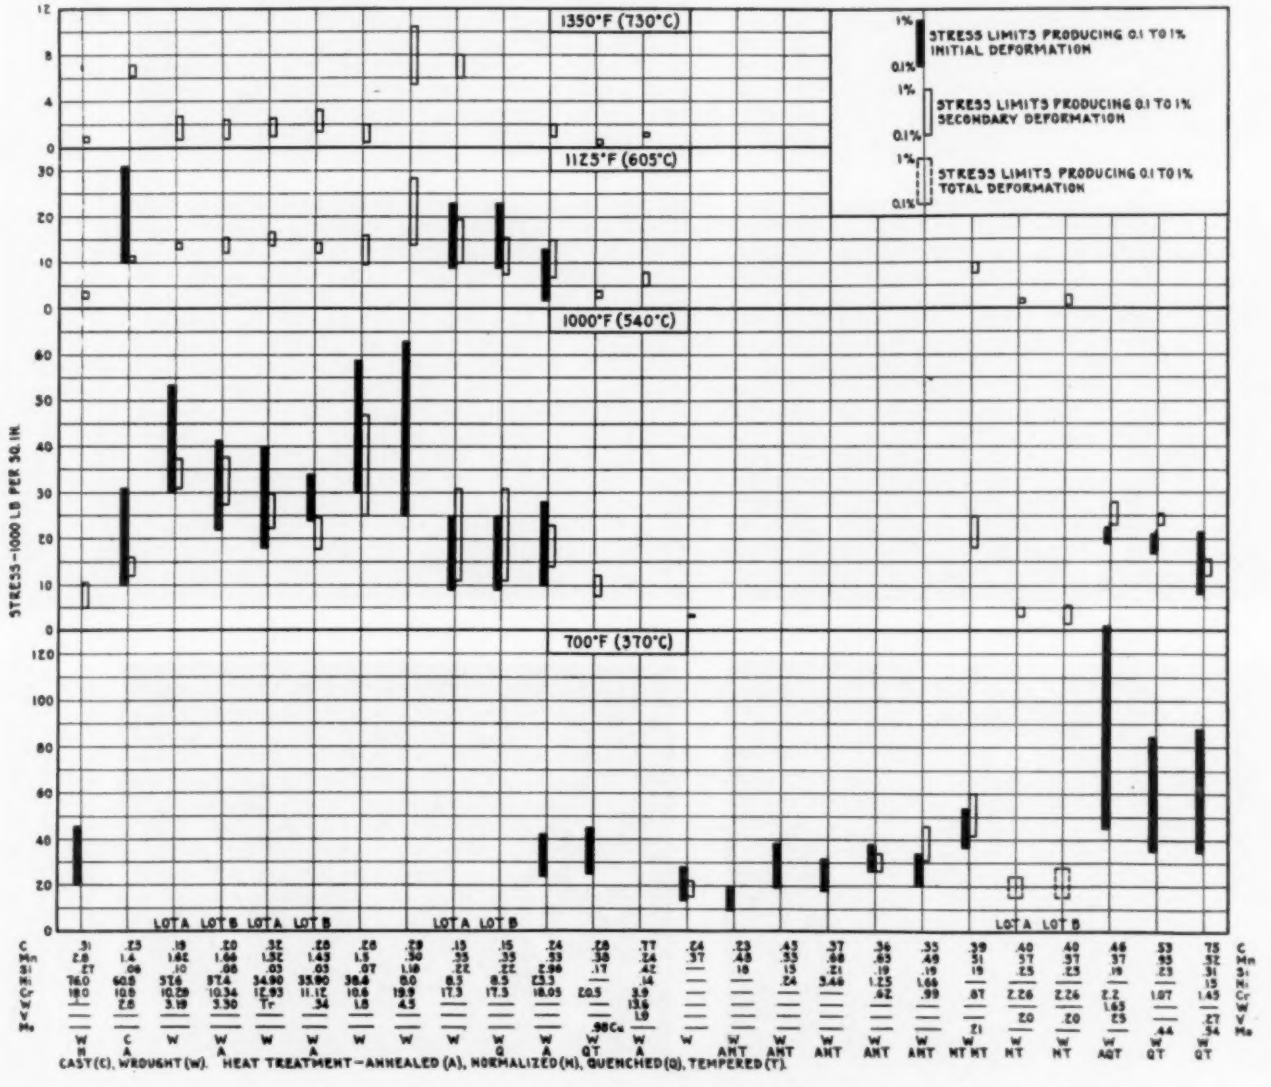

FIG. 42 COMPARISONS OF ALLOYS ON THE BASIS OF THE STRESSES PRODUCING BOTH INITIAL AND SECONDARY DEFORMATION
(Note: Secondary deformation is calculated for 1000 hours.)

such, for example, as superior resistance to grain growth on recrystallization which results from deformation and subsequent heating in cyclic temperature operation.

The third group of metals consisted of nickel-chromium-iron-alloy castings melted in a high-frequency induction furnace. Their chemical compositions were selected to cover a broad area in the nickel-chromium-iron system, and the tests of the metals were made at 1000 deg. fahr. after annealing or normalizing to produce softening, grain refinement, and diffusion.

It was found that the addition of nickel to iron containing about 0.20 per cent carbon, 0.75 per cent manganese, and 0.7 per cent silicon resulted in no marked changes in the stresses required to produce 1 per cent elongation in the first 1000 hours.

On the other hand, the addition of a little chromium to the iron alloys with about 40 per cent or more of nickel, produced a marked increase in the load-carrying ability. The most effective amounts of chromium were between 5 and 20 per cent; higher proportions produced further increases, but these were not commensurate with increases produced by additions below 20 per cent.

The highest load-carrying ability was obtained in the castings containing about 50 per cent each of nickel and chromium, but this alloy would be expected to offer difficulties in the foundry, and, with the proportions of carbon, silicon, and manganese present, had the serious disadvantage of low ductility.

In the case of the wrought commercial alloy containing 0.15 per cent carbon, 18 per cent chromium and 8 per cent nickel,

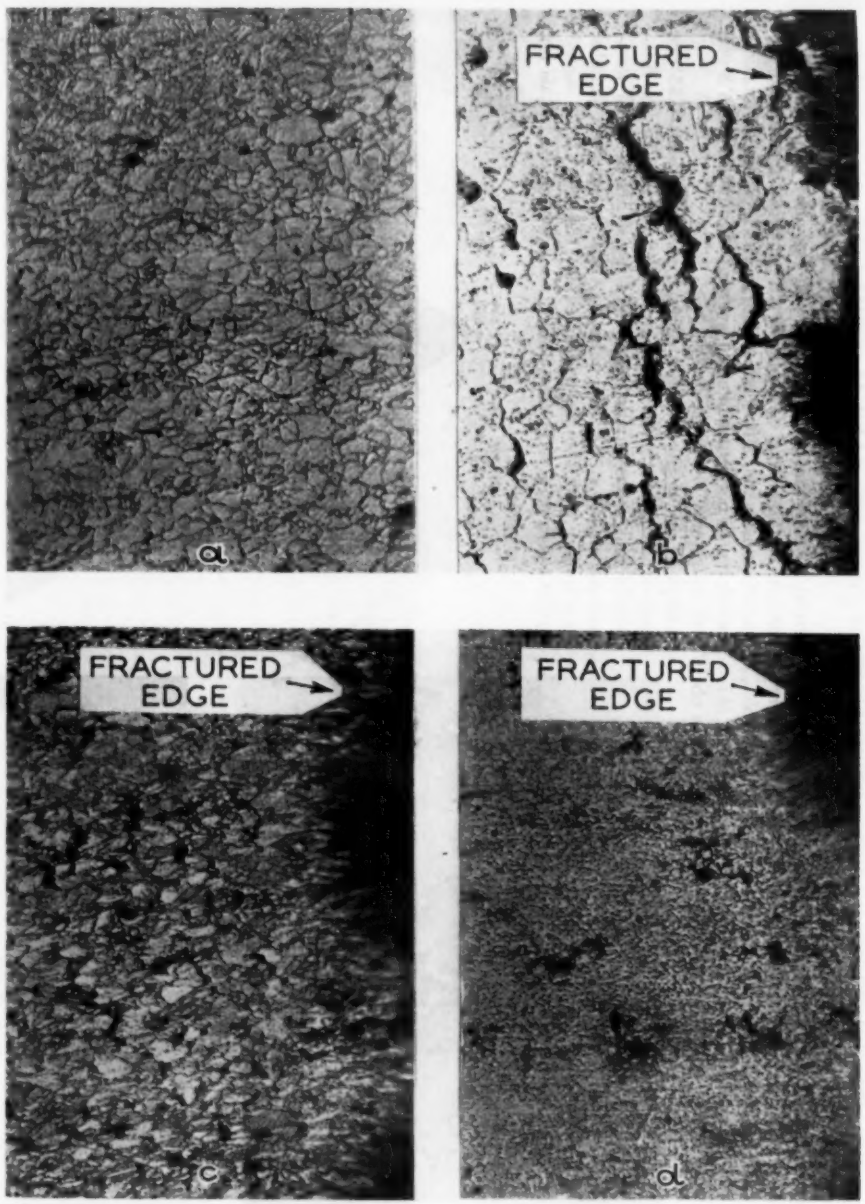

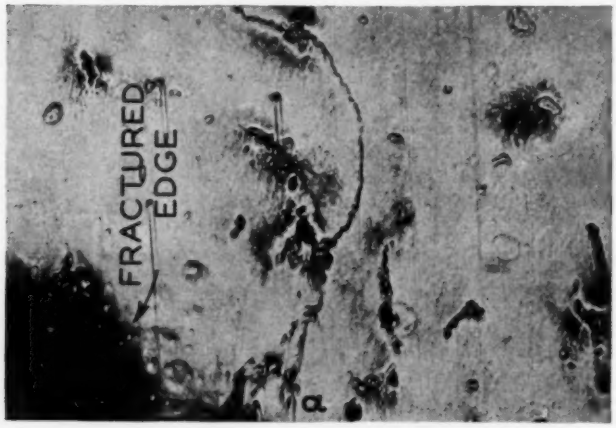

FIG. 46 STRUCTURES OF THE ROLLED BARS OF ALLOY E1567 BEFORE AND AFTER TEST AT DIFFERENT TEMPERATURES. ×250

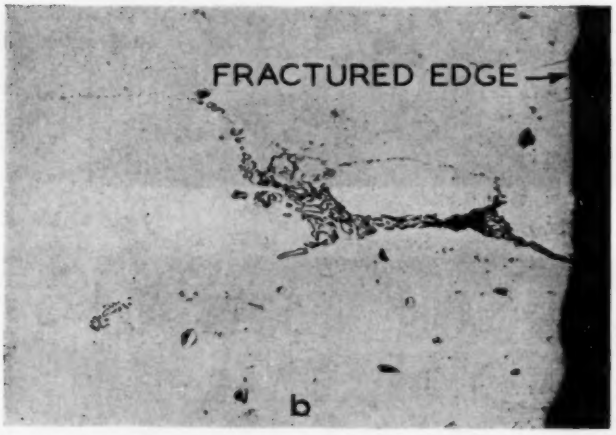

a Original bar of lot B. *b* 23,300 lb. per sq. in. at 1185 deg. fahr. for 180 hr.; metal at fracture. Total elongation, 2.4 per cent (Lot A). *c* 35,000 lb. per sq. in. at 1185 deg. fahr. for 138 hr.; metal at fracture. Total elongation, 13 per cent. *d* 10,000 lb. per sq. in. at 1360 deg. fahr. for 70 hr.; metal at fracture. Total elongation, 37 per cent. Etched as indicated in Fig. 43.

intercrystalline weakness was observed at temperatures between 1165 and 1380 deg. fahr., and to some extent also at 990 deg. fahr. This was noted in both fine-grained and coarse-grained samples, although the latter seemed to show the greater tendency in this direction. A similar tendency but in a smaller degree was observed at 1160 and 1390 deg. fahr. in the alloy containing 0.3 per cent carbon, 1 per cent silicon, 4.5 per cent tungsten, 20 per cent chromium, and 8 per cent nickel, and at 1185 deg. in an alloy containing 38 per cent nickel, 11 per cent chromium, and 1.8 per cent tungsten.

In the case of the wrought alloy containing about 0.15 per cent carbon, 18 per cent chromium, and 8 per cent nickel, fine-grained and coarse-grained samples showed about equal load-carrying ability at 990 deg. fahr., but the fine-grained samples were weaker than the coarse-grained at 1180 deg. This should not be taken as a recommendation of coarse-grained metals for high-temperature service since fracture may occur with less total elongation than in the corresponding fine-grained metals and so counteract any advantages from lower rates of flow. There is also the possible added disadvantage of weakness in resisting shock.

With one exception the wrought commercial alloys of nickel, chromium, and iron which showed superiority at about 1380 deg. fahr. did not necessarily show superiority at lower temperatures. This exception was the alloy containing about 20 per cent chromium, 8 per cent nickel, 4.5 per cent tungsten, 0.3 per

cent carbon, and 1 per cent silicon, which had the highest load-carrying ability of all of the alloys of group I.

A study was made of the effect of deformation in the flow tests at different temperatures on the hardness and impact resistance of a chromium-vanadium steel at ordinary temperatures. No marked changes were found in the hardness or impact resistance so long as no measurable deformation was produced in the prior flow tests. At temperatures at which strain hardening occurs, deformation in the flow tests produced a small increase in the hardness and a decrease in the impact resistance of the steel at atmospheric temperatures; deformation in the flow tests at higher temperatures did not affect these at atmospheric temperatures.

ACKNOWLEDGMENTS

The authors are indebted to H. K. Herschman, Associate Metallurgist, for the micrographs included in this report, to H. A. Bright, Chemist, for the chemical analysis of the alloys, and to H. C. Cross, Junior Metallurgist, for carrying out the hardness and impact tests on the flow-test specimens and for assistance, from time to time, in the flow tests. The very efficient aid of Dr. R. L. Dowdell, Senior Metallurgist, and W. A. Tucker, Senior Laboratory Assistant, has contributed greatly to the progress of the work in its later phases and is gratefully acknowledged.

Discussion

F. K. Ziegler.[16] While the results obtained in the tests upon various metals and alloys at elevated temperatures will doubtless be of considerable value to designers of structures operating at temperatures up to 1400 deg. fahr., there is still a distinct need for data on heat-resisting alloys which operate at temperatures up to 2000 deg. fahr. The manufacturers of heat-resisting alloys are at present using figures which are based upon a very high factor of safety, since no comprehensive experiments have been carried on at temperatures in the range where heat-resisting alloys are most economical to use.

Every manufacturer of heat-resisting alloys hopes that in the very near future some work will be done at the high temperatures, and it is suggested that such work be undertaken as soon as possible and that the work be carried on with the same degree of care and accuracy shown by the authors of this paper.

John L. Cox.[17] Few who have not had close association with the determination of creep stresses have any proper appreciation of the tedious drudgery involved in their evaluation and graphic presentation in useful form. The paper is the epitome of over two years' steady work and contains much information nowhere else obtainable with anything like its degree of accuracy. The thanks of the engineering fraternity are due its authors for their painstaking work.

The data given largely concern alloys of a type coming steadily into more general use, as to the behavior of which under prolonged loading at elevated temperatures we have had little real knowledge. In the usual tables of properties of such metals are found the tensile strength and yield point under short-time testing. What the behavior of the materials was under long exposure to stress at high temperatures has been largely a matter of conjecture or of experience to those who have used them. We are now in the way of getting much nearer to the facts, for in spite of many attempts to find a correlation factor between the short- and long-time testing, nothing satisfactory has yet been developed nor is likely to be.

So many possible variables enter into long-time testing that in spite of the utmost care the results of different laboratories, even of the first class, on duplicate specimens, still vary widely. Differences in the sensitivity of the provision for measuring elongation, differences in the distribution of heat in the furnace, differences in the accuracy at which the temperature is maintained constant, differences in the methods of applying the load, and differences in the place and manner of installing even identical equipment have their influences on the results.

In making use of such figures as those produced by the authors, several points must be considered. The curves resulting from all such researches are at best the average of only a few specimens, generally from but one bar or casting of their respective compositions. One must not assume that such compositions always give equal results. The specimens broken may be the best or the worst of their kind, or intermediate in quality. Variations in composition are bound to occur in attempts to run identical compositions, and allowances must be made for all such variations. In spite of these considerations, the more accurate information now available permits the use of a lower factor of safety or a lower coefficient of ignorance.

In many cases the strength shown at higher temperatures will seem astonishingly small in view of known performances of the materials. When such is the case, it probably means that the conditions of service are less severe than supposed, that there may be cycles of alternate heating and cooling to reduce the time at maximum temperature, or that the working heat of the parts is not as high as supposed, or that actual changes of shape were greater than supposed.

Attention may be called to the differences between curves showing 1 per cent elongation in 10,000 hours, the minimum of the paper, and in 100,000 hours, available in one or two instances. This may be as much as 2 to 1, the longer loading giving the lower reading. As 10,000 hours is practically a year's use and 100,000 hours ten years', it is only in cases where practically no distortion is permissible, as in steam turbines, that creep in a longer time or less creep in a shorter time is of real interest.

It might be pointed out that alloy E-1912 is higher in carbon than is advisable for V2A when used at the temperatures of the test. The carbon for such service should not exceed 0.07 and is preferably lower if embrittlement is to be avoided, it being usually produced by carbide precipitation at grain boundaries.

J. J. Kanter.[18] It is evident from the paper that the interpretation of flow tests of metals is associated with certain practical difficulties. A relationship involving time, temperature, stress, and deformation is obviously one presenting numerous aspects when applied to engineering problems. In order to obtain convenient summaries of flow test data, it is apparent that certain well-chosen units and constants pertaining to long-time tests eventually will be generally accepted. The nature of these constants will depend to a great extent upon the assumptions about flow characteristics that can be widely agreed upon. Up to the present time nearly every investigator has presented his data from a slightly different viewpoint, and as a result there are no broadly understood flow-test constants.

The authors have adopted several units for expressing the stress-deformation relationships that they have recorded. At temperatures where strain-hardening effects preponderate they report percentages of total deformation. At higher temperatures, where creep is more easily observed to be continuous, they use stress values yielding various percentages of flow per 1000 hours. The use of units involving only 1000 hours are best justified, perhaps, by the fact that little extrapolation is implied; i.e., the time periods covered in the actual testing in a number of cases are 1000 or more hours.

Reports of long-time tensile tests by other investigators give flow-stress values in terms of time periods up to 100,000 hours. Such values obviously are based upon extrapolations. Their physical significance may be somewhat open to question.

A number of tests, however, conducted for periods in the neighborhood of 10,000 hours have come from various sources. Such tests show that, at least for 10,000 hours, certain of the materials do not exceed the rates of creep established in the first several hundred hours of testing. For the materials for which this fact has been thoroughly substantiated, we perhaps are justified in computing flow-test constants in terms of total deformations for a 10,000-hour period.

Considering the temperature range for steels as consisting of two distinct parts—a lower division for which initial elongation is expressed and an upper characterized by secondary elongation—is quite descriptive of the relative plastic differences in metals that exist between low and high temperatures, but a certain difficulty that requires some emphasis presents itself. As metals are heated through the range of extreme strain-hardening to temperatures at which they are comparatively plastic, the transition takes place gradually. It is difficult to say what the limiting temperature is at which flow rates subsequent to the initial period cease to be of negligible consequence. This is a

[16] Manager, Alloy Division, Ohio Steel Foundry Company, Springfield, Ohio.

[17] Assistant to President, Midvale Company, Philadelphia, Pa. Mem. A.S.M.E.

[18] Crane Company, Chicago, Ill.

problem of considerable importance because so many applications of steels are being made at temperatures which are situated in the middle of this doubtful range.

To illustrate that *initial flow* and *secondary flow* sometimes must be considered as relative terms only, a variable temperature flow test for low-carbon open-hearth steel is shown. In this test, while the stress was held constant at 1000 lb. per sq. in., the temperature was raised periodically, in steps of 50 deg. fahr. (28 deg. cent.) from 550 deg. fahr. (290 deg. cent.) to 950 deg. fahr. (510 deg. cent.), the entire test requiring 58 days (1392 hours). Studying the time-deformation curve obtained, it is found that at each of the temperatures considered more or less deceleration of flow takes place as the testing proceeds. (Fig. 53.)

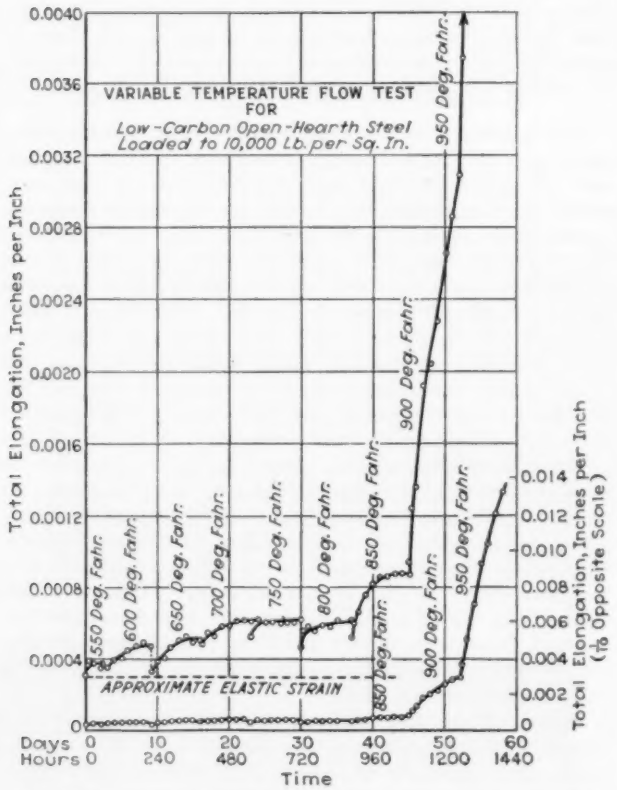

FIG. 53 VARIABLE TEMPERATURE FLOW TEST FOR LOW-CARBON OPEN-HEARTH STEEL

It does not seem entirely necessary to set up separate stress constants for expressing so-called initial and secondary flow. Inasmuch as flow or creep so seldom occurs at an ideally constant rate in the temperature ranges where we must recognize creep, flow-stress constants might be somewhat simplified if all were expressed in terms of total deformation for given periods of time. The troublesome decision between values in the highly important transition ranges would then be avoided.

R. L. PEEK.[19] The writer is wondering if, had the rate of creep been computed in the way described for a constant stress intensity, it would not be found that the rate of creep is either constant or decreasing, except perhaps in the immediate vicinity of the point of rupture. The point of this is that it seems likely that an increasing rate of flow under constant stress intensity indicates some failure of the material, and hence incipient rupture. If this is true, stress intensities producing such increasing rates are obviously unsafe, and if for lower stress intensities the rate decreases with elongation (a conclusion that the writer has suggested as following from the data), it may be possible to use the distinction between the two ranges of stress intensities corresponding to these two conditions as a criterion to determine the safe limits of loading.

ARTHUR MCCUTCHAN.[20] The tests reported in this paper tend to show that the strongest casting alloys for 1000 deg. fahr. service are those with little or no iron, 50 to 80 per cent nickel, and 50 to 20 per cent chromium. The authors suggest the addition of tungsten to improve the ductility of castings made of the composition.

These metals are relatively expensive, and mention is made of difficulty in fabrication. The 18–8 composition while found to have lower load-carrying ability at 1000 deg. fahr. can be formed either hot or cold, although with some difficulty as judged by the price demanded for tubing of this composition. The question arises as to whether the load-carrying ability of the high-nickel alloy at relatively high temperatures such as 1000 deg. fahr. is enough better to warrant its use in preference to 18–8 alloy. This has reference to superheater headers and tubes, piping, valve bodies, etc., operating at 1000 deg. fahr. Specifically, if tubing of 18–8 composition KA2S costs 8 to 10 times as much per pound as carbon steel, should not this alloy of superior load-carrying ability cost commemsurately more?

It is desirable to have data as to the relative sulphur attack on this alloy as compared with that on ordinary KA2S or similar composition having 3 to 4 per cent silicon. The latter material has been reported as having a high resistance to corrosion from hot sulphur dioxide, which might be present, for example, in the flue gases of a high-temperature superheater. In general, the high nickel-chromoum alloy described corresponds to Nichrome which shows good resistance to SO_2 attack.[21]

The question of the advantage or disadvantage of using very low carbon 18–8 alloy to avoid possible embrittlement due to carbide precipitation, as against the better load-carrying ability of high-carbon contents, is one that is very perplexing to the consumer at present. Especially as some difficulty seems to exist in producing the 18–8 alloy with carbon under 0.07 per cent.

The value given for stress to produce 0.1 per cent elongation in 1000 hours with 18–8 material (designated as E1912) chances to agree with that found by Professor Norton at 1100 deg. fahr., although considerably lower at 1000 deg. fahr. As to the different shape of the curve for 0.1 per cent elongation noted in several figures from the general form of stress-temperature flow curves, is it not possible that the shape of these curves might be considerably altered if tests had been made at intervening temperatures?

In many instances a creep rate one-tenth of the lowest reported in this paper has been made the basis for comparing the resistance to creep of metals at elevated temperatures. It is wondered if such extrapolation of test results is considered unwarranted in view of the methods of measuring deformation now employed.

Experiences in Chlorinating Condenser Circulating Water

By VINCENT M. FROST,[1] NEWARK, N. J., AND W. F. RIPPE,[2] KEARNY, N. J.

This paper gives the experiences of the authors over a period of two years in an endeavor to better the heat transfer and reduce condenser cleaning costs at the Kearny, N. J., power station of the Public Service Electric & Gas Company. The condensing apparatus there consists of five 50,000-sq. ft. condensers of the two-pass type, each having 10,000 one-inch tubes 19 ft. 2½ in. long. Chlorine control apparatus was installed, and the paper gives details regarding its operations, and includes water analyses, as well as data on condenser tests, amount of chlorine required, etc. The advantages and disadvantages of chlorination are set forth, together with the reasons for adopting it for the station in question.

IN AN ENDEAVOR to better the heat transfer and reduce the cost of cleaning condensers in the power stations of the Public Service Electric & Gas Company, it was decided to experiment with the use of chlorine gas in treating the circulating water. A cooperative arrangement was made with the Wallace & Tiernan Company, specialists in the application of chlorine control apparatus, and it was decided to try out the method at Kearny Station. This paper is intended to describe the results of our experiences to date along these lines.

V. M. FROST

Kearny Station is located in New Jersey on the west bank of the Hackensack River about 1½ miles from Newark Bay. Slime troubles seriously affected the vacua obtainable in the condensers, and it was found necessary to clean the condensers with rubber plugs at least once a week in the warm weather and twice a month in midwinter. Various methods of brushing and boiling the tubes are also used to improve the heat transfer. These methods, though not entirely satisfactory, were the best available. The character of the river water is shown by Table 1, which represents analyses of water samples covering a full day in the summer. These samples were taken every two hours. The analyses were made by the Department of Sewage Disposal, College of Agriculture, New Brunswick, N. J.

The average of some of the pertinent items is herewith given:

Total solids, p.p.m.	19,410
Suspended solids, p.p.m.	52
pH	7.2
Chlorides, p.p.m.	9,550
Common salt, p.p.m.	15,760
Dissolved oxygen, p.p.m.	1.0

It can be seen from the low oxygen content that the water is very polluted. The salt content indicates about one-half sea water.

W. F. RIPPE

The condensing apparatus at Kearny consists of five 50,000-sq. ft. condensers. They are of the two-pass type, with vertically divided water boxes, and each one has 10,000 one-inch tubes of No. 16 gage Admiralty mixture 19 ft. 2½ in. long. Each condenser is provided with two single-speed circulating pumps of approximately 45,000 g.p.m. capacity, so connected that one pump can supply either half or all of its own condenser or of any other condenser in the station. During normal operation with relatively cold water each condenser is operated individually with one of its own pumps.

The arrangement of the canals, pumps, and screens is shown in Fig. 1. Each condenser has its own intake canal which extends from the face of the dock, passing through the foundations of the bunker and boiler house to the suction chamber located beneath the turbine foundations. The canals are of rectangular cross-section, 9 ft. 6 in. deep and 6 ft. 6 in. wide. Each canal is provided with revolving screens located in the bunker-house basement, as shown on section *C-C* of Fig. 1. The screens are about 200 ft. from their respective suction chambers. The velocity of the water in the canal is 1.6 ft. per sec. with one pump in service, and 2.9 ft. per sec. with two pumps in service.

It was decided to try chlorinating one unit, and No. 4 unit was chosen arbitrarily. This unit, which is the same as No. 2 unit in every respect, consists of a 47,250-kw. Westinghouse turbo-generator unit and a Westinghouse radial-flow condenser equipped with two steam-jet air pumps and one hydraulic air pump. Since the two units are identical in every respect and operate under practically the same load conditions, this gives a fair means of comparison.

After deciding on what unit to install the equipment, the next question to come up was where to put the equipment. The choice lay between injecting the chlorine in the canal at the screen or in the suction pipe of the pumps. It was finally decided to install the equipment in the screen room and inject the chlorine solution immediately behind the screens for the following reasons:

1 The chlorine apparatus should be kept out of the heart of the plant, as it is a hazard.

[1] Asst. to General Superintendent of Generation, Public Service Electric & Gas Co. Mem. A.S.M.E. Mr. Frost was graduated from the Lawrence Scientific School of Harvard University, receiving his degree in Mechanical Engineering in 1902. Following his graduation, he was employed by Westinghouse, Church, Kerr & Co. and the Westinghouse Machine Company on steam-turbine and condenser work, including erection, operation, and repair. He served as assistant engineer and watch engineer at the Williamsburg Power Station of the Transit Development Company, Brooklyn, N. Y., and as chief engineer of the Perth Amboy Plant of the American Smelting and Refining Company. Since 1913, he has been with Public Service Electric and Gas Company.

[2] Test Engineer, Kearny Station, Public Service Electric & Gas Co. Jun. A.S.M.E. Mr. Rippe was born in New York City, on October 19, 1900. He entered Sibley College of Mechanical Engineering at Cornell University in 1918 and was graduated in 1922. Upon graduation he entered the employ of the Public Service Electric and Gas Company as a cadet engineer, completing the course in 1925, and has been with this company since that time.

Presented at a Meeting of the Metropolitan Section of the A.S.M.E., New York, November 21, 1929.

[a] See Appendix, under "Suspended Solids."

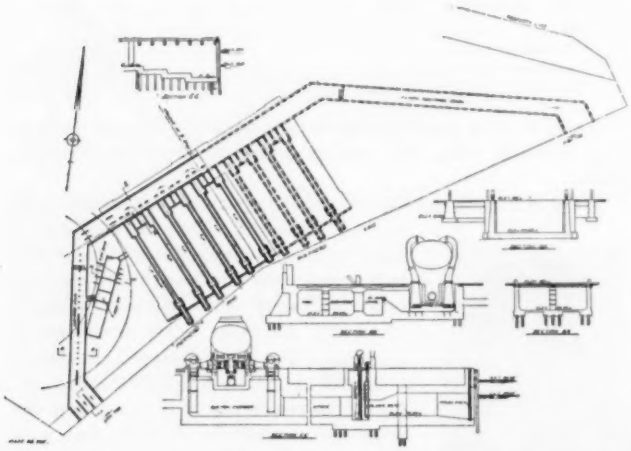

FIG. 1 ARRANGEMENT OF CANALS, PUMPS, AND SCREENS, KEARNY POWER STATION

2 Due to the comparatively small suction chamber and the isolation of units there would be no appreciable dilution.

With one pump in service, it takes $2^1/_2$ min. for the water to travel from the screen through the pump to the condenser, while with two pumps in service it requires $1^1/_2$ min. The velocity of the water through the condenser tubes is 4.8 ft. per sec. with one pump in service and 8.6 ft. per sec. with two.

This investigation is based on the theory that slime fouling of surface condensers is the result of definite biological growth and is dependent upon conditions of temperature and the presence of normal water organisms in the circulating supply. Slime is a conglomerate of inorganic matter, namely, mud and silt bound together by algae growths of a jelly-like nature. If the chlorine dosage destroys the algae and prevents growth, there will be nothing to hold the inorganic matter together and slime will not form. On this basis it was believed that intermittent dosage at correct intervals would prevent the growth and reduce the total amount of chlorine to be used. Patents covering this intermittent process have been granted to Dr. J. Baker, of the Wallace & Tiernan Company.

The equipment installed in No. 4 screen room is shown in Fig. 2 and consists of three chlorinators, each capable of handling 720 lb. of chlorine per day with a battery of 150-lb. chlorine tanks, a program clock, and the necessary piping. The operation of this equipment is as follows: The clock trips a relay which operates a valve in the water line supplying water to the injectors on the chlorinators. The discharge of chlorine solution is carried from each machine down into the canal by means of hose. The program clock can be so set as to give any desired frequency and length of dosage. The amounts of chlorine fed and the frequencies are shown in Fig. 3.

Figs. 4 and 5 give the story of the investigation. The data plotted are weekly averages of hourly readings taken over the two-year period, with corrections for slight load variations. The air leakages of both units during the period under discussion were about the same, so this item has been neglected.

Unit No. 4 was taken out of service in January, 1928, for general overhauling, and during this period was given a thorough cleaning so that when it went back into service the following April it showed a better heat transfer than No. 2. It gradually became worse, however, and by August was about the same as No. 2. The big difference between the two units in June, 1928, was caused by tests being run on No. 4 at an intentionally reduced vacuum.

Chlorination of No. 4 was started on August 10, 1928, after both No. 4 and No. 2 had been thoroughly cleaned by baking

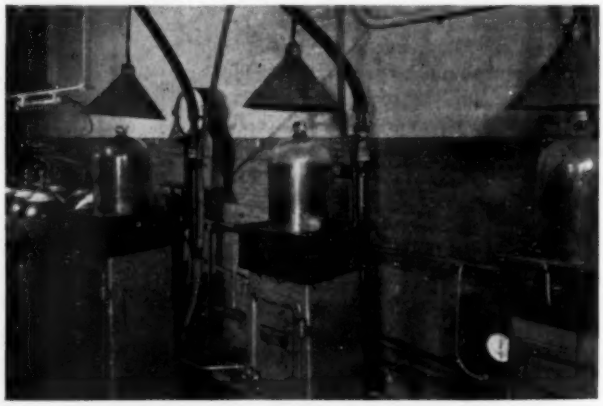

FIG. 2 EQUIPMENT INSTALLED IN NO. 4 SCREEN ROOM

and rubber plugs. After chlorination started, the increase in vacuum of No. 4 over No. 2 was very marked, and frequent examinations showed the absence of slime in the tubes. This gain amounted to 0.2 in. in the middle of October, 1928, but some of this gain may be ascribed to better original cleaning of No. 4 than of 2, although an endeavor was made to get both condensers in the same condition. It was not expected that there would be such a sudden gain in heat transfer, which is the reason for the foregoing statement. During this period No. 2 slimed badly as usual, and even the weekly use of rubber plugs could not hold it near No. 4 in performance.

The dosage chart, Fig. 3, shows that the amount of chlorine used per day varies from 320 lb. to 72 lb. Due to lack of data on the intermittent method of treatment, the dosage was purely experimental. The reduction in the use of chlorine was effected by reducing the percentage of time the chlorine was being injected rather than the concentrations. Whereas at the start

the chlorine was being injected for 2 min. every 10 min., by the middle of October it was found that injection for 3 min. every hour was sufficient to keep the condenser free of slime. It must be borne in mind that it was desired to keep the chlorine dosage sufficiently high to prevent the least indication of slime, and for that reason some of the dosages may be excessive.

In October, 1928, since it was apparent that the slime could be prevented, it was decided to investigate the possibilities of cleaning a very dirty condenser with chlorine. Chlorination of No. 4 was therefore stopped on October 19, 1928, and the condenser was allowed to become dirty. Chlorination was again started on November 26, 1928, but for a while there was no apparent benefit and No. 4 became worse than No. 2, as shown in the first week of December, 1928. It is believed that the chlorine would eventually have brought No. 4 back to its original advantageous condition, but owing to its heavy accumulation of slime this would have been very slow work. It was decided therefore to clean the tubes of both condensers as thoroughly as possible and start another comparative run.

An examination of the tubes of No. 4 condenser at this time showed a hard scale, which it was not expected that the chlorine would remove. Therefore on December 15, 1928, this condenser was boiled on the water side with chemicals, making it as clean as it was conceived to be possible. This resulted in increasing the coefficient of heat transfer from 185 to 270, and brought the vacuum to a point 0.35 in. Hg better than that in No. 2. Immediately after the boiling, chlorination was continued with the hope of keeping the condenser as near as possible to its condition immediately after the boiling. The advantage was increased to 0.4 in. Hg in the latter part of January, 1929, when it was decided to put No. 2 on a par with No. 4 by boiling it also. This was done and there was then very little difference between it and No. 4. On February 1, 1929, unit No. 2 was taken out of service for its annual overhauling, but the chlorination of No. 4 was continued with the idea that when No. 2 was put back into service the two units would start on an even basis. On April

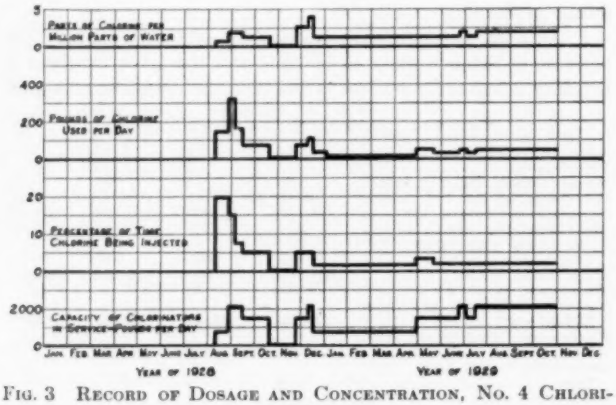

FIG. 3 RECORD OF DOSAGE AND CONCENTRATION, NO. 4 CHLORINATOR

10, 1929, No. 2 was put back in service with a very clean condenser and practically no difference in vacuum between it and No. 4.

Upon referring to Fig. 3 it will be seen that from January 1 to May 1, 1929, it was possible to keep the condenser free of slime with only 12 lb. of chlorine per day. This was done by operating one chlorinator for three minutes every hour for an eight-hour period each day. Here again the concentration of chlorine was maintained, and the reduction in the amount used was effected by cutting down on the percentage of time that the chlorinator was in service.

The dosage was increased on May 1 when the water temperature reached 50 deg. fahr., as the growth of algae increases rapidly above this temperature. It is questionable whether or not this method of treating the water for an eight-hour period of the entire day is the most efficient, but suffice it to say that in this case it was effective. The quantity of chlorine used was

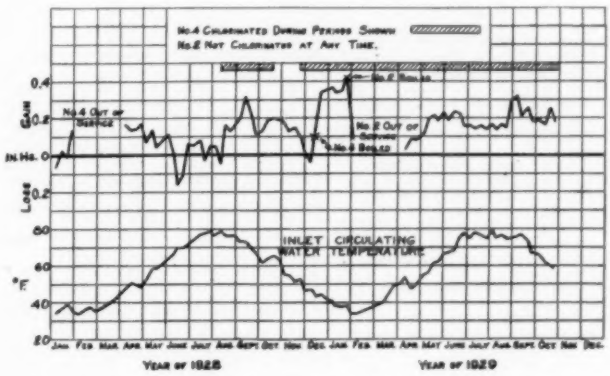

FIG. 4 GAIN IN VACUUM OF NO. 4 CONDENSER OVER NO. 2 CONDENSER

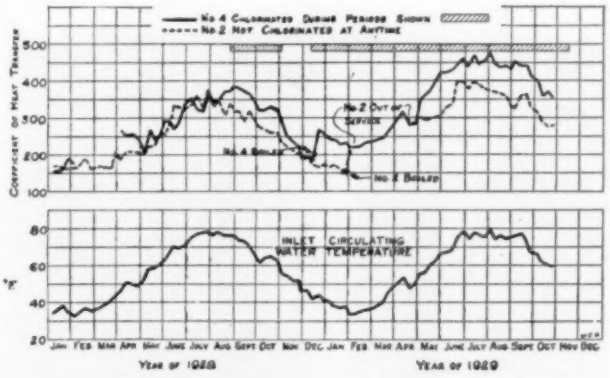

FIG. 5 HEAT TRANSFER OF NO. 2 AND NO. 4 CONDENSERS

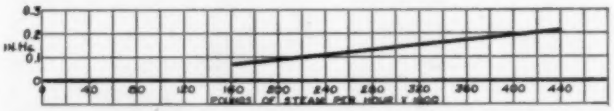

FIG. 6 INCREASE OF VACUUM OF NO. 4 CONDENSER AFTER HAVING BEEN CHLORINATED FOR ONE YEAR

so small that any reduction would be immaterial in this particular instance.

At this point, the most significant part of the entire investigation is presented. The two condensers started out on an even basis, but in a month No. 4 was 0.2 in. better than No. 2, even though No. 2 was being cleaned regularly with rubber plugs. A gain in vacuum of approximately 0.2 in. was maintained. The big increase on September 1, 1928, was caused by No. 2 not being cleaned with rubber plugs for three weeks, but as soon as this was done it was brought down to the 0.2-in. difference again. Comparing No. 4 with other units during the period that No. 2 was out of service shows a gain of about 0.15 in.

Condenser performance tests were made on No. 4 condenser with weighed condensate in June, 1928, and July, 1929, the data of which show the gain in heat transfer due to chlorination. These data are given in Tables 2 and 3. The higher flow of circulating water in the 1929 tests is accounted for by higher tides, which cut down on the suction lift of the pumps and thereby increased

TABLE 2 TEST OF NO. 4 CONDENSER

Date, 1928	6/26	6/26	6/25	6/25

REMARKS: 1. Turbine operated non-bleeding. 2. Two circulating pumps in service. 3. Air leakage measured by nozzle in air-pump discharge.

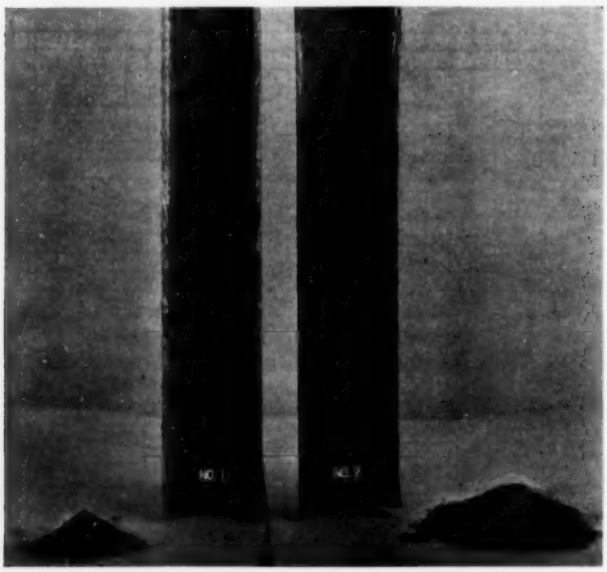

FIG. 7 CONDITION OF TUBES FROM CHLORINATED (NO. 1) AND UNCHLORINATED (NO. 2) CONDENSERS

the flow. In order to have a fair means of comparison the tests were corrected to the same water flow and temperature; the difference is shown in Fig. 6. The average load of this unit gives about 300,000 lb. of exhaust steam per hour, which corresponds to a gain of 0.15 in. Hg of vacuum.

Fig. 7 shows the condition of two tubes removed from No. 2 and No. 4 condensers in August, 1929, after No. 4 had been chlorinated for one year. The piles at the bottom show the relative amounts of deposits on a four-foot length. The picture tells its own story.

One of the most important drawbacks in chlorinating circulating water is the fact that it is a hazard. Chlorine gas, although not poisonous, has a choking effect and will drive men out of the plant if a large enough quantity is allowed to escape. The equipment shown in Fig. 2 gave considerable trouble, especially in the early stages, due to leaks and various mechanical difficulties. Because of the nature of the gas, the policy has been to provide that all future installations shall be outside the main building, for if a tank of chlorine were to be discharged in the main building it would drive every one into the open and cause a shutdown.

With this in mind, when it was decided to extend the experiment, the layout shown in Fig. 8 was installed on unit No. 3 in July, 1929. The point of injection of the chlorine solution is the same as on No. 4, i.e., immediately behind the screens, but the essential differences are as follows:

1 All equipment is installed in a separate building outside

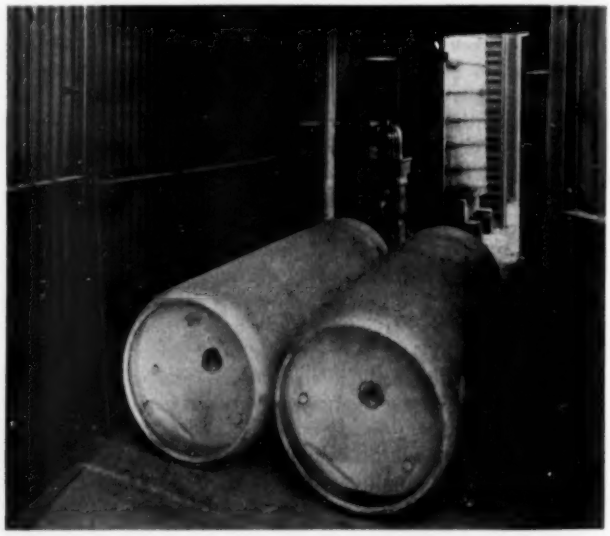

FIG. 8 INSTALLATION OF ONE-TON CHLORINE CONTAINERS IN BUILDING OUTSIDE MAIN STRUCTURE

the main structure. This lessens the hazard in case of leaks or failure of the apparatus.

2 One-ton containers are used instead of 150-lb. tanks. The chlorine is cheaper when so bought, and the labor involved in handling a one-ton container is less than the equivalent 13 small

TABLE 3 TEST OF NO. 4 CONDENSER

Date, 1929	7/16	7/17	7/15	7/11
Duration, hr	3	2	3	3
Room temperature, deg. fahr	80	78	81	87
Barometer, in. Hg	30.18	30.15	30.32	30.40

B.t.u. per sq. ft. per hr. per deg. fahr. (arith.)	350	412	410	441
Vacuum at air pump, in. Hg	28.81	28.74	28.63	28.40
Air leakage, cu. ft. per min	14.6	10.3	9.6	8.7

REMARKS: 1. Turbine operated non-bleeding. 2. Two circulating pumps in service. 3. Air leakage measured by nozzle in air-pump discharge.

tanks. The fewer connections with the one-ton containers lessens the possibility of leaks and reduces the labor of connecting up tanks.

3 The chlorinator injects the solution continuously into the tower filled with limestone, and the pump operates intermittently, taking solution from the tower and pumping it into the canal. Due to the continuous operation of the chlorinator less capacity is required, and the chlorinators function better when in continuous service. The disadvantage is the extra pump and tower necessary for this particular feature.

At the time the new equipment was ready for operation, the condenser was very dirty and an effort was made first to determine whether or not the chlorine would clean it. Apparently it would eventually clean it of all slime, but the ideal method seems to be to start with as clean a condenser as possible, with the expectation that the chlorine will maintain that condition.

The question of corrosion of condenser water boxes and tubes has been brought up. There has been no sign of corrosion of No. 4 condenser after being chlorinated for a period of over a year. The amount of chlorine in the water is so small and the time it is in the water is so short that it is not believed any serious trouble will arise from this source. Repeated tests have usually shown no residual chlorine in the water entering the condenser, and none at any time leaving the condenser during dosing periods. The maximum residual chlorine found at any time at the inlet to the condenser was 0.3 part per million.

There is no doubt of the ability to keep the condensers at Kearny free of slime by the use of chlorine. Since No. 4 was boiled out in December, 1928, no cleaning has been done except for the chlorine treatment and the removal of loose matter in the tube ends. This fact alone proves the treatment's effectiveness. That there is a saving due to the better vacuum maintained than when cleaned only with rubber plugs, has also been shown. The estimated average gain in vacuum due to chlorination on a unit at Kearny operating at a 75 per cent load factor is 0.15 in. Hg, amounting to almost 1 per cent gain in steam consumption.

The amount of chlorine required to chlorinate a condenser at Kearny is based on the following data:

River-water temperature, deg. fahr.	Pounds per day	Number of days	Pounds of chlorine for period
32–50	40	121	4,840
50–70	60	152	9,120
70–80	75	92	6,900
Total		365	20,860

The advantages obtained by chlorination are:

1 Gain in vacuum
2 Elimination of rubber-plug cleaning
3 Elimination of boiling of condensers
4 Elimination of necessity of taking a condenser out of service to clean it, thus increasing the service availability of the unit. This also eliminates the extra cost of steam used for starting turbines.

The disadvantages of chlorination are:

1 Cost of chlorine
2 Maintenance of chlorinating equipment
3 Fixed charges on additional investment
4 Hazard.

These items for and against chlorination have been weighed for the conditions obtaining at Kearny Station, and it seems advantageous to install the system. In different plants the various items will vary in importance due to differences in character and temperature of water, loading conditions, etc.

Acknowledgment is due Dr. J. Baker and W. J. O'Connell for their cooperation and assistance in the work described.

Appendix

EXPLANATION OF WATER ANALYSES

Total Solids. Two analyses were made on each sample. The high results are due to the fact that the samples were sea water. The total solids then, for the most part, represent soluble material.

Suspended Solids. Three analyses, two for check, were run on each sample. Those marked (*a*) were evidently high because of the error in sampling, i.e., dragging of the "thief."

pH. Each sample was checked by two different indicators.

Acidity. This was determined by using phenolphthalein as an indicator. Therefore the acidity is due to CO_2 or mineral acids, or to both.

Alkalinity. This was determined by using methyl orange as an indicator. As there is no phenolphthalein alkalinity, the alkalinity in this test represents bicarbonates *only*.

Chlorides. Three analyses were run on each sample.

B.O.D. (Biochemical Oxygen Demand.) These results are liable to discrepancy due to the samples being sea water. The B.O.D. was a five-day test. The straight samples (no dilution) after incubation at 20 deg. cent. for five days showed no decrease in D.O. except in the three cases shown. The other dilutions, 50 per cent (50 per cent dilution water and 50 per cent sample) and 25 per cent (75 per cent dilution water and 25 per cent sample), also show a variety of results. This can be accounted for by the presence of chlorides, and more likely of nitrates, of which latter there may be a large quantity.

Discussion

BERT HOUGHTON.[3] Certainly every man operating condensers with harbor water will appreciate the difficulty of cleaning them by mechanical means. If the chemical method described will produce the desired result without attacking the condenser metal, it will indeed be welcome.

However, the writer is reminded of a similar experiment tried several years ago at the Hudson Avenue Station. In that case it was not condenser circulating water, but well water which was circulated through the generator air coolers, and it was about 15 per cent salt water. These air coolers became heavily coated with slime after a few months of operation. The water was analyzed bacteriologically and found to contain algae. The recognized method for the prevention of algae growth, the writer was advised, was chlorine treatment. The system at Hudson Avenue was such that the chlorine could be introduced at the discharge of the pumps, the treated water flowing into a large storage tank, in which there was considerable turbulence. It was felt that the conditions were particularly advantageous for thoroughly mixing chlorine with the water. An average of three pounds of chlorine per million pounds of water was used, the chlorine being fed continuously. This experiment was carried on for several weeks, but as the slime did not disappear, it was dropped.

The results obtained, however, coincide to some extent with those of the authors. They mention the fact that, starting with a dirty condenser, they were not able to eliminate algae growth. They have found, however, that starting with a clean condenser they can prevent algae growth. The interesting feature to

[3] Operating Superintendent, Brooklyn Edison Company, Brooklyn, N. Y. Mem. A.S.M.E.

the writer, in view of his experience, is that this growth could be prevented and the condensers kept clean with so small an amount of chlorine, of the order of 0.1 to 0.2 lb. per million pounds of circulating water. (The intermittent rate is higher—this refers to the average.)

The writer has made a comparison of tests on the condenser of

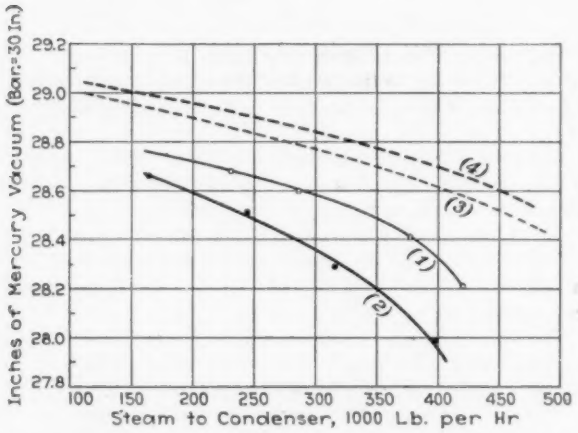

FIG. 9 COMPARISON OF CONDENSER PERFORMANCE AT KEARNY AND HUDSON AVENUE STATIONS

(1) Kearny No. 4, 1928: 50,000 sq. ft., 47,250 kw.; unchlorinated; circulating-water inlet temperature, 70 deg. fahr.; velocity, 9.7 ft. per sec.
(2) Kearny No. 4, 1929: 50,000 sq. ft.; 47,250 kw.; chlorinated; circulating-water inlet temperature, 78 deg. fahr.; velocity, 8.6 ft. per sec.
(3) Hudson Ave. No. 3: 70,000 sq. ft.; 50,000 kw.; old tubes, rubber plugged; circulating water temperature, 72 deg. fahr.; velocity, 8.4 ft. per sec.
(4) Hudson Ave. No. 2: 70,000 sq. ft.; 50,000 kw.; new tubes; circulating-water temperature, 72 deg. fahr.; velocity, 8.4 ft. per sec.

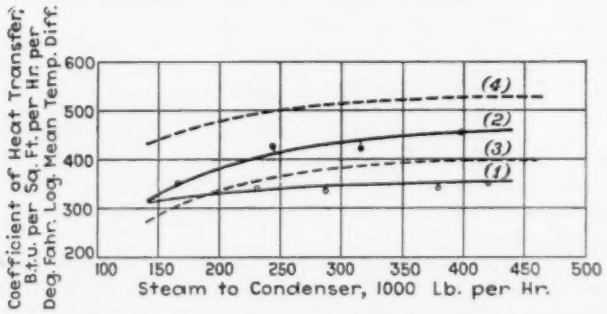

FIG. 10 COMPARISON OF CONDENSER PERFORMANCE AT KEARNY AND HUDSON AVENUE STATIONS

[(1), (2), (3), and (4): See notes under Fig. 9.]

unit No. 4, Kearny Station, with tests on units No. 2 and No. 3, Hudson Avenue Station. All three condensers are of the Westinghouse two-pass radial-flow type. Those at Hudson Avenue have a more liberal surface-to-kw.-capacity ratio, namely, 1.4 as against 1.06 for the Kearny No. 4 condenser. The two Hudson Avenue units are identical in design, and each has two circulating pumps with a combined capacity of 100,000 g.p.m. The Kearny No. 4 condenser has two circulating pumps with a capacity of 90,000 g.p.m.

Since the condensers in the two stations are similar in design, even though those at Hudson Avenue have surfaces of 70,000 sq. ft. each while Kearny No. 4 has only 50,000 sq. ft., a comparison can be made both directly and by applying adjustment factors to the results obtained in the two stations. There are two comparisons to be made, namely, No. 4 Kearny using chlorinated circulating water, with No. 2 Hudson Avenue with new tubes; and No. 4 Kearny without the use of chlorinated circulating water, with No. 3 Hudson Avenue after cleaning old tubes with rubber plugs. A few graphs will illustrate the comparisons.

The dottled lines on all graphs refer to Hudson Avenue units, the heavy ones being No. 2 with new tubes, the lighter ones, No. 3 with old tubes rubber plugged. The solid lines refer to Kearny Unit No. 4, the heavy ones after use of chlorinated circulating water. Data for the solid curves were taken from Tables 2 and 3 of the paper.

In Fig. 9 the curves are, in order of highest vacuum, Hudson Avenue No. 2 with new tubes; Hudson Avenue No. 3 with old tubes rubber plugged; Kearny No. 4 with unchlorinated circulating water; and Kearny No. 4 with chlorinated circulating water. The better performance of No. 2 and No. 3 Hudson Avenue is partly due to their having larger surfaces. This is particularly noticeable at high rates of steam flow; at 400,000 lb. per hr. there is a difference in vacuum of 0.3 in. of mercury

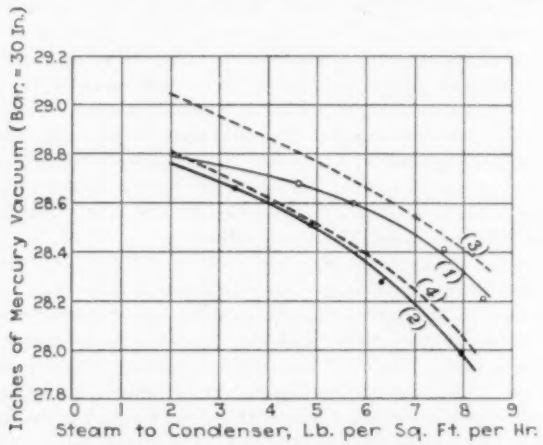

FIG. 11 COMPARISON OF CONDENSER PERFORMANCE AT KEARNY AND HUDSON AVENUE STATIONS

[(1), (2), (3), and (4) same as for Fig. 9, except that for (3), temperature is 70 deg. fahr. and for (4), is 78 deg. fahr.]

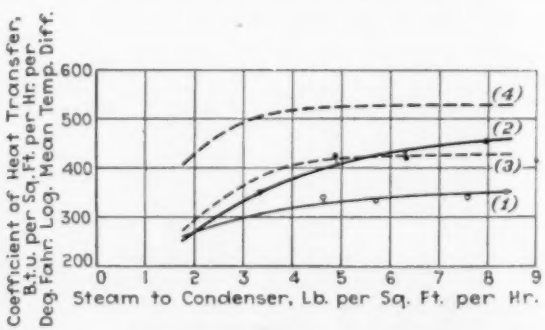

FIG. 12 COMPARISON OF CONDENSER PERFORMANCE AT KEARNY AND HUDSON AVENUE STATIONS

[(1), (2), (3), and (4) same as for Fig. 9, except that for (3) velocity is corrected to 9.7 ft. per sec., and for (4) to 8.6 ft. per sec.]

from the unchlorinated-water test, and 0.7 in. of mercury from the chlorinated-water test. The higher vacuum obtained with unchlorinated circulating water at Kearny is explained by the fact that the circulating-water-inlet temperature was 70 deg. fahr. as against 78 deg. fahr. for the chlorinated water.

Fig. 10 shows the heat-transfer coefficient of the condensers under the same conditions as in Fig. 9. Here the Hudson Avenue No. 2 with new tubes shows the highest coefficient, followed in order by Kearny No. 4 with chlorinated circulating water, Hudson Avenue No. 3 with old tubes rubber plugged, and Kearny No. 4 with unchlorinated water. The difference

between the two Kearny No. 4 curves is larger than it would be if the circulating-water temperatures had been the same.

In order to eliminate the effect of the sizes of the condensers, comparisons were made on the basis of pounds of steam per square foot of condenser surface per hour. The results of the Hudson Avenue tests were also corrected to conditions comparable to the tests on the Kearny Unit No. 4.

Thus Fig. 11 shows curves for Kearny No. 4 merely reduced to pounds per square foot per hour, while Hudson Avenue No. 2 has the test with the new tubes corrected to 78 deg. fahr. inlet temperature, which was that of the chlorinated water. Hudson Avenue No. 3 with old tubes rubber plugged was corrected to 70 deg. fahr. circulating-water temperature to correspond with the unchlorinated circulating water at Kearny. This graph shows the vacuum with the new tubes at Hudson Avenue to be only about 0.05 in. of mercury better than with chlorinated circulating water at Kearny. The chlorinated water is thus apparently very effective in improving the vacuum.

Hudson Avenue No. 3 with old tubes rubber plugged shows considerably improvement in vacuum over the Kearny No. 4 unit with unchlorinated water. There would actually be a larger difference, however, because the velocity at Hudson Avenue was only 8.4 ft. per sec. as against 9.7 ft. per sec. at Kearny. This shows that rubber plugging gives better results at Hudson Avenue than at Kearny.

Fig. 12 shows the heat-transfer coefficients under the corrected conditions. The comparison of Kearny No. 4, chlorinated water, with Hudson Avenue No. 2, new tubes, shows the latter to have the higher coefficient. Moreover, the Hudson Avenue curve is for 8.6 ft. per sec. velocity and 72 deg. fahr. temperature, while the Kearny unit is for 8.6 ft. per sec. velocity and 78 deg. fahr. inlet-water temperature. If these temperatures were the same, the difference between the curves would be increased, due to the factor of mean temperature difference increasing much faster than the additional heat transferred.

In the case of Hudson Avenue No. 3 and Kearny No. 4 with unchlorinated water the velocities are both 9.7 ft. per sec.; with the former the water-inlet temperature was 72 deg. fahr. while with the latter it was 70 deg. fahr.

The comparison would be more satisfactory if the Kearny tests had been made at more nearly the same conditions of circulating-water temperature and velocity. Nevertheless, the results of graph Fig. 11 indicate that further investigation is well warranted. A study of the effect of the chlorine on the life of the condenser metal would be of great interest.

M. H. Curley.[4] It would appear the authors have conclusively proved that condenser tubes can be kept clean from slime by use of chlorine, especially when such slime is a result of sewage pollution of the circulating water. The writer was particularly interested, as chlorine is being tried as a means of controlling mussel growth at the Northport Plant of the Long Island Lighting Company. He had an opportunity of examining the condenser under treatment in April, 1929, noting particularly the absence of slime on the interior of the tubes.

Bengough and May, of the Institute of Metals in London, England, are probably the world's foremost investigators of condensers and condenser tubes. In one of their reports issued early in 1925 under the sub-subject of "Water Treatment," they have this to say: "Slight chlorination of cooling water seems effective in killing or preventing the growth of organisms upon the tube wall, making it unnecessary to employ means of tube cleaning which promote corrosion." Apparently, while it has been known for some time that the use of chlorine would keep the tubes clean, no practical method of applying the chlorine treatment was available, and it is due to the development of practical apparatus by Wallace & Tiernan that full use of this treatment is made possible.

On first hearing about the experimental use of chlorine in the circulating system at Kearny, the writer was particularly interested, having in mind its use in control of mussel growth, as mussels in the circulating-water ducts of the company with which he is connected are far more serious than is the fouling of tubes. For the past two years, he has been investigating tube failures from inlet erosion-corrosion and has found that no trouble from this source exists where heavy sewage pollution is present. The sewage pollution, however, always results in bad slime on the tubes. The answer to an inlet erosion-corrosion, where a heavy coating of slime is present, is, no doubt, due to either or both of two reasons: namely, the slime coating protects the surface of the tubes against the action of the oxygen in solution in the circulating water; or the nitrates in the sewage consume the dissolved oxygen. When the oxygen content is low or nil, no inlet erosion takes place. It is also noticeable that no mussel growth is present where there is a heavy slime coating. Mussels of course cannot exist in water low in oxygen. In Table 1 of the paper, the circulating-water analyses show a very low oxygen content and it is of interest to know that there is no evidence of inlet erosion-corrosion on any of the tubes at the Kearny Station.

In view of the above, it would be well to point out a possible danger in the removal of slime from tubes by the use of chlorine, but not from the standpoint of any damage that may result from the chlorine itself.

In certain waters having possibly slight sewage pollution, but not sufficient to reduce to dissolved oxygen below the danger point, it is easily possible that considerable cleaning is required to remove the slime from the tubes. If the chlorinating system is applied, there is possible danger of cleaning the tubes so thoroughly that inlet erosion will be started. This danger can probably be avoided by using only enough chlorine to clean the tubes so as to leave a slight scum on the surface, this scum acting as protection against inlet erosion attack.

Near the beginning of the paper the authors give their reasons for injecting chlorine in the canal at the screen instead of at the suction pipe at the pump and later they bring up the question of the corrosion of condenser water boxes and tubes by the chlorine, also stating that the maximum residual chlorine found at any time at the inlet to the condenser was only 0.3 part per million. The fact that practically no residual chlorine actually entered the condenser eliminates in itself any question of danger of the corrosion of the condenser water boxes and tubes, and would also seem to indicate that it is most advisable to inject the chlorine in the stream of water going to the condensers as far from the inlet to the condenser as is practical.

The action of the chlorine is, apparently, to kill the algae growth, and this can be done in the stream of water on the way to the condenser as readily as it can be done after forming in the tubes.

The paper would have been much more conclusive had it given some figures of the savings effected in dollars and cents, comparing the cost of other methods of cleaning with the cost of chlorine treatment. Taking the figures given by the authors, it would appear that at the factor given and the size of the unit, the monthly output is 24,500,000 kw-hr. Assuming 10 lb. steam per kw-hr., this gives 245,000,000 lb. of steam. A betterment in the water rate of 1 per cent will show a saving on the above monthly output from this unit of approximately 2,500,000 lb. of steam. At 20 cents, the approximate fuel cost per 1000 lb. of steam shows a saving of $490 on the above monthly output. The summer condition of 75 lb. of chlorine per day, 30 days in a

[4] Long Island Lighting Co., Bay Shore, N. Y. Assoc-Mem. A.S.M.E.

month, gives 2250 lb. of chlorine, which, at 6 cents per lb. shows a cost of $135 for raw material. Assuming an investment of approximately $5000, at 16 per cent this gives about $66 per month for interest and depreciation charges, making a total cost of roughly $200 a month without any labor expense. This indicates a saving in use of the chlorine method of cleaning of approximately $300 per month over the method of cleaning by the use of rubber plugs. It would be of interest to know if the authors can give us the approximate monthly cost of cleaning condensers other than the one in which the chlorine is in use. This question of cleaning condensers is one about which the writer feels we know very little. The average plant plans to maintain an average vacuum and cleans whenever, in some one's opinion, it is necessary to do so to maintain the desired vacuum, irrespective of whether it is more costly to shut the unit down than it would be to maintain it in service over a longer period of time at the reduced efficiency due to the dirtier condition of the tubes. It is very rare to find the actual cost of cleaning condensers billed against the savings effected by such cleaning.

The Public Service Company and the Wallace & Tiernan Company are to be commended for taking the initiative in the use of chlorine for cleaning condenser tubes, and we should all be grateful to the authors for giving us the results of their work, which are bound to be very useful.

FSP-53-11

Electrical-Conductance Measurements of Water and Steam, and Applications in Steam Plants

By MAX HECHT[1] and D. S. McKINNEY,[2] PITTSBURGH, PA.

In this paper a conductance method is presented for determining the concentration of salts in steam-plant water supplies. The method is applied to determine the purity of steam, of supplies used for boiler-feed purposes, and the concentration of boiler and evaporator water. The conductance data are refined by applying both a water and a CO_2 correction. The method for establishing the CO_2 correction is based on the preparation of a standard "synthetic" water, and eliminates the errors accompanying the chemical analysis of "pure" water. The conductance meter used may be calibrated in terms of dissolved salts. The relation of dissolved salts to conductance is discussed. Simple commercial equipment is used for measuring conductance. The data are obtained rapidly by the steam-plant personnel, and the results may be applied easily to the control of water conditions.

OPERATORS appreciate the necessity of excluding any contamination from the steam and water cycle in steam power plants. Circulating water introduced via leaky surface condensers contaminates the water cycle. Erratic control of concentration of water in steam-generating apparatus and carry-over therefrom contaminate the steam cycle. The importance of entrainment rather than moisture should demand the critical attention of station operators. The entrainment of boiler-water salts in steam causes scaling and burn-outs in superheater tubes, and if the entrainment is carried into the turbine, blade deposits contribute to loss in turbine capacity and efficiency. The entrainment is also a factor in the deterioration of blade material because of erosion. In a review of a discussion of corrosion of iron, Whitney states that once corrosion of the metal of turbine blades is started, the water condensed in the steam passing through the turbine removes the corrosion products rapidly. The corrosion is influenced by the oxygen contained in the boiler feedwater. The deterioration is not noticeable in the initial turbine stages, which contact with dry and superheated steam, but is in evidence in the stages where the temperature of the steam is 100 deg. cent. (3)[3]. The possibility of one other factor which may influence the erosion of blade material is suggested: The rate of formation of water droplets may be accelerated in the lower pressure stages of the turbine because of the presence in the vapor of anhydrous dusts. The dusts are produced when the soluble salts and insoluble products discharged with the steam from the boiler drum are dehydrated in the superheater. It may be considered that the individual dust particles, which may be electrically charged, act as nuclei for the condensation of vapor surrounding them when favorable temperature conditions are reached in the lower-temperature stages of the turbine. The water-enveloped particles may induce a more severe erosive action than are caused by droplets free from dust.

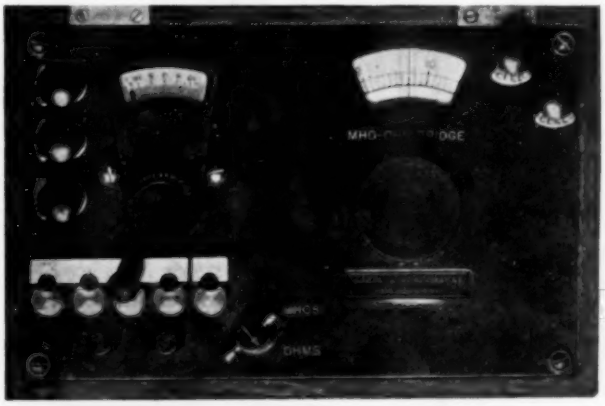

FIG. 1 PORTABLE CONDUCTANCE BRIDGE

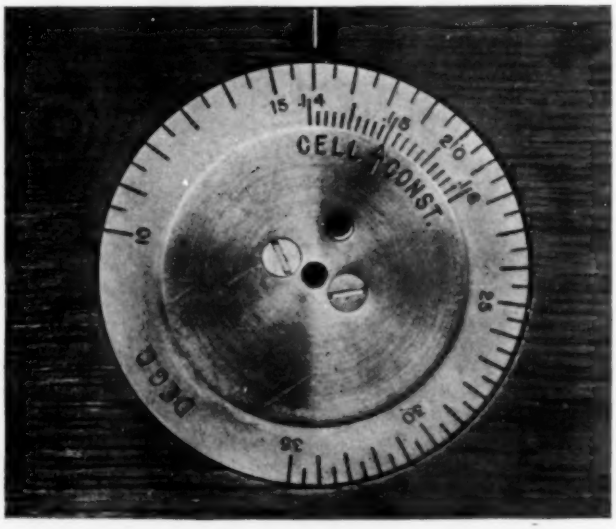

FIG. 2 TEMPERATURE AND CELL COMPENSATORS

SCOPE OF METHOD

The conductance method may be applied for all purposes where the relation between the "pure" and the contaminating supply is desired, or where concentration of soluble salts is to be controlled.

[3] Numbers in parentheses refer to bibliography at end of paper.

Contributed by the Joint Research Committee on Boiler-Feedwater Studies and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The conductance method is applied herein specifically to boiler-room problems. The paper includes a presentation of the conductance method for determining the per cent by weight of entrainment of boiler water in steam, the control of concentration of water in boilers and evaporators, the detection of carry-over from evaporators, and related studies to demonstrate the precision of the conductance method. Condenser-leakage detection by the conductance method is omitted as complete descripitons appear in the technical literature. See bibliography items (4) to (14); item (10) is of specific interest.

Theory

It will suffice for this discussion to state that the conductance of an aqueous solution depends only on the ions of the dissolved substances between the electrodes of a conductance cell. Furthermore, the specific conductance of a solution is a measure of the total of ionized substances, and depends on the kinds and quantity of the ions present. The theory of conductance in aqueous solutions is discussed by Creighton (15).

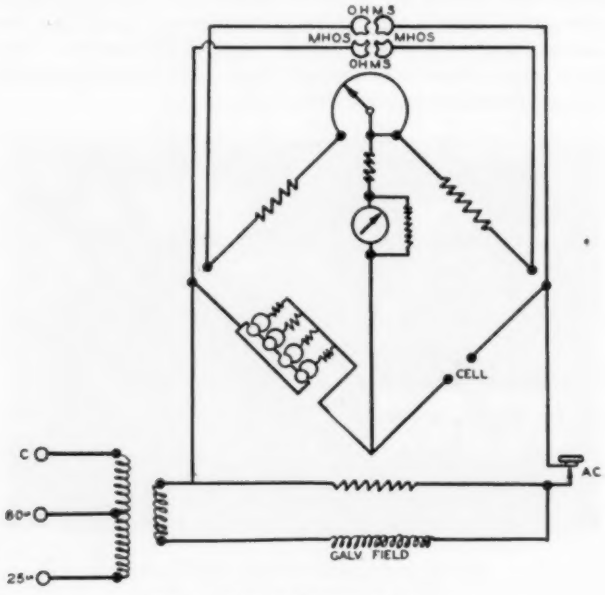

Fig. 3 Bridge Wiring Diagram

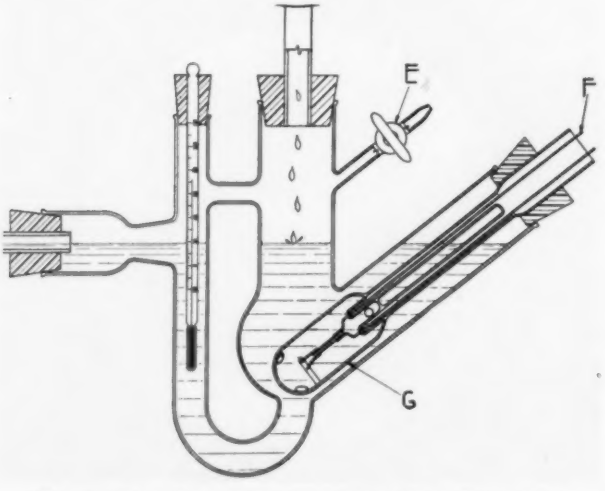

Fig. 4 Flow Cell and Conductance-Cell Electrode

Fitze (16) applied the conductance method for estimating moisture in steam leaving the boiler drum. He bases his application on the assumption that "impurities in the steam are due to entrained moisture carried over from the boiler, which, it is logical to assume, will carry over solids in the same proportion as the boiler water." In Fitze's method a per cent moisture curve was produced by measuring the conductance of boiler water and condensed steam, the latter generated in the boiler under observation. The conductance meter was calibrated in terms of the per cent of moisture by weight. This method may be considered to produce relative or apparent moisture results.

It is believed that the entrainment of boiler water in steam may be more correctly expressed if both the conductance of steam leaving the drum and the conductance of boiler water in the drum are coincidently measured, and the conductances after applying a water correction (conductance of pure water) and a correction for CO_2, are expressed as a ratio. It should be noted that hydrogen sulphide (H_2S) and ammonia (NH_3) also increase the conductance, and if present, corrections must be applied. If the ratio is multiplied by 100, this expression will show the per cent by weight of boiler water entrained in the steam.

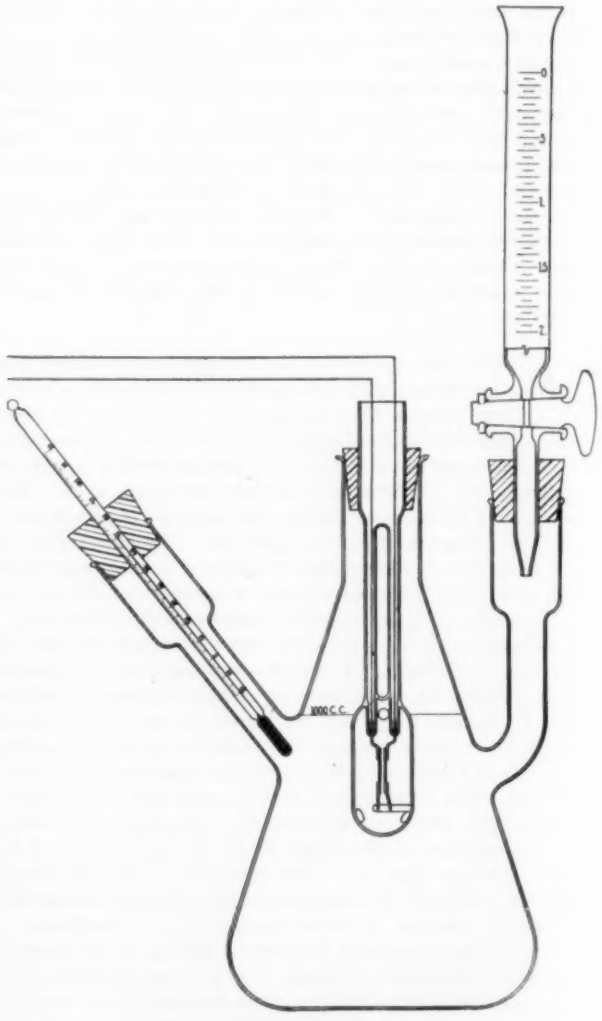

Fig. 5 Conductance Flask

$$\frac{\text{Conductance of steam}}{\text{Conductance of boiler water}} \times 100 = \text{Per cent by weight of entrainment of boiler water in steam}$$

It is not necessary to produce a calibration curve as described by Fitze.

Fitze and the authors observe similar conditions: the entrainment values are greater in magnitude than the moisture values obtained by the calorimeter method. It should be considered that the calorimeter furnishes data for estimating moisture, whereas the conductance data measure dissolved salts. For the specific purposes of obtaining data for estimating cleanliness of steam, it is apparent that the entrainment method is the appropriate one to apply.

Apparatus

The apparatus used for the investigation included a conductance meter, flow cells, a conductance cell, and a flask.

Conductance Bridge. This is a portable mho-ohm Wheatstone bridge operated on either 25- or 60-cycle alternating current. A special and very useful feature incorporated in the bridge is a temperature and cell-constant compensator. A general view of the bridge is shown in Fig. 1, and of the compensators in Fig. 2. The bridge has a range in specific conductance from 0.01 to 0.000001. The slide-wire range is from 1 to 12 mhos, each mho being divided into 10 divisions. The temperature compensator covers a range from 5 to 45 deg. cent. (41 to 113 deg. fahr.). The standardization point is 25 deg. cent. (77 deg. fahr.). The conductance-cell-constant compensator has a range from 0.07 to 0.11. The manufacturers state the instrument is calibrated to an accuracy of 1 per cent up to the 0.000001 ratio. Above that point the error may be as much as 5 per cent. The wiring diagram of the bridge is shown in Fig. 3.

Conductance Cell. The glass conductance cell fitted with platinized platinum electrodes is inserted in the flow cell or conductance flask. The cell was calibrated before the test runs were made; the cell constant was 0.861. This calibration is described in the appendix.

Flow Cell. This type of cell permits the measurement of a flowing supply, and prevents atmospheric contact and pollution. Two forms of flow cell were used. The one furnished with the apparatus is shown in Fig. 4. The improved flow cell, as shown in Fig. 6, was designed by the authors. In this design all of the water entering the cell must pass between the electrodes before discharging from the cell. The conductance flask (Fig. 5) was used in the correlated studies which follow the entrainment presentation.

All of the above apparatus, furnished by the Leeds and Northrup Company, is portable, and amply rugged and sensitive for both laboratory and plant use.

Sampling Connections on Boilers. An A.S.M.E. steam-sample nozzle was installed in a vertical run in the superheater-inlet steam lead. A connection for boiler-water samples was installed in the drum. The steam and water supplies were cooled under pressure in individual copper cooling coils, and the cooled supplies were passed through the flow cell, Fig. 4 or 6. A diagrammatic layout of the sampling system is shown in Fig. 7.

The importance of feedwater treatment and the control of boiler-water concentration justifies consideration by both the boiler manufacturer and operator in selecting proper locations and installing facilities on the boiler for procuring representative samples. Evans (17) discusses the variations in concentration in boilers due to rating, location of sampling point, and method of feed, and points out that variations in daily analyses are a source of great annoyance to the operators. One of the authors made a water transverse (18) across a cross-drum boiler and showed the wide variation in concentration.

TABLE 1 DESCRIPTION OF BOILER UNIT NO. 22

Item No.		
1	Type	B. & W. cross drum
2	Method of firing	Pulverized fuel
3	Water cooling applied	Side and rear walls Horizontal water screen

14	Water-holding capacity of boiler to drum center, lb	120,000

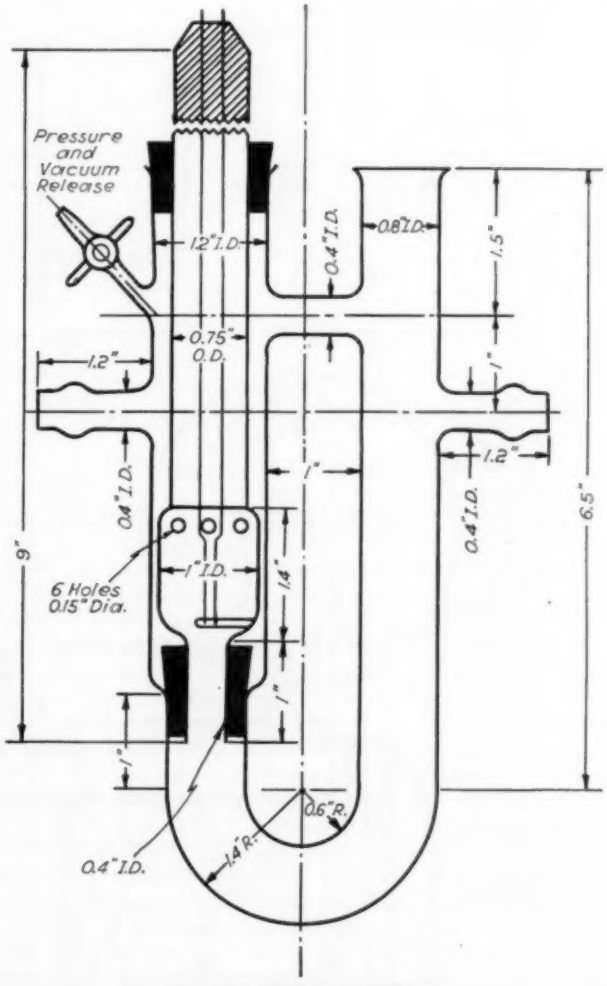

FIG. 6 REVISED FLOW-CELL

Entrainment Tests

The description of the boiler on which the entrainment tests were made is given in Table 1. The baffle arrangement in the drum is shown in Fig. 8. The steam is conducted to the superheater header by means of two leads from the drum. A throt-

tling calorimeter was installed in the "A" lead. The steam sample for conductance measurements was drawn from a connection to the throttling calorimeter on the "B" steam lead, at which the pressures before the calorimeter and the temperature at the calorimeter orifice were recorded. The recorded data were not used in these tests. The boiler-water-sample line was a $1^1/_2$-in. perforated pipe extending across the drum, above and parallel to the continuous feedwater pipe; the discharge holes in the latter are directed downward. The sample line was projected out from the drumhead via an unused extended water-

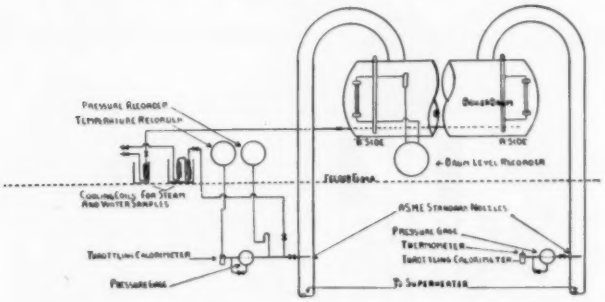

FIG. 7 SAMPLING SYSTEM AND ARRANGEMENT ON BOILER

included evaporation rates, water level, and steam quality by calorimeter, were observed once each 5 min. Conductance of steam was measured once each minute, and conductance of boiler water at the start and end of each test run.

METHOD FOR ESTIMATING ENTRAINMENT

Before each test run, the cooling coils were flushed, the discharge valves of the cooling coils were throttled, the flow cell was connected to the coil, and the cooling water was supplied at a rate to reduce the temperature of the condensed steam to within the range of the temperature compensator. Condensate was delivered from the steam coil at the rate of one quart per minute, and the boiler water from its coil at the rate of $2^1/_2$ quarts per minute. Conductance of the boiler water was observed prior to the start of the test, and when the readings became concordant, the values were recorded. The flow cell was connected to the discharge from the steam coil until consecutive readings were consistent, which gave assurance that the flow cell and conductance cell were free from boiler water. The conductance of the condensed steam was read once each minute, first adjusting the compensator for the observed temperature. Since the readings occurred at the low end of the bridge scale, a considerable travel of the slide wire was required to show a readable deflection of the galvanometer. In order to compensate for a possible error

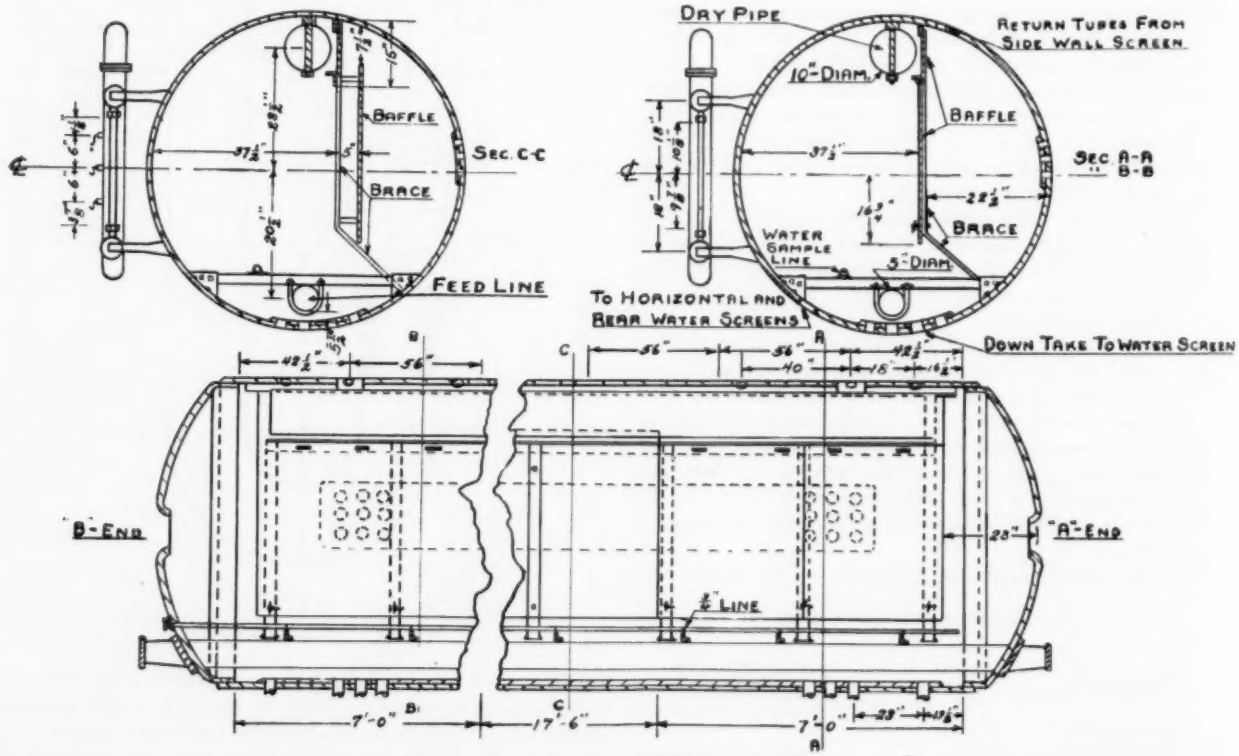

FIG. 8 BAFFLING ARRANGEMENT IN BOILER DRUM

glass connection. All external lines from the steam- and water-sample connections, including the cooling coils, were copper. No evidences of copper salts were found in samples which were completely analyzed, hence it was assumed that for the period the steam and water were in contact with the metals, the conductance introduced by their salts was negligible.

Data Observed. The boiler was under observation for a four-month period, and during this period 22 test runs were made to obtain simultaneous data on entrainment and steam quality, varying the rating and the water level. The data, which

in reading, the slide wire was rotated clockwise to show a positive deflection, and then was rotated counter clockwise until the galvanometer approached zero. This procedure was reversed for consecutive readings. After a test run was completed, the conductance of the boiler water was again measured. The average of the initial and final boiler-water readings was taken to represent the conductance of the boiler water during the $^1/_2$-hr. test run. At least $^1/_2$ hr. lapsed between tests to permit the stabilization of water and steam conditions.

A water correction of 0.9×10^{-6} mhos per cm. was deducted

from all conductance readings of steam and boiler water. Creighton (16) refers to Kendall (19), who has shown that by distilling tap water to which a few cubic centimeters of Nessler's solution has been added in Jena glass vessels and using a block-tin condenser in contact with air, water having a specific conductance of 0.9×10^{-6} mhos per cm. at 25 deg. cent. can be obtained in one distillation. The authors have observed a conductance of 1.49×10^{-6} mhos per cm. at 25 deg. cent. for distilled Pittsburgh domestic water. (Distilled in a Barnstead still having a block-tin-lined condenser, and collected and stored in large glass carboys.) This value is considerably lower than they were able to detect at the station where conductances of condensed steam, condensate, and distilled make-up were measured. In the absence of conductance data for water in contact with iron and copper, the Kendall value was adopted as the "water correction."

Each reading of conductance of steam and boiler water was corrected by deducting this correction, and each steam value was then divided by the boiler-water conductance. The quotient when multiplied by 100 is termed "entrainment in per cent by weight of boiler water in the steam." In a later section of this paper, it will be shown that the conductance of gases, and in particular CO_2, must be considered and a correction must be made in the application of conductance measurements to "pure" water supplies. The correction values are shown in the chart, Fig. 13, developed for Allegheny River water contamination of

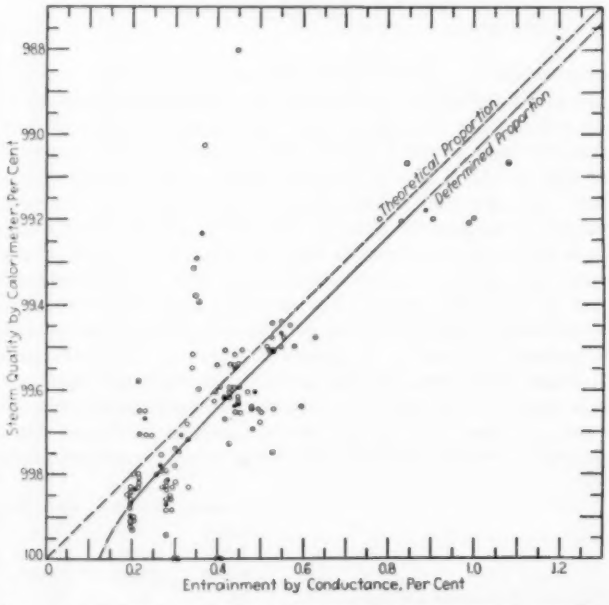

FIG. 9 RELATION OF STEAM QUALITY BY CALORIMETER AND ENTRAINMENT BY CONDUCTANCE

boiler feedwater. The CO_2 content of the condensed steam in these tests measured 0.75 part per million (p.p.m.). No correction was applied to the data since the error is large in estimating so low a CO_2 value. Where a considerable amount of CO_2 is present in the water, a deduction must be applied to the conductance of steam.

RELATION BETWEEN MOISTURE AND ENTRAINMENT

Efforts to plot the observed data for steam quality and entrainment against the other variables, water levels, and ratings indicated no direct relations. It is believed that this is due to the few number of test runs, and to the effects of other factors which were not observed. For example, variations in boiler-water concentration for the various test runs, fluctuation in concentration of boiler feedwater, normal fluctuation in flow rate of feedwater, and finally deviations of observed and actual water levels. A relationship is apparent between the steam quality by calorimeter and entrainment by conductance, and is shown graphically in Fig. 9. The steam-quality data plotted represent one reading each 5 min. and the simultaneously observed entrainment data represent the average of five one-minute readings. The 45-deg. diagonal passing through the origin represents the theoretical identity of the percentage of moisture in the steam and entrain-

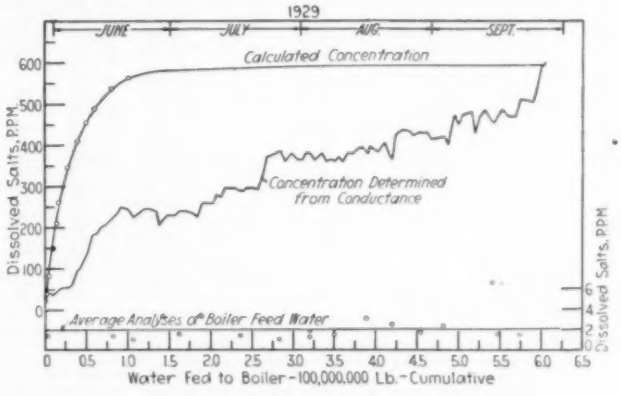

FIG. 10 CONCENTRATION OF BOILER WATER

ment. In the areas included between the diagonal and the abscissa, the per cent entrainment exceeds the per cent moisture by calorimeter. Observations plotted in this area indicate a possible throttling action by the dry pipe of the steam leaving the drum. In the area between the diagonal and the ordinate, the per cent moisture by calorimeter exceeds the per cent entrainment by conductance. Since the steam cannot carry moisture in excess of the amount entrained therein, values in the area above the diagonal would indicate an impossible condition. The observed values are represented by the circles for all runs. The dots represent the average per test run. The average for the calorimeter normal, test 12, and for tests 16, 17, and 18, in which attempts were made to observe steam quality under no steam-flow conditions, are shown on the 100 per cent quality line. If these four values are not considered, it will be observed the related data parallel in general the theoretical proportionality graph, but fall slightly below it. It is further noted for the same group of determinations that the distribution of points is much wider on the steam-quality scale than on the entrainment scale. This indicates that the entrainment method is more accurate than the calorimetric procedure. The wide divergence of entrainment values from steam quality, for very low and no steam-flow conditions, may be interpreted to represent non-equilibrium conditions as respects the quality of steam, because of the rapid reduction in evaporation rates to a condition suitable for establishing a calorimeter normal. For the observed conditions, it appears that the entrainment in steam is greater in magnitude for the lower steam-flow conditions than is found under the normal steam output of the boiler. Agreement is found with Fitze concerning the difficulties of establishing the calorimeter normal, even at lower boiler pressures. During the service run of the boiler a daily observation was made for concentration, using the conductance method. These values were translated to dissolved salts, parts per million, using the calibration curve *A-A*, in Fig. 12. The interpolated dissolved salts were plotted in Fig. 10. The calculated concentration curve was also plotted, based on the average per cent entrainment, 0.35 per cent, column 7, Table 2. The development and application of the formulas

Notes: Values in columns 9 and 10 corrected for conductance of pure water.
Values in column 8 calculated from formula in appendix.
Values in column 11 calculated from column 7 × column 12.
Values in column 12 interpolated from calibration curve Fig. 12.
Run 16—Burners off 12 min. before run started. Feedwater valves and steam valves shut.
Run 17—Burners off 70 min. before run started. Feedwater valves and steam valves shut, closed non-return valves.
Run 18—One burner lit, 10 minutes before run started. Feedwater valves and steam valves shut, closed non-return valves.
After run no. 15, calorimeter was disassembled, and mill scale removed which partly obstructed orifice.

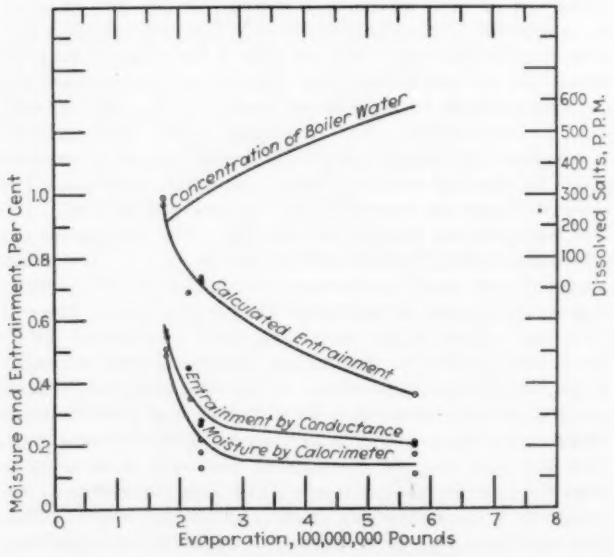

FIG. 11 STEAM QUALITY BY VARIOUS METHODS

for this calculation are discussed in the Appendix. The value used for entrainment (0.35 per cent) is the average of test runs 1, 3, 9, 10, 11, 13, 21, and 22, in which the evaporation rates were maintained between 230,000 and 250,000 lb. per hr. This output is normally maintained by the boiler for 20 hr. daily. The water levels in the drum were maintained below the drum center, which conforms to regular operating practice. The average of dissolved salts of the feedwater supplied to the boiler was 2.08 p.p.m. This value is read from Fig. 13, the calibration curve developed for dissolved salts in "pure" water in the presence of CO_2. The tabulated values for the calculated concentration plotted in Fig. 10 are given in Table 8. It will be observed by reference to Fig. 10 that the concentration at infinite evaporation (no blowdowns) is 594 parts per million (p.p.m.), and at 600,000,000 lb. evaporation the concentration determined by conductance was found to be 585 p.p.m. (The boiler was removed from service for inspection purposes.) The agreement of the calculated and determined value for concentration supports the view that the entrainment value used, 0.35 per cent, correctly expresses the average carry-over from the boiler drum. It is shown in the Appendix that the entrainment may be calculated, using the concentration of the salts in the feedwater and in the boiler water. The acceptance of the interpolated dissolved-salt values of boiler water based on conductance measurements is justified by the agreement shown in Fig. 12 of curves *A-A* and *B-B*. Similarly the use of the interpolated dissolved-salt values of feedwater is justified by the agreement shown between the dissolved salts in feedwater and in condensed steam shown in column 8, Table 7. A summary of the significant values is:

	Laboratory analysis		Field test
	Boiler feedwater	Condensed steam	Condensed steam
Number of samples averaged.....	22	2	20
Dissolved salts, calculated from the analysis, p.p.m.....	2.63	1.63	...
Dissolved salts, interpolated from conductance, p.p.m.....	2.08	2.50	1.1[b]
Specific conductance, mhos per cm. × 10^{-6} at 25 deg. cent.....	5.45[a]	6.10[a]	2.20

[a] Time interval between sampling and analysis, one week.
[b] Calculated from entrainment data.

The interpolation of conductance to dissolved salts is made from the graph in Fig. 13. The entrainment was calculated using the boiler-feedwater interpolated value of 2.08 p.p.m. The comparison between the determined and calculated entrainment and steam quality by calorimeter plotted against total evaporation is shown in Fig. 11; at the maximum evaporation agreement is observed between the calculated and determined entrainment. The tabulated data are shown in Table 3. The agreement as

Oxides, iron and alumina (R_2O_3)	4.2
Sum of colloidal salts	19.6 (*b*)
Dissolved solids ($a + b$)	159.9

Note: The colloidal salts are considered to have a negligible effect on the conductance of water.

The weights of chemically pure reagents were calculated from the dissolved ion values in Table 5, to produce when dissolved, the "synthetic" water containing 1000 p.p.m. of dissolved salts. The weights are shown in Table 5-A.

shown between the determined entrainment and moisture by calorimeter was anticipated from the concordance observed in Fig. 9.

In Fig. 10 a wider divergence is observed during the initial part of the run between the observed dissolved salts (interpolated from conductance) and the theoretical concentration, but at the end of the run the two curves coincide. Similarly in Fig. 11 closer agreement is observed at the end of the run between the steam quality by various procedures than is found in the early part of the run. It is further observed that the steam quality apparently improved with the increase in concentration of boiler water and total evaporation. Hence it may be noted that for the observed case some condition existed in the more dilute water which is unfavorable to the production of dry and clean steam.

Boiler- and Evaporator-Water Concentration Measured by Conductance

In attempts to measure concentration of boiler water by conductance an electrode was designed by other investigators (private communications) for insertion through the drum of a boiler. The difficulties encountered included the deterioration of the insulation of the cell element by the boiler water, and inability suitably to locate the element in a zone of uniform water concentration and temperature. Relatively large errors in measurements may be caused by local variations in concentration and temperature when fresh feedwater is introduced into the drum adjacent to the location of the cell. These observations apply as well to evaporators, and in the following discussion it should be remembered that concentration in evaporator salines is included, even though not specifically discussed.

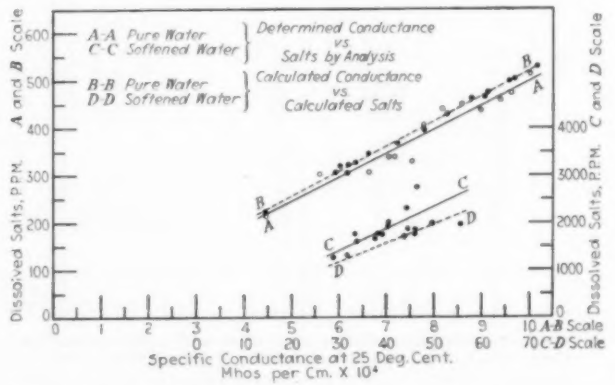

FIG. 12 RELATION OF SPECIFIC CONDUCTANCE TO THE DISSOLVED SALTS IN BOILER WATER

These difficulties were avoided by adopting the simpler procedure of withdrawing water through an internally installed perforated pipe extending across the drum. The water was cooled under pressure to prevent "flashing," and the conductance was measured as the water passed continuously through a glass flow cell (Fig. 6) in which the conductance cell was installed. Compensation was made for temperature observed before each

TABLE 5-A WEIGHTS OF REAGENTS FOR "SYNTHETIC" RIVER WATER

Reagents, chemically pure grade:	Weight in solution milligrams
Calcium sulphate, $CaSO_4.2H_2O$	596.4

Sodium bicarbonate, $NaHCO_3$	164.5
Sodium sulphate, Na_2SO_4	66.2
Sodium chloride, NaCl	157.4
Sodium nitrate, $NaNO_3$	2.8
Sum of dissolved salts	1268.9

The weights of reagents were dissolved in laboratory distilled water, (boiled to free the water of atmospheric gases, cooled, but excluding CO_2). 1 cc. of the solution contains 1 p.p.m. dissolved salts (anhydrous basis).

conductance reading. The readings were reported in specific conductance at 25 deg. cent.

As previously stated, the conductance of water varies directly as the dissolved salt content, provided the relation of the ions in the water remains the same. For each supply of water or steam in a specific station, the relation of conductance and dissolved salts will be a constant; however, the constants will differ from one another for various supplies. When desired, the calibration of the conductance meter is made in terms of dissolved salts, parts per million, the adopted procedure for stating concentration in plant control (20). The calibration, once established, is permanent, and is applicable to all boilers in the station unless a major change is made in the quality of feedwater or chemical treatment.

[b] Used average of sp. cond. values observed in tests numbers 1 to 5.

The data required for calibrating the meter include a series of conductance readings, and dissolved salt concentrations, the latter determined by analysis, over the range of concentration anticipated in the service run of a boiler or an evaporator. The smooth curve drawn through the plotted points establishes the desired relation for the boiler water under observation, and permits the ready conversion of conductance units to dissolved salts. When the conductance is to be expressed in specific-conductance units, it must be referred to a stated temperature, and the cell constant must be known and applied. Temperature correction and cell-constant calibration are discussed in the Appendix. In the laboratory analysis of water, the weights are obtained both of the dried residue after evaporating a measured volume of filtered water and of the constituents of the residue. The analysis report gives the weight in parts per million of colloidal and non-ionized materials which include organic matter, silica, and oxides of iron and aluminum, and of ionized materials which may include calcium, magnesium, sodium, carbonate, bicarbonate, hydroxide, sulphate, phosphate, chloride, and nitrate. The evaporated residue is termed "dissolved solids." When the sum of the colloidal and non-ionized materials is subtracted from the dissolved solids, the difference is termed "dissolved salts."

Conductance by Calculation

The conductance may be calculated from the ionic analysis by multiplying each ion present by the respective equivalent ionic-conductance factor. The sum of the products equals the conductance of the water expressed in specific-conductance units. It may be considered that practically complete ionization of salts occurs in water at the concentrations normally met with in the various supplies in the steam plant. Neglecting the colloidal substances, which lack conductance characteristics, the water contains metallic and non-metallic ions, each possessing a distinct ionic equivalent conductance. The factors for converting the ions to conductance, and the application of the factors to a typical boiler-water analysis, are shown in Table 9. The calculation of the ionic analysis to hypothetical combination to determine the dissolved salts is both unnecessary and erroneous (20). The comparison of the measured and calculated conductance provides a means of determining the relation between dissolved salts and conductance and for checking the analytical procedure.

As previously stated, observations for steam quality were made on a boiler during its service run. The feedwater supplied to the boiler was a mixture of 98 per cent condensate and 2 per cent distilled make-up. The boiler water was sampled periodically. These samples were completely analyzed, and the conductance was both measured and calculated. The data are shown graphically in Fig. 12 and are tabulated in Table 4, showing the relation between conductance and dissolved salts. A similar procedure was used at another station for establishing the relation between conductance and dissolved salts of boiler water. This boiler was supplied with 100 per cent zeolite-softened feedwater. These data are also included in the graph and table.

Conductance Method Produces Close Results

The values are reported as specific conductance at 25 deg. cent. The water correction 0.9×10^{-6} mhos per cm. has a very small effect on the observed values of boiler water, hence the origin of the graphs may be considered at zero conductance and dissolved salts. In Fig. 12 the curves marked *A-A* and *B-B* refer to the station where "pure" feedwater was concentrated, and curves marked *C-C* and *D-D* refer to the station where zeolite-softened water was concentrated. The calibration curves for each station are respectively *A-A* and *C-C*. They represent the relation of observed conductance (column 4) and dissolved salts by analysis (column 2) in Table 4. The curves drawn to check this procedure, *B-B* and *D-D* for each respective station, represent the relation of calculated conductance (column 5) and dissolved salts calculated from the analysis (column 3). The boiler-water concentration in terms of dissolved-salts range for the "pure" water station was from 215 to 474 p.p.m., and for the zeolite-softened water station, from 1100 to 2750 p.p.m. The agreement between the two procedures is shown by the values taken from each curve and shown in columns 6 and 7. It may be concluded that the conductance method produces results well within the error of analysis. It is obvious that the conductance measurement made in less than one minute after the sample is available is preferable as a plant procedure for concentration control, when compared to the many hours required for the completion of the analysis.

CO_2 Correction of Conductance

The authors recently recommended the installation of conductance apparatus for recording the quality of condensate returned to a central heating plant through an extensive condensate-return system. Since it was desired to calibrate the recorded data in terms of actual dissolved salts, a laboratory investigation was made to determine the effect of varying concentration of CO_2 on the conductance of water and the development of a CO_2 correction curve. Also in the case of evaporators, when CO_2 gas is evolved from the water fed to the evaporators, the conductivity of the condensed vapor is not a true measure of dissolved salts unless the conductance is compensated for the influence of CO_2.

A survey of the available "pure" water supplies in the various steam stations and of laboratory-distilled water produced evidence that the laboratory supply prepared in a Barnstead still, and having a block-tin-lined condenser, had a minimum of con-

Measured conductance		44.7

ductance measured after cooling the boiled water and preventing contact with CO_2. When calibrating the conductance meter by selecting the "best" supply at the station, an error may be unavoidably introduced because the quality of the supply may vary. It is convenient to use a "standard" water for calibrating the conductance meter in terms of dissolved salts, the calibration including a CO_2 correction.

Method for Developing CO_2 Corrections for Conductance

The procedure used in the development of the standard "synthetic" water eliminated the necessity of making a series of complete analyses of distilled supplies. The analytical errors introduced would be greater in magnitude than the actual dissolved salts in the water. The method used was to add increasing increments of dissolved salts to laboratory-distilled water, measuring the conductance, then adding varied amounts of CO_2 saturated water and remeasuring the conductance.

The "synthetic" water was made by averaging 20 analyses of Allegheny River water which include the yearly range in dissolved salts. Allegheny River water supplies three of the steam stations in Pittsburgh operated by the Duquesne Light Company and its subsidiaries. The data obtained are being applied to each station for steam-quality studies.

The necessary volume of the laboratory-distilled water was boiled to free it of atmospheric gases and then cooled, preventing the absorption of CO_2. Various volumes of the "synthetic" water were added to the CO_2-free distilled water to obtain increasing weights of dissolved salts, preparing a 1.1 liter volume of each concentration. The conductance of the solution was measured using the conductance flask, Fig. 5. The CO_2 was estimated in a sample removed from the flask (21). Another sample was saturated at room temperature with CO_2 gas released from a CO_2 tank. Approximately 5-cc. increments of the CO_2 saturated solution were added to the main solution. A conductance reading was observed, following which a 50-cc. portion was removed for estimating the CO_2. This procedure was repeated for the increase in concentration of CO_2 up to the desired maximum.

A curve was drawn for each increment of dissolved salts showing the relation between CO_2 and conductance. These curves were extended to zero CO_2. The conductance of the water at zero CO_2 was then plotted against dissolved salts added, and the curve extended to a conductance of 0.07×10^{-6} (the conductance of pure water at 25 deg. cent.) (22). This point represents zero dissolved salts. The negative of the dissolved salts indicated by this intersection is the concentration of the distilled water. In these data this value was 0.6 p.p.m. (It must be appreciated that accurate determination of this value by chemical analysis would be difficult.) This value represents the water correction, which is added to the data of column 2, Table 6, for construction of the final curve. The final curve so obtained is shown in Fig. 13, marked zero CO_2. From the first family of curves, values of conductance for even parts per million of CO_2 may be read and curves for various CO_2 contents constructed.

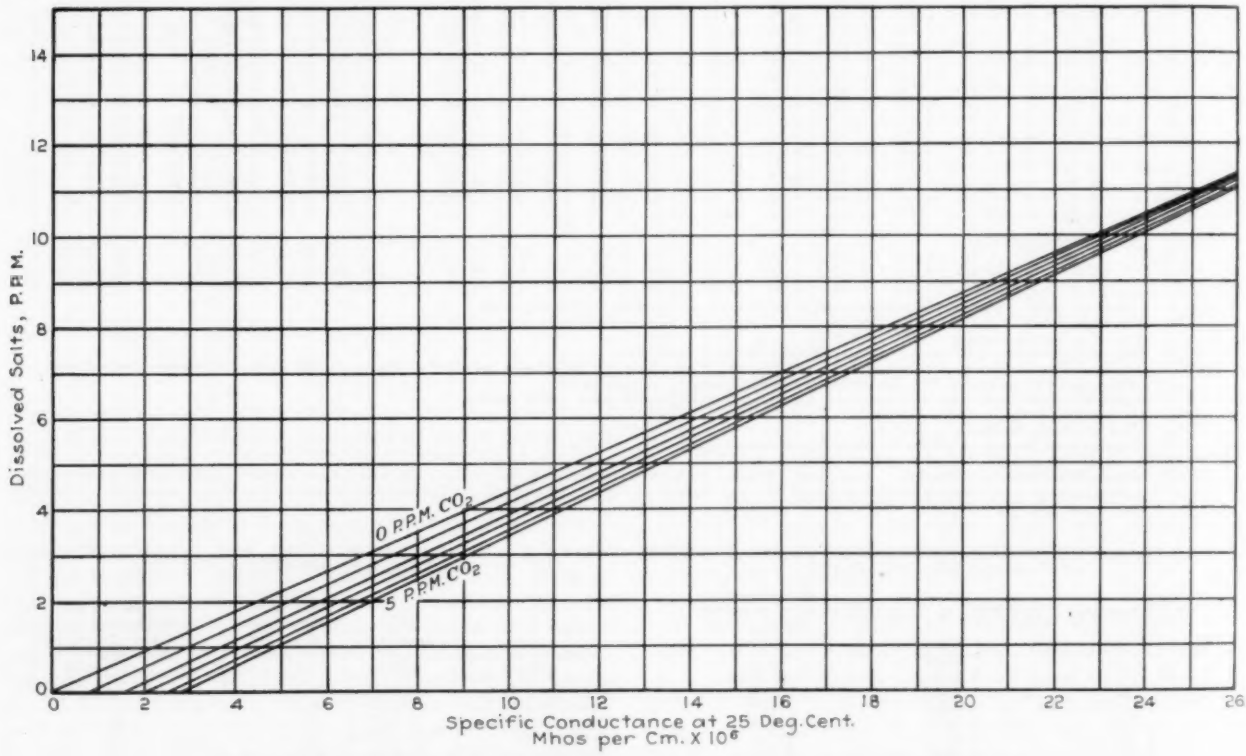

Fig. 13 Dissolved Salts in Feedwater and Correction of Conductance for CO_2

The curve shown in Fig. 13 was used to obtain the dissolved-salt values, column 8, shown in Table 7. The related data shown in the table support the view that the conductance method may be considered accurate for pure-water supplies, as in the chemical procedure unavoidable errors are introduced: first, dust inclusions while the water is evaporated, and second, the analytical errors in estimating small amounts of constituents.

Application of Conductance

In addition to the detection of condenser leakage, the conductance method is valuable for tracing and locating introductions of raw water at other points in the feedwater cycle.

One practical application of conductance equipment will be described in tracing the source of contamination in a large re-

turn system. Two steam plants of the Allegheny County Steam Heating Company supply the central business section of Pittsburgh with steam for heating purposes, and the extensive distribution system includes facilities for the return of the major portion of condensation to the boilers. It is essential that the returns be free of scale-forming contamination, for at one plant these returns provide 80 per cent of the feedwater, and at the other plant the returns will eventually amount to 65 per cent of the feedwater. Boiler outage for cleaning purposes cannot be scheduled during the six-month heating season, throughout which period the heat-transfer surfaces of the boilers must be kept free from scale. To insure this clean condition, a limited amount of treatment is added to the boiler water. Obviously if the contamination in the returns is held to a minimum, the treatment dosage may also be limited, and the generated steam furnished is clean.

The source of contamination is the domestic city-water supply, introduced into the returns by leaks in the customers' water heaters, since the city-water pressure exceeds the steam pressure used for this service. Conductivity recorders are installed at each steam plant, and are equipped with manually adjusted compensators for temperature and CO_2 correction. The recorded data are shown in terms of dissolved salts. The station chemist makes a daily test for CO_2 in the condensate and adjusts the CO_2 compensator. The station operator observes the temperature of the condensate once per shift, and adjusts the temperature compensator. The recorder is provided with alarm contacts which give both a bell and light signal when the dissolved salts reach the maximum setting, which is 25 p.p.m. dissolved salts. The station operator advises the maintenance division when the continuous record above 25 p.p.m. is noted, and a survey is started to locate the point of contamination. Samples of condensate are obtained at junctions of the various branches and the main return line. Measurements are made using the portable conductance bridge to identify the contaminating branch. Samples are then obtained at each customer's premises, and the leaking location is readily found. The customer cooperates by making the repair to the leaky coil, and until it is made the condensate at this location is diverted to the sewer.

In the usual instances where the surveys were made, the detection was made by the above procedure in a single working day. A system of detection lends itself to similar applications in the industrial field where process steam condensed may be returned to the boiler.

Carry-over of evaporator liquor into the vapor requires immediate correction if deposits in boilers are to be held to a minimum. The continuous observation for small amounts of carry-over by chemical means is difficult and time-consuming. The application of a conductance recorder for this purpose provides a visible record, and the operation of the evaporator can be immediately adjusted to eliminate the production of poor-quality vapor. Relatively large amounts of CO_2 are evolved in the evaporator due to the thermal decomposition of the bicarbonate and carbonate present in the evaporator feedwater. Correction must be applied to the conductance in order to obtain the dissolved-salt content. An installation of recorders has been made on evaporators at the Colfax power station for this purpose. The recorders are equipped with CO_2 and temperature compensators. The conductance cells are installed in receptacles through which a portion of the condensed vapor from the evaporator passes. The concentration of liquor is measured using a portable conductance bridge. This system permits a more ready control of quality than has been previously experienced.

The trend in recent boiler-plant practice is toward treatment of feedwater, even in distilled-water stations. Such water conditions demand a more intensive control of concentration in the boilers if entrainment of salts in the steam is to be held at a minimum. Respecting the apparatus, it appears that continuous blowdown systems equipped with heat exchangers are past the experimental stage. However, there is need for improvement in the methods of controlling concentrations within desired limits with the use of such equipment. Conductance methods are readily applicable to the problem of measuring concentration and steam quality. The measurements are easily observed provided adequate sampling facilities are available. The measurements may consist of "spot" readings if a portable conductance meter is used, or, where a continuous record is desired, the conductance of condensed steam and of boiler water may be recorded. The entrainment of salts in the steam is readily calculated from these data.

Sampling facilities are installed on the boilers at the Colfax station for obtaining steam and water samples, and the conductance data are being used for limiting entrainment and control of concentration. The portable conductance bridge and a flow cell are used for obtaining the readings.

It is possible to consider as a practical application a system of indicating or recording conductance apparatus combined with motor-operated valves automatically controlling concentration in steam-generating vessels. The recorder may show actual concentration. If alarm contacts are electrically connected to a controller, a motor-operated valve on a continuous-blowdown system may be regulated to maintain concentrations in the water between suitable limits. It is further considered that a system of automatic control can be applied to evaporators, whereby thermal conditions within the evaporator may be adjusted automatically to permit the production of clean vapor. In this application, conditions of back pressure and dilution of the liquor may be adjusted automatically by motorizing both the vapor-outlet and blowdown valves, the regulation to be made via a controller, energized when the vapor quality exceeds a set maximum value.

Conclusions

The conductance method has been successfully applied to boiler-room problems for observing entrainment in steam and concentration of salts in steam-generating vessels.

The accuracy of the conductance method equals that of chemical analysis when concentrated water supplies are tested. The accuracy of the conductance method if corrected for CO_2 is superior to that of chemical analysis when pure water supplies are tested.

The entrainment method described is shown to evaluate correctly the amount of carry-over from steam-generating apparatus. The speed and simplicity of obtaining conductance data recommends it as a valuable plant method.

Acknowledgment is made to the engineering personnel of the Power Stations Department of the Duquesne Light Company for the assistance lent in accumulating the calorimetric data, and for the critical review of the manuscript.

Appendix

Conductance Cell Constant. The cell constant of the conductance electrode should be known so that the observed conductance data will be comparable regardless of the cell used. The constant should be redetermined if the electrodes require cleaning or replatinizing. In commercial practice the electrode areas and spacing are not 1 sq. cm. (0.155 sq. in.) nor 1 cm. (0.3937 in.), respectively. However, the cell constant may be found by determining the conductance of any solution whose specific conductance has been exactly established. Generally a potassium chloride solution is used for this purpose. Creighton gives a

value of specific conductance for 0.1 N potassium chloride of 0.0128988 mhos per cm. at 25 deg. cent. (15). The 0.1 N solution is prepared by dissolving exactly 7.4556 grams of chemically pure potassium chloride in distilled water, in a 1-liter volumetric flask, and diluting the solution to exactly 1 liter. The solution should be prepared at 25 deg. cent. The cell electrode and a thermometer are inserted in a glass vessel, and a volume of the prepared solution is added to the vessel sufficient to submerge the electrodes. The temperature of the solution should be adjusted to 25 deg. cent. ± 1 deg. The observed conductance and corresponding temperatures are plotted, and the conductance at 25 deg. cent. is read from the graph. The value is substituted for c in the equation, which is solved for K.

$$K = \frac{k}{c}$$

where K = cell constant
k = specific conductance of 0.1 N potassium chloride at 25 deg. cent.
c = measured conductance of 0.1 N potassium chloride at 25 deg. cent.

If the conductance meter measures resistance, the reciprocal of the reading should be used for c.

Note 1. Two standard temperatures, 18 and 25 deg. cent. appear in the literature. The 25-deg. standard more nearly approximates room-temperature conditions. This temperature appears in recently published methods.

Note 2. When out of service the electrodes should be submerged in distilled water. If the electrode surfaces have been allowed to dry, they should be rinsed with denatured alcohol and distilled water before using. When first using electrodes, or after replatinizing, a period of 30 min. should elapse before readings are taken.

Note 3. If the electrodes have been contaminated, they should be replatinized. A 3 per cent platinic chloride solution with $^1/_{40}$ per cent of lead acetate is used for platinizing. The electrodes are immersed in the solution and the leads connected to a dry cell supplying sufficient voltage to cause a barely appreciable evolution of gas. The polarity is reversed frequently and the operation continued for 3 to 5 min. until the electrodes are both covered with a velvety black deposit.

Temperature Correction. The specific conductance of aqueous solutions increases with temperature rise. In practice, an approximate temperature correction may be applied, since it is not always convenient to measure the conductance at the 25-deg. cent. standard. Any conductance (L_m) measured at a temperature t_m may be calculated to a standard temperature t_s by substitution in the following formula:

$$L_s = \frac{L_m\,(t_s + K)}{t_m + K}$$

If temperatures are measured in degrees centigrade, K = 20.6; if in degrees fahrenheit, K = 5. The standard temperature used herein is 25 deg. cent. or 77 deg. fahr. The coefficient 2.1 per cent per deg. cent. or 1.2 per cent per deg. fahr. may be used for small temperature differences (10).

Conductance Calculations. Reference is made in the paper to the calculation of conductance from the ions found in water. The factors for converting the parts per million to the specific conductance values are given in Table 9, and an example of the calculation is also shown.

Calculation of Boiler-Water Concentration and Entrainment From Chemical Analyses. The development and application of formulas for checking the rate of concentration, and of entrainment permit verifying the actual concentration, which is shown plotted in Fig. 10, and steam quality and entrainment, columns 6 and 7, respectively, in Table 2.

Rate of Concentration of Boiler Water.

Let F = total boiler feed in lb. × 10^6
C = concentration of boiler water in p.p.m.
c = concentration of boiler feedwater in p.p.m.
K = holding capacity of boiler in lb. × 10^6
E = entrainment as fraction of F.

Then

$$\frac{dC}{dF} = \frac{c - CE}{K}$$

and

$$\int_{F_1}^{F_2} dF = \int_{C_1}^{C_2} \frac{K\,dC}{c - CE} = \frac{K}{E}\int_{C_1}^{C_2} \frac{dC}{(c/E) - C}$$

Then

$$F_2 - F_1 = \frac{K}{E}\log_e (c - C_1E) = \frac{K}{E}\log_e (c - C_2E)$$

$$F_2 - F_1 = \frac{K}{E}\log_e \frac{(c - C_1E)}{(c - C_2E)}$$

Changing to $\log_{10}$ and transposing,

$$E(F_2 - F_1) = 2.303K \log \frac{(c - C_1E)}{(c - C_2E)} \quad \ldots\ldots\ldots [1]$$

Case 1. To Determine if Blowdown Is Necessary to Limit Concentration. It will be appreciated that at infinite evaporation (assuming no scale is deposited) the weight of solids entering the boiler must equal the weight leaving it entrained in the steam, or

$$c = C_2E \quad \text{and} \quad C_2 = \frac{c}{E}$$

This may be derived mathematically as follows: Equation [1] may be written

$$c - C_2E = \frac{c - C_1E}{10^{\frac{E(F_2 - F_1)}{2.303K}}}$$

The limit of the right-hand side of the equation as F approaches infinity is zero, hence when F equals infinity,

$$c = C_2E \quad \text{and} \quad C_2 = \frac{c}{E}$$

If substitution in this formula leads to a value of C_2 below the maximum allowable value, no blowdown is necessary. Example (Case 1):

c = 2.08, from Table 7, average of column 8
E = 0.35 per cent = 0.0035 from Table 2 average of column 7

$$C_2 = \frac{2.08}{0.0035} = 594.3 \text{ p.p.m.}$$

From experience, the maximum allowable concentration of boiler water has been empirically set at 4250 p.p.m. Hence no blowdowns are necessary for control of dissolved salts. Blowdowns may be made if suspended solids are present in the water, provided the boiler has been banked. The purpose of the blowdown is to prevent the sedimentation on the lower tube-bank surfaces.

Case 2. Change in Concentration With No Blowdowns.

$F_2 - F_1$ = Evaporation
c = C_1
F_1 = K

Equation [1] then becomes

$$\frac{E(F_2 - F_1)}{2.303K} = \frac{E(\text{evap.})}{2.303K} = \log \frac{c(1 - E)}{c - C_2E} \quad \ldots\ldots [2]$$

Example (Case 2): The concentrations calculated at various evaporations with no blowdowns, using Equation [2], are shown in Table 8, and these values are plotted in Fig. 10. The values used for the calculations are:

c = 2.08, from Table 7, average of column 8
K = 0.12 million lb., from Table 1, item 14
E = 0.35 per cent = 0.0035, from Table 2, average of column 7.

The steps in the calculations are illustrated when calculating the concentration for the evaporation of 10,000,000 lb. Substituting in Equation [2],

$$\frac{0.0035 \times 10}{2.303 \times 0.12} = \log \frac{2.08(1 - 0.0035)}{2.08 - C_2 \times 0.0035}$$

$$0.1266 = \log \frac{2.08(1 - 0.0035)}{2.08 - C_2 \times 0.0035}$$

$$1.3384 = \frac{2.08\ (1 - 0.0035)}{2.08 - C_2 \times 0.0035}$$

$$C_2 = 151.6$$

Case 3. Change in Concentration With Continuous Blowdown. By substituting in Equation [2], the maximum allowable value for C_2, F_2 can be calculated. Blowdown should commence at this point.

Let B = blowdown in lb. $\times 10^6$
C_3 = concentration of boiler water after blowdown and refilling to original water level.

Then

$$C_3 = C_2 \frac{K - B}{K} + c \frac{B}{K}$$

Substitute C_2 in Equation [2] and recalculate F_2; call this value F_3. Then, $F_2 - F_3 + B$ = amount of water (in lb. $\times 10^6$) that may be fed to the boiler before the next blowdown. Since each succeeding cycle will be identical, this is all the calculation required.

Case 5. Scale or Sludge Formation. In case scale or sludge is being formed in the boiler, the calculated value of C_2 will exceed that actually attained. In this case c should be decreased by the concentration of scale forming materials in the boiler feedwater.

Case 6. Change in Water Level. Calculate C_2 using Equation [2]. Let K be holding capacity at the original water level, and K_1 be the holding capacity at the new water level. Let C_3 be the concentration at the new water level. Then

$$C_3 = C_2 \times \frac{K - K_1}{K}$$

The various holding capacities of the boiler must be calculated for corresponding water levels from the boiler dimensions.

Note: In general, knowing any two of the quantities, c, C_2, and E_1 the third quantity may be calculated for any value of F_2 using Equation [2]. It should be noted that very slight errors in the determination of E (or of c if the boiler feed is of high purity) will make large differences in C_2.

It should also be noted that the equation leads to a value of C which assumes uniform concentration in the boiler. Since the concentration at various points in the boiler varies considerably (18), sampling arrangements must be made to secure as near an average sample as is possible.

Discussion

Sidney Cornell.[4] The theory of conductance depends upon the ions dissolved, and the accuracy of the measurements gets back on final analysis to the determination of total solids in distillate, condensate, or mixed feed. Some serious errors can occur in the assumed simple matter of this determination of total solids by direct evaporation of a liter of distillate and subsequent weighing.

The accuracy of measurement of conductance is high, a calibration to an accuracy of 1 per cent being mentioned by the authors, but in the simple matter of total solid determination errors often of startling amount may be encountered, thereby throwing the accuracy of the entire measurement out.

Calculations of per cent of entrainment or of carry-over contamination can readily be made from the data, as illustrated by the authors, but for calibration or for calculation of total solids in any of the liquids measured by conductance a determination of total solids by direct weight must be made.

[4] Consulting Chemical Engineer, Griscom-Russell Company, New York, N. Y.

Unfortunately no standardized methods have as yet been proposed for this important matter. Serious contamination can occur in distillate samples in the sampling, in the holding, and in the evaporation to dryness. More serious errors can be encountered in the every-day matter of weighing. The make-up of synthetic waters in turn is exposed to marked errors from the same sources, and the following may be taken as a tenative standard for the determination of total solids in distillate.

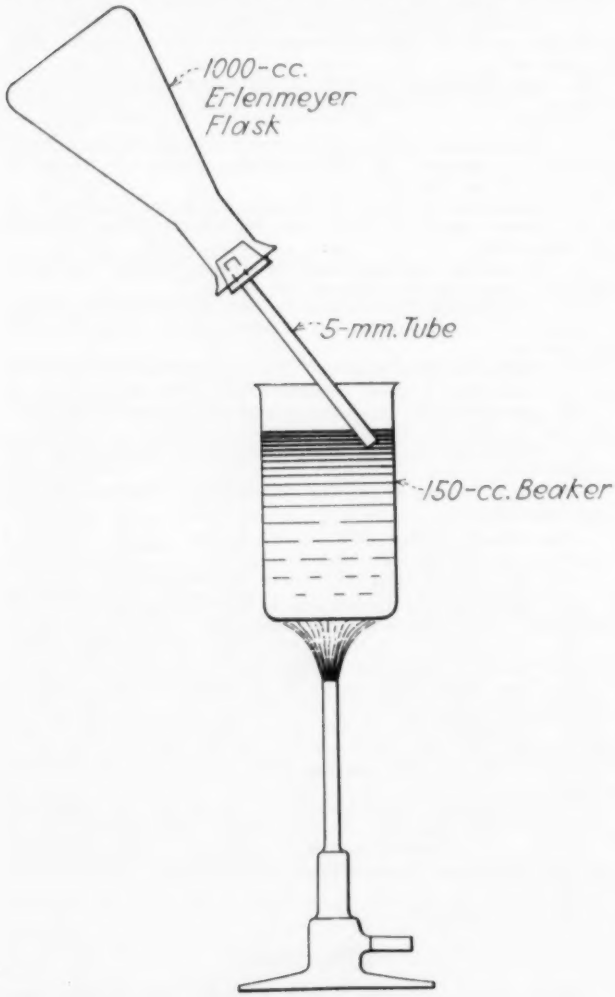

FIG. 14

Distillate from evaporators may run to as low as 1 p.p.m. total solids and to range upward to as high as 10 p.p.m. for condensate, and the laboratory evaporation of a liter sample may take four or five hours to dryness. A liter sample can be taken as a standard quantity for this test; no smaller because of the measurement by weight involved, and no larger because contamination from outside sources will upset the advantage. Hence an Erlenmeyer Pyrex 1000-cc. flask calibrated and marked should be made the sampling vessel. Fit to this flask a XXXX cork with single hole, and 5-mm. glass tube 5 in. long. Avoid a rubber cork as contamination will always occur, and a glass stopper cannot be fitted to this size neck. This sample is inverted over a 150-cc. Pyrex beaker, the sample flowing down until the end of the tube is covered and the beaker is on the hot plate. Obviously continuous feed takes place, with no possibility of outside contamination, as might occur with beaker transfer. Avoid all washing with distilled water, as often laboratory distilled water contains 2 p.p.m. total solids. If condensation takes place on the Erlenmeyer flask and tends to flow back into the beaker, place the flask at an angle, as shown in Fig. 14, supporting it on the chemical stand.

Naturally the sample flask, the beaker, and the tube must be chemically clean to start with and the beaker be correctly weighed.

A 150-cc. beaker will weigh approximately 50 grams. Very few laboratories possess correct weights; in fact, daily usage causes a rapid deterioration in their accuracy. Further, heat, light, draft, etc., affect the accuracy of a chemical balance. It is admitted that a few hours' time in the weighing of assays causes a marked variation. Thus if it were possible the sample should be evaporated instantly to dryness and the beaker be weighed before and after. Obviously this is impossible. To avoid error it is very necessary to weigh the sample beaker by the tare method, using a metal dish with sand or shot therein and getting final balance with the rider. The rider type of balance is superior for this sort of work, and the rider must be correct, and one with Bureau of Standards certificate is probably the safest to use. The beaker should have been heated on a hot plate or in an oven to 125 deg. cent. for 10 min., placed in a desiccator until cool, and weighed. When the sample is evaporated to dryness, the beaker should again be brought to 125 deg. cent. for 10 min., cooled in the desiccator, and weighed, the rider over the beam being the only weight difference. In fact a 1 mg., a 5, and a 10 are the weights used.

Obviously the balance case must be dry, it must have the usual pot of sulphuric acid or other dehydrating means therein, and it should be equipped with a thermometer. The volume of a 150-cc. beaker is in itself one to impose some variation by temperature alone, and as 25 deg. cent. is mentioned on the third page of the paper under discussion as the standardization point for the cell, this might be taken for the weighing.

The writer has noted errors of 100 per cent by different chemists in the matter of total solids in distillate, and when full appreciation of the fact that a measurement by direct weight of 1 part in 50,000 is necessary, some betterment in technique may be evolved. That is, the beaker mentioned weighs 50 grams. The total solids in 1 liter of distillate may be as low as 1 p.p.m., or 0.001 gram, and of course weighing on the usual chemical balance to 0.0001 gram.

In any event, no sample should be allowed to rest overnight once evaporation has started, as dust is always falling, and it takes very little contamination to impose wide errors.

The effect of gases, their measurement in small quantity in turn, is a difficult matter, but this matter of weighing of total solids alone requires unusual care to be correct. Based on this correctness rests the calibration of the conductance measuring instrument.

JOE A. BERGIN.[5] The authors have treated the subject of conductance of solutions very thoroughly in this paper, and have given much consideration to applying corrections to make the data presented comparable. When the determinations have been made in a thoroughly scientific manner and the slight corrections for pure water and dissolved carbon dioxide have been applied, the results are valuable in steam-power-station practice. There must be, however, proper precautions used in performing the conductance tests.

Conductance measurements for determining condenser leakage are now quite generally used and are reliable for the purpose. Using the conductance method for determining moisture in the steam and the carry-over or entrainment of mineral salts does

[5] Superintendent, Philo Plant, Ohio Power Company, Philo, Ohio. Mem. A.S.M.E.

not present any unusual difficulties after certain constants have determined and applied. The conventional calorimeter for measuring moisture in the steam is far from dependable, and there is a dire need of a more reliable method since the advent of high steam pressures and boilers operating at increasingly higher ratings.

The control of boiler and evaporator concentrations presents no great difficulties. The conductance method has been in use some time for determining the time for blowing down. It does not seem impossible to control motor-operated blow-off valves by the conductance of the boiler or evaporator water and to automatically control the concentration.

To properly use and apply the electrical conductance measurements in any steam-power plant it is necessary to do certain preliminary work, such as preparing graphs for the various conditions of the water used. The graphs prepared for one plant cannot be used in another, and in some plants the characteristics of the water change from day to day with the wind and weather.

The results obtained by the authors compare favorably with those obtained by the time-consuming methods now in use and considered reliable. The method may seem to be a great deviation from standard power-station practice, but electrical conductance measurements may be quickly made and dependable results obtained wth the use of proper equipment and careful sampling.

BERT HOUGHTON.[6] During the past few years carry-over in steam has demanded an increasing interest. This has been due to the increased size of boiler installations and more particularly to the increased steaming rates per unit of steaming area. At these steaming rates, with consequent increase of violent ebullition in the steam drum, greater difficulty has been experienced in designing efficient steam baffles to effectively prevent carry-over. Several cases are on record in which carry-over has been sufficiently serious to cause turbine shutdowns.

It has been customary to determine the quality of the saturated steam leaving the boiler by a throttling calorimeter and to estimate carry-over from the steam quality obtained. This method is indirect, and usually the indications thus obtained are not as high as the carry-over actually present in the steam. The development of a more direct method for the determination of carry-over is therefore timely.

The proposed method for obtaining "entrainment in per cent by weight of boiler water in steam" necessarily assumes an accurate boiler-water sample. The concentration of dissolved solids in boiler-water samples taken simultaneously at different points in a boiler varies widely, at times as much as 400 per cent. Percentages based on data as inaccurate as boiler-water samples can hardly give reliable information unless sufficient points on the boiler are taken to insure comparatively average boiler-water concentration. The writer does not feel that it is necessary to convert "entrainment in steam" to "entrainment in per cent by weight of boiler water in steam" and can only view such a procedure as introducing an unnecessary error.

In Fig. 11 the authors present data indicating that entrainment in steam diminishes as boiler-water concentration increases. This is contrary to fact in ordinary boiler practice. Many investigators have shown that carry-over not only increases but increases rapidly with increasing boiler-water concentrations. The writer believes that if the boiler-water concentration had carried higher than the 600 p.p.m. indicated, the evidence would have been unmistakable and the apparent errors avoided.

The authors make a correction for carbon dioxide in steam. A daily analysis is made and the CO_2 compensator set accordingly. Such a procedure assumes that the concentration of CO_2 and other entrained gases is constant over a period of time. Gases usually found in steam, that is, air and carbon dioxide, vary materially in concentration, thus making accurate compensation difficult. To make the conductivity method reliable, means should be developed to minimize the entrained-gas correction.

The conductance method is applicable to the measurement of dissolved solids in the steam. With the feed-treatment methods in use in many boiler plants, suspended as well as dissolved solids are present in boiler water. These suspended solids are entrained with the steam, and from a practical standpoint will cause the same clogging in superheaters, valves, and turbine blades as the dissolved solids which the authors have determined by the conductance method.

In the appendix, formulas have been developed to calculate the solids in the boiler, and it is brought out that a point of maximum is reached in boiler-water concentration, solids being entrained with the steam as rapidly as they enter with the feedwater. There is another agency that prevents the building up of boiler-water concentrations, and that is "leaky" blowdown valves. The writer has seldom heard of cases in which boiler water concentrations built up but that a "leaky" blow-down valve was involved.

The writer wishes to commend the authors on their work and believes that this conductance method, so long in use for condensates and feedwaters, may yet be developed to the point where it will be a standard method for the determination of carry-over in steam.

J. A. HANCE.[7] The writer has had no experience with the apparatus described, but has reviewed the paper and has also conferred with our electrical and chemical departments and others, and submits the following comments.

Our chemical laboratory makes analyses, from time to time, of various boiler feedwaters. These analyses are made in accordance with conventional methods, and the results obtained show the principal elements that are present, but they have no definite way of determining how these elements are combined in the water. Similar samples sent to other laboratories show divergent results.

Likewise calorimeter tests made to determine the quality of the steam frequently show widely different results.

The methods proposed in this paper appear generally to be based on sound principles, and the writer is of the opinion that the method is of value in determining the dryness of steam, but he is not certain as to its value in determining the suitability of certain waters for boiler use.

It appears that the electrical conductance of water would vary with each element present and also with the quantity of each element that may be present. If one were to consider only the elements that are listed in Table 5 and consider each element varying in quantity from zero to a maximum by small increments, he would obtain an infinite number of combinations, many of which would probably show the same electrical conductance. It would also appear that certain waters may show a satisfactory electrical conductance, but may contain elements that may have corrosive or scale-forming influences which would render them unfit for use.

It is not clear how steam-generating plants could correct the water without resorting to conventional chemical analysis. It would require very careful or trained observers or physicists to make the corrections and the calculations referred to.

H. F. JOHNSTONE.[8] The device which the authors have per-

[6] Operating Superintendent, Brooklyn Edison Company, Brooklyn, N. Y. Mem. A.S.M.E.

[7] Baldwin Locomotive Works, Philadelphia, Pa.

[8] Special Research Associate in Chemical Engineering, University of Illinois, Urbana, Ill.

fected will find a large use, not only in determining carry-over in steam boilers and following impurities in return lines, but also in the control of chemical processes in which there may be a change of conductance due to the reactions involved. The writer is most interested in the observations that the authors make in which "it appears that the entrainment in steam is greater in magnitude for the lower steam-flow conditions than is found under the normal steam output of the boiler," and also, "the steam quality apparently improved with the increase in concentration of boiler water and total evaporation, . . . for the observed case some condition existed in the more dilute water which is unfavorable to the production of dry and clean steam." A systematic study of the steam produced by a boiler by means of the conductance method may lead to some valuable information about foaming, of which so little is known at present. The writer wishes to congratulate the authors and the Society on this very useful paper.

M. D. Baker.[9] The conductivity bridge has proved to be a valuable asset for a comparative study of water and water conditions in central power stations. After a standard cycle has been established so that all the salts in the water are comparatively the same, a very close check can be maintained on regulation of treatment needed. In the cycle at the Springdale Station of the West Penn Power Company, the contamination is mostly Allegheny River water through condenser leakage, and the treatment is trisodium phosphate and sodium hydroxide. The carry-over with the steam and the evaporated make-up is carefully watched so as to have as pure a water as possible in the feedwater cycle. By measuring the conductivity of the water supplies, a control has been established so that a weekly check on boiler waters has become a matter of routine.

We have found that the conductivity bridge can be used with very accurate results only on waters containing less than 20 p.p.m. total solids. When the concentration is above this, results are varying and erroneous and can be used only comparatively. Due to the presence of various ions in the solution, the degree of ionization may vary with the preponderance of any one, and tabulated results have shown such a wide discrepancy that the bridge cannot be considered an accurate indicator of conditions when concentrations are high.

During a protracted study of boiler-water concentrations, in which over 1100 determinations were made, the parts per million by evaporation were plotted against conductance in mhos $\times 10^{-6}$; the resulting curve sheet was a mass of dots with absolutely no relationship between the various boilers. During this test, control conditions were as near ideal as was possible to maintain. Similar results were obtained in an effort to check on parts per million in evaporator concentrate. It was noted that a curve accurate to within 10 per cent could be drawn for each run of a boiler or evaporator, but that this curve would not be satisfactory for any other piece of apparatus and would not be satisfactory for the next run of the same boiler or evaporator.

Entrainment tests were run on a boiler similar to the one described in the article, but it was found necessary to collect entrainment samples and take calorimeter readings on each saturated steam lead. This was caused by the variation in concentration of the two ends of the boiler. Due to the inaccuracy of conductance reading at the higher concentrations, a 1 per cent solution of the boiler water was used. After making all necessary corrections, more consistent results and closer checks as to the moisture content determination of the calorimeter were obtained. Tests were run on boilers having boiler-water concentrations varying from 600 to 1250 p.p.m.

Due to the erratic results obtained with higher concentration in a solution, the writer has been unable to compare any analysis with conductance units. Some comparison has been obtained by using a 1 per cent solution and multiplying this result by 100. An example of this is one sample of Allegheny River water which had a conductance of 210×10^{-6} mhos, a 1 per cent solution of the same having a conductance of 2.56×10^{-6} mhos. Theoretical conductance based on analysis was 249×10^{-6} mhos. This is the closest agreement between theoretical and actual conductance which the writer has ever been able to obtain.

Conclusions: The conductivity bridge is a valuable instrument in tracing and determining contamination and as a guide in controlling feedwater conditions. It is also of value as a method of determining entrainment and for obtaining comparative data when concentrations exceed 20 p.p.m. Its great advantages are speed and the fact that the operators can use the instrument and obtain comparative results.

E. B. Powell.[10] The paper is of special interest at this time, and the writer would appeal to the authors to continue the work which they have so capably taken up.

With the growth in use of high-pressure steam turbines and engines of so-called "back pressure" type, exhausting to industrial process systems having no return or but small return of condensate, steam contamination by entrainment becomes of increasingly serious concern. In plants of this type economic considerations will usually dictate chemical treatment of the boiler-feed make-up, rather than distillation of make-up, wherever the available water supply is susceptible of the required degree of "purification" by chemical means. In general, this will result in much higher solid content in boiler feed, and in consequence much higher rate of concentration of dissolved and suspended solids in the water within the boiler, than occurs in the more conventional type of utility power plant. Moisture entrainment in steam from the boilers of this newer type of plant must therefore be subject to even closer control.

The work which the authors have described and that covered by earlier papers mentioned in their bibliography has been devoted primarily to the development of a mechanism for observation and measurement of entrainment. Obviously this can be looked upon only as an introduction to a larger study. From the laboratory aspect Prof. C. W. Foulk has made admirable progress in the development of the theory of priming. The testing of the elements of his theory by the criterion of the operating boiler plant is still to be undertaken, and, in fact, although priming is one of the oldest problems associated with the steam boiler, the field remains but scantily explored. The authors have made a most valuable contribution in preparing the ground for further analysis. The data of their paper suggest numerous lines of attack leading toward a more thorough understanding of the phenomenon. It is to be hoped that, having carried the work to the extent which they have, the authors may be persuaded to continue their studies and investigations at least to the point of clearing the many elements of uncertainty to which they call attention, such as the increase of entrainment at low rates of boiler steaming, which would seem to cast considerable doubt upon current methods of steam calorimeter calibration and the wide departure of the individual conductivity and calorimetric determinations from the mean relationship indicated by the average of an extensive series of such observations.

E. L. McDonald.[11] The writer's first experience with the

electrical conductance method of measuring water contaminations dates back to 1919, when current at a fixed voltage was passed through two carbon electrodes (with fixed distances and exposures) immersed in glass jars of condensed steam, condensate, and river water, giving relative conductivities and, in turn, condenser leakage (properly corrected for temperature). Curves plotted for various temperatures and dilutions facilitated the determinations.

Since 1927 the writer has experimented with electrical recorders, using this same principle and for the same purpose.

More recently he has experimented with the same apparatus and also with the portable conductance bridge type for determining carry-over on 1400-lb. boiler units. The portable instrument is in daily use for determining boiler-water concentrations.

Much of the writer's experience substantiates the findings of the authors; however, in attempting to determine the carry-over on the 1400-lb. boiler units, an inexplainable and as yet unsolved problem has been met which throws doubt into the value of such a method where higher pressures and temperatures are concerned, at least until more experimental work is conducted.

Very briefly, the situation is this:

The conductivity method has been used and proves reliable for determining soluble salts in various waters throughout the plant. Solutions of known quantities have been used to check its accuracy, and evaporative tests have been made on a great number of boiler-water samples to also prove this.

In attempting to determine carry-over in the 1400-lb. boiler units, equipment was installed similar to that used by the authors (A.S.M.E. steam sampling tube and condenser coils), and a great number of both steam and water samples were taken.

Solids were determined on all samples by both the electrical-resistance method and by carefully conducted evaporative tests.

Both of these methods checked reasonably close on the 1400-lb. boiler water, but in no case could a check be obtained on the 1400-lb. steam sample. The total solids in solution by actual weight averaged about seven times the amount indicated by the resistance method. The per cent carry-over of solids by actual weight agreed closely with that indicated by relative M.O. alkalinity.

Space and time will not permit presenting details, but the conclusions drawn to date are:

The electrical-resistance method is based on the complete ionization of solids in solution. Practically all solids in this boiler water were in solution and apparently completely ionized. The check against actual evaporative tests verifies this.

Some chemical change apparently takes place when converting water to steam at high pressures which decomposes or changes the relative conductivity of the constituents in the boiler water (aside from CO_2); otherwise the electrical method, which checks the solids in the boiler water, would also check on the steam samples, which should contain the same solids.

The electrical method appears to indicate the approximate per cent moisture carry-over, but not the total solids carried over. Calorimeter determinations, while not entirely reliable at this pressure, showed moisture carry-over in the same region as the electric figures.

Chemical methods (evaporative tests and M.O. alkalinity) give total solids in solution, but not per cent moisture carry-over.

On the tests in question, there was a rather definite difference between total solids in solution and approximate per cent moisture carry-over, the former being about seven times the latter, but to date the definite reason for this great difference is unaccounted for.

Some additional experiments are being carried out as time permits, which may clear this point, and it is hoped that some comments or suggestions may be evolved from the discussion submitted that will be of value.

In the meantime it is suggested that if the electrical-conductance method is to be used for determining solids or moisture or carry-over on high-pressure equipment, it should be checked against the weight as determined by an evaporative test, which in the final analysis (assuming the sampling is representative) is the actual amount of solids leaving the boiler drum.

No attempt is made to present the vast amount of data collected during these experiments, but merely to outline briefly the difficulty encountered and the final deductions to date.

W. N. Greer.[12] The paper has described the measurements in terms of specific conductances, and it might be well to elaborate on the value of making or, at least, of tabulating conductivity measurements in terms of specific conductances. The specific conductance is equal to the measured conductance multiplied by the cell constant and/or the specific conductance is equal to the cell constant divided by the measured resistance. Since the cell constant of the conductivity cell is a function of the area of the electrodes and their distance apart, it is at once evident that conductivity cells of the same design will seldom have the same cell constant, due to small variations in manufacture, especially those made in the hands of the glass blower. Tabulating the results, then, in terms of specific conductance makes the results comparative and independent of the conductivity cell used.

The modified design of the flow-type conductivity cell described in the paper is no doubt an improvement over that previously described by Messrs. Parker and Greer and referred to in the paper. The improvement is primarily concerned with the position of the electrodes in the flow chamber, since in this new design the solution flows more or less directly through the electrode proper, immediately subjecting it to changes in the solution, whereas in the previous design the solution had a tendency to flow around the electrodes, and the latter was not immediately subjected to small changes of the solution.

Authors' Closure

Questions of like nature have been developed in the discussions presented; hence the authors will answer them as a group rather than directing their reply specifically to the separate discussions. Because of the interest expressed in the discussion and of the value of the supplemental data obtained subsequent to the submission of the manuscript, the authors take the liberty in answering the questions of including the additional data in their closure. In general, the discussion is directed to sampling, standardization of the method, and the interpretation of the conductance data.

Concerning the physical features involved in the boiler-test set-up, the importance of adequate sampling facilities was sufficiently stressed to the engineering personnel, and facilities were provided for sampling both steam and boiler water. In the case of boiler unit 22, steam sampling nozzles were properly located in the two steam leads from the drum to the superheater inlet manifold. Because of previous experience, and the background of the boiler-water traverse test (see reference item 18) boiler-water samples were not secured from the gage-glass water columns as such samples would not be representative of the average maximum concentration in the drum. It was observed that a sampling line installed in and extended across the length of the drum produced samples showing correct concentration of boiler water in the drum. In the traverse referred to, this observation had been checked by installation of a line in the drum as described, and in addition a sample nipple was located at each fifth header-tube cap in the 52 uptake water headers extending across the

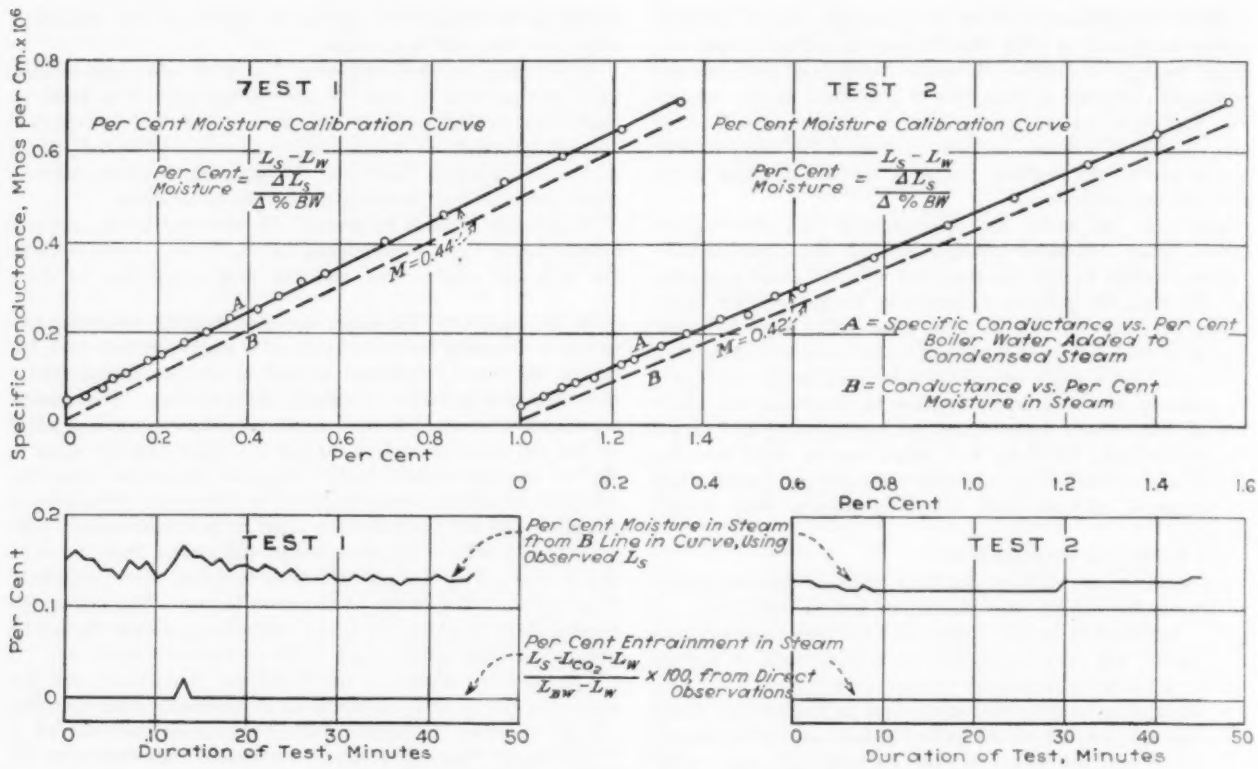

FIG. 15 COMPARISON OF CONDUCTANCE METHODS FOR STEAM QUALITY

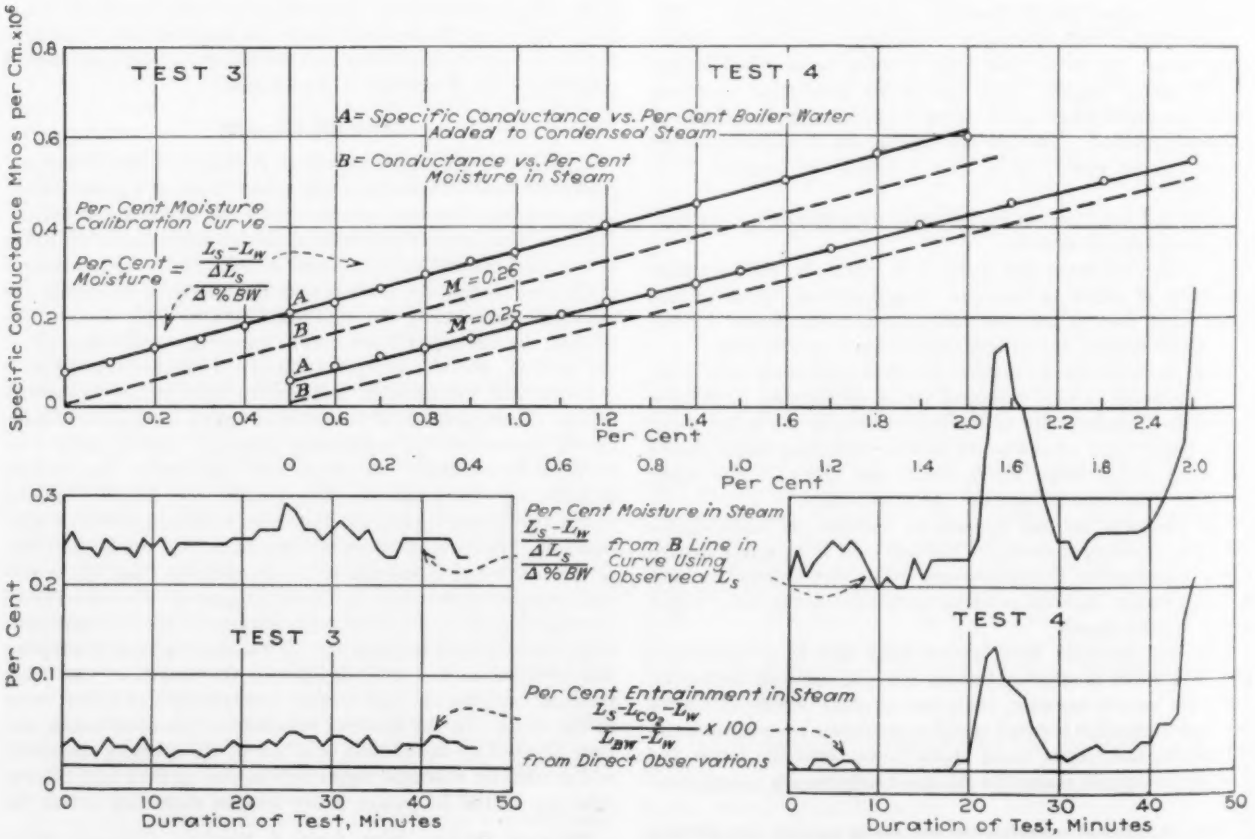

FIG. 16 COMPARISON OF CONDUCTANCE METHODS FOR STEAM QUALITY

boiler. Each of the individual lines was connected to a separate cooling coil. The concentration of boiler water was measured by the conductance method. Samples were taken hourly for 24 hours. The comparisons of concentrations are based on the averaged results for the test period. The average concentration of boiler water from the drum sampling line was found to measure 6.6×10^{-6} mhos per cm., a difference of but 11 per cent from the average concentration of the 10 header samples, 7.3×10^{-6} mhos per cm. It was observed, however, that the location of the two feedwater inlet pipes influenced the concentration of boiler water in the drum. For example, at the drum center the concentration was observed to be at a maximum, 8.5×10^{-6} mhos per cm., 55 per cent higher than the minimum concentration of 5.5×10^{-6} mhos per cm. found directly under the feedwater distributor. For obtaining the data used in the development of the entrainment from boilers where Zeolite-softened water was evaporated, a boiler-water sampling line was located lengthwise in the drum of a multidrum boiler wherein the steam generation was at a maximum. The steam sampling nozzle pointing downward was located adjacent to the drum in the horizontal steam line leading to the main steam header. The physical layout of the plant did not permit locating the nozzle in a vertical run of the pipe; nevertheless the indications of entrainment as shown in Figs. 15 and 16 are considered correct, since evidence of entrainment from this station was detected remote from the plant.

Sampling nozzles of new design for both steam and boiler water have been developed by the authors and the engineering personnel, and a schedule of tests will be started in several multidrum boilers. Comparisons will be made for steam quality by the conventional quality method and the conductance method.

The condenser circulating-water supply at Pittsburgh is considered fresh but polluted in character; hence condenser leakage cannot be readily detected by any chemical test. Immediate stoppage is made if leakage is indicated by the conductance method. The make-up is evaporated. Therefore as "pure" water is supplied to the boilers, no undue concentration of boiler-water salts has been found. At Colfax, blowdown of boiler water is not necessary during the operating service run of the boiler; hence the valves are not operated. The loss of concentration because of leaky blow-down valves is a valuable comment. The valves are, however, checked regularly by touch for indication of leakage while the boiler is in service. The concentration was found to be but 703 parts per million of dissolved salts by gravimetric analysis in an adjacent boiler when the boiler was drained. The boiler was operated over the same period as boiler unit 22 and during its 3565 service hours evaporated 716,000,000 lb. of water.

The conductance measurement of the station supplies can be obtained readily by the operating personnel. The chemist's services are required initially, however, for the preparation of the necessary calibration curves. Once such curves are established for each of the *various* water supplies used in the station, they are permanent, unless a major change occurs in the quality of the water supplies. It is obvious that the relation of *dissolved salts* and specific conductance of steam, raw water, and concentrated boiler water in a single station cannot be plotted on a single chart, since the ion distribution of these waters differs. Unfortunately for the users of industrial water, there is no standard procedure available for the chemical analysis of such supplies. The authors have modified the Standard Methods of Water Analysis (see reference item 21) as per the footnotes included in Table 7. When waters of the "pure" quality are subjected to chemical analysis, a minimum of 4 liters is evaporated for the dissolved solids determination; and as is customary in the majority of industrial laboratories, the evaporation is conducted in platinum over a steam bath to avoid evaporation losses; precautions are exercised to maintain the atmosphere in the vicinity of the evaporation in a clean condition; analytical balances are maintained in proper condition by experienced repair men; precision analytical weights are used, and are calibrated monthly against Bureau of Standards certified weights, used for no other purpose. With the weighing precautions as enumerated, it will be conceded that the gravimetric determination represents the most accurate one the chemist has at hand. Because of the doubt of determining accurately the dissolved salts of a water containing from but two to five parts per million and in spite of

(At Colfax power station, Twelfth Street heating plant, and Stanwix heating plant.)

the excellent agreement of the data tabulated in Table 7, column 3, the authors believed the most accurate method of establishing for "pure" water the relation of dissolved salts and specific conductance was by the use of a "synthetic water." The linear relations in the concentrated waters is checked by the plot of the "Calculated Conductance vs. Calculated Salts," Fig. 12, and in the supplemental Fig. 17, in which additional data are supplied. Inspection of the tabulated data and the summary in Table 10 shows that the deviation of the observed and calculated conductance is well within the experimental error of the analysis.

The data in Table 4, boiler fed with "pure" feedwater, and in Table 7, boiler feedwater, have been similarly summarized.

The authors conclude from the foregoing that the submitted comments concerning the non-concordance of the conductance

data and dissolved salts appear to be not well founded. It must be considered that in deriving the calculated conductance the individual value for each sample is subject to all of the errors in the determination of the individual ions.

Another questioned item is the interpretation of the term dissolved salts in terms of specific conductance. The chemist uses the following nomenclature in reporting the results of analysis of water. The total dissolved solids of a water included suspended solids and dissolved solids. The weighed residue obtained after evaporating a measured volume of filtered water is designated as dissolved solids. The dissolved solids includes the colloidal and non-conducting items, organic matter, silica, and the oxides of iron and aluminum, and the ionized substances possessing conductance characteristics, termed dissolved salts. The correlation of conductance may only be made with reference to the dissolved salts. It is probable that with a clearer understanding of these terms a user of the conductance method who has implied that the results are erroneous may be able to readjust the voluminous data compiled by him and make them usable. The authors are not aware of any method other than the gravimetric method for determining rapidly the total dissolved solids in water.

It will be observed from the supplemental data herewith, Table 11 and Figs. 14 and 15, that the carbon-dioxide compensation of supplies containing measurable amounts of carbon dioxide must be made if accuracy in the entrainment value is desired. The frequency of making the CO_2 test is based upon the local plant conditions and the rate of change of CO_2 concentration in the steam discharged from the boiler. The steam condensate returns referred to in the paper possessed a constant CO_2 content; hence a daily test suffices. In the tests on entrainment of steam generated in boilers using Zeolite-softened water, the CO_2 test was made at 10-minute intervals throughout each test run. In these runs the conductance of the steam was measured each minute, and the readings were used to compare the method of test for moisture in steam as published by Fitze (see reference item 16) with the method presented by the authors. The authors believe the following formula correctly expresses Fitze's method:

$$\frac{L_S - L_W}{\frac{\Delta L_S}{\Delta \%BW}} = \text{per cent moisture}$$

Where

L_S = measured conductance of steam

L_W = water correction derived by transposition of curve

$\frac{L_S}{\%BW}$ = the change in the conductance of steam caused by the addition of 1 per cent boiler water

The formula for the authors' method included the constants for water correction and the derived value for the CO_2 correction.

$\frac{L_S - L_{CO_2} - L_W}{L_{BW} - L_W} \times 100$ equals per cent by weight of entrainment of boiler water in steam

Where

L_S = measured conductance of steam

L_W = water correction 0.9×10^{-6} mhos per cm.

L_{CO_2} = carbon dioxide correction

L_{BW} = conductance of boiler water

The curves for obtaining the CO_2 correction are shown in Fig. 17, calculated from the data given in Table 6.

The tabulated data shown in Table 11 also include the entrain-

ment in per cent calculated using the dissolved salts found (by chemical analysis) in the steam and boiler water. Considering the value so obtained as a standard, it will be observed that the data secured by the authors' procedure approximate the standard considerably closer than do the data supplied by Fitze, wherein no CO_2 compensation is made.

The authors have not arrived at any additional explanation of the observation, "it appears that the entrainment in steam is greater in magnitude for lower steam-flow conditions than is found under the normal steam output of the boiler," and, "the steam quality apparently improved with the increase in concentration of boiler water and total evaporation." They wish to point out that sufficient evidence by other than conductance measurement is included in the paper to support Fig. 11 for the observed conditions.

The final general factor which is mentioned is the change of conductance because of change in concentration of the individual ions. Considering the experimental data reported in this paper, the authors believe that boiler concentrations up to 5000 parts per million of dissolved salts may be considered as dilute solutions. The graphs shown in the Figs. 12 and 16 are considered linear. It has been noted that the equivalent conductance of salts, such as NaCl, $\frac{1}{2}$ $CaCl_2$, $NaNO_3$, $\frac{1}{2}$ Na_2SO_4, and $\frac{1}{2}$ Na_2CO_3, show a more rapid decrease in equivalent conductance from zero concentration up to approximately 300 parts per million of the salt, and beyond this concentration the slopes of the graphs are linear. The slope for NaOH is linear throughout its range. The authors confess that they do not know how the ions are combined within the boiler at operating temperatures and pressures, and hesitate to correct the data they have accumulated for the small change in the conductance. The substantial agreement that they have found between the observed and calculated relations as shown in Figs. 12 and 16 permits them to conclude that the error they may have made in their calibration of the meter units in terms of dissolved salts may be considered of minor value.

The authors are grateful to the discussors for their presentation of the various aspects of the paper and believe that a large field is open for investigation both in the industry and in the engineering schools

FSP-53-12

Design of Thick-Walled Tubes Subjected to Pressure and Heat Input

By E. W. LUSTER,[1] ELIZABETH, N. J.

With the increases in pressure and oil temperature, which have accompanied the development of distillation and cracking equipment in recent years, has arisen the need for a rational method for the design of thick tubes subjected to internal pressure and heat input. The author has accordingly developed in the present paper formulas for temperature and pressure stresses in such tubes, and for calculating the optimum tube for given conditions. Examples of calculations are given, as well as particulars of experimental investigations, both completed and contemplated, for the determination of the values of the constants employed in the formulas.

WITH the increases in pressure and oil temperature which have taken place in oil-refinery distillation and cracking equipment within recent years, the need of a rational method for the design of thick tubes subjected to internal pressure and heat input has become increasingly urgent.

In presenting this paper no claim is made that a tested and final solution has been found. The question of combined temperature and pressure stresses is a controversial one, a large group of engineers of high standing denying the existence of the temperature stresses. From the mathematical work which accompanies this report, the development of the theory to which the author adheres may be followed. In the laboratories of the Standard Oil Development Company the determination of constants for use in the equations developed is being given intensive study, and, as the ultimate step in rounding out the work, it is hoped by testing tubes under pressure and heat input, to prove or disprove the theory. The ultimate solution of this problem will not be due entirely to the efforts of mechanical engineers as the difficulties facing the designer have a metallurgical as well as a mechanical aspect.

While the present paper was prepared primarily for use in the design of oil-refinery pipe stills and cracking furnaces, it has a direct application in the design of any equipment employing tubes subjected to internal pressure and heat input from the outside, and with a change in mathematical signs will cover the design of tubes in which heat flows outwardly.

[1] Assistant Manager of General Engineering Department, Standard Oil Development Company. Mem. A.S.M.E. The author was graduated from Rutgers University, 1914, with a B.S. degree in electrical and mechanical engineering. Spent one and one-half years in power-plant test work. Joined the Standard Oil Company in June, 1916. Attended first Military Training Camp and served as lieutenant and captain in the Second Regiment of the U. S. Engineers, Second Division of the A.E.F. in France, and later in the Army of Occupation in Germany. Following discharge from the army was resident engineer for the Societa Italo-Americana Pel Petrolio in Genoa, Italy, until the end of 1923, erecting bulk storage and bunkering stations in Italy and North Africa. Returned to the United States the first of 1924 and has since been in charge of the design of process equipment for the Standard Oil Development Company.

Presented at a meeting of the Plainfield Section of the A.S.M.E., Plainfield, N. J., April 3, 1930.

In the design of our earlier cracking units, that is, those built up to 1926, no account was taken of temperature stresses. The allowable stress in the tubes was taken as that given by the A.S.M.E. Boiler Code, and the stress in the tubes was calculated by the thick-wall formulas. As oil temperatures were relatively low, from 850 to 860 deg., and the pressure moderate, being 350 lb. at the outlet tube of the furnace, and as very liberal allowance was made to care for the loss of wall thickness due to corrosion, tube failures were rare, loss of property negligible, and injury to attendants non-existent.

In 1926 cracking units for 750 lb. oil discharge pressures were built which gave an oil pressure at the inlet tube of the furnaces of around 1000 lb. In the design of these units also no temperature-stress allowance was made, though the tubes were designed with a liberal corrosion allowance and of sufficient thickness to withstand at the hottest tube the full pressure which could be developed by the feed pumps, namely, some 1200 lb. By suitable oil flow the tube carrying the hottest oil was not in a section of the furnace where it would be subjected to high heat inputs. For these reasons tube failures in these settings have also been extremely rare.

The next step in the development of cracking furnaces called for a setting which had no zones of low heat input. A furnace was required in which the oil and flue gas traveled in a countercurrent manner, the heat input being as nearly uniform throughout the setting as possible. Such a furnace has the tube carrying the hottest oil in the so-called "radiant" section of the furnace where the heat inputs average 10,000 B.t.u. per sq. ft. of exposed tube surface.

(Note that in this paper heat inputs will be spoken of in this manner instead of the heat input per square foot of projected areas, which is the practice of some designers.)

It was realized that the securing of a fair heat input through a relatively thick tube, through the layer of hard coke which builds up on the inner wall of the tube due to the conversion of the cracking stock to gasoline, and finally through the oil film which exists between the coke layer and the oil, would give rise to metal temperatures greatly in excess of those encountered in boilers. It was also realized that the condition would be aggravated by the fact that the oil receiving the heat would be at an elevated temperature, have a low thermal conductivity, and would not be boiling at least to the extent that water does in a steam boiler. It was estimated that under these conditions the tubes would have an outside wall temperature of from 950 to 1100 deg. or higher, depending upon the various factors mentioned.

The allowable stresses in metals and alloys at such elevated temperatures were very poorly defined, and it was obvious that the initial steps toward a rational design for such tubes had to be, first, the selection of a proper metal, and, second, the determination of safe stresses for this metal.

The temperatures mentioned above are within the range over which a metal is considered to elongate at a uniform rate when subjected to a sufficiently high stress. Although this phenomenon has been the subject of numerous publications, it may not be amiss to mention that this uniform elongation is known as

"creep." To put it a little differently, it may be said that at a given temperature there is some stress which will, in a given period of time, cause the metal to elongate or creep a definite percentage of its original length. The 100,000-hr. creep is the one in most general usage, and is the stress which, at a given

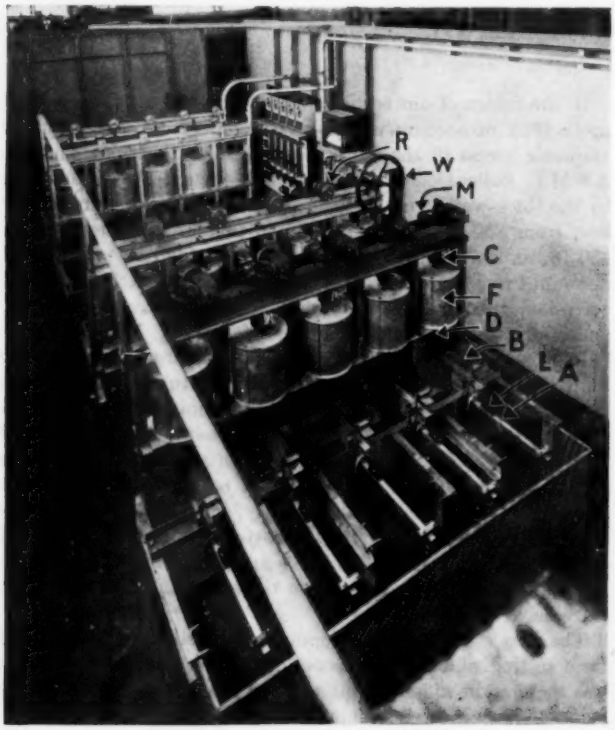

FIG. 1 ELECTRIC FURNACE USED IN CREEP DETERMINATIONS

temperature, causes the metal to elongate 1 per cent of its original length in 100,000 hr. (11.4 years).

Some of the tube manufacturers had already made creep determinations on a few alloys, but because of the many conditions to be met in oil-refinery work it was felt advisable to install equipment and make determinations for those materials for which a possible use could be foreseen. Creep-determination equipment consists essentially of an electric heating furnace, a system for loading the test specimen, a micrometer for reading the elongations, and thermal control equipment for maintaining the furnace temperature at any desired point. Our metallurgical laboratory has available at present twenty-five such furnaces arranged in batteries of five.

The furnace is shown at *F* in Fig. 1, and was constructed by the metallurgical division of the company from information supplied by the Union Carbide and Carbon Corporation. It consists of an alundum tube $1^1/_8$ in. in inside diameter and is space-wound with Nichrome IV wire. Alundum cement is applied over the spaced wire and the tube and wire covered with 4 in. of insulation. The furnaces are $12^1/_2$ in. long and give a very uniform temperature distribution over the middle 6 in. of the specimen. The sample to be tested is screwed into blocks *C* and *D*, Fig. 1, and the load applied by the double lever *A* and *B* which has a multiplying ratio of 100 to 1. By this system stresses up to 75,000 lb. per sq. in. may be applied to the standard 0.505-in.-diameter test specimen. Elongation of the test specimen is measured by means of a large-size micrometer, the gear and worm of which have been calibrated. The micrometer device *M* is turned by wheel *W* when necessary to keep the bubble in lever *L* in the center of the glass. The dial *R* is calibrated to twenty-five millionths of an inch, and readings estimated to the nearest five millionths.

The temperature is controlled within five degrees plus or minus by means of potentiometer controls, relays, and resistors. The control *C* of Fig. 2 operates a relay *X* which in turn cuts in or out a part of resistor *R*-1. Resistor *R*-2 is in series with the furnace, which, after once being set for a given temperature, need not be changed. Fig. 2 shows a control system for five furnaces, each equipped with a controller. The temperature of each specimen is recorded on the potentiometer recorder shown at *T* in Fig. 3. Fig. 3 also shows the control system for a bank of five furnaces operated simultaneously at the same

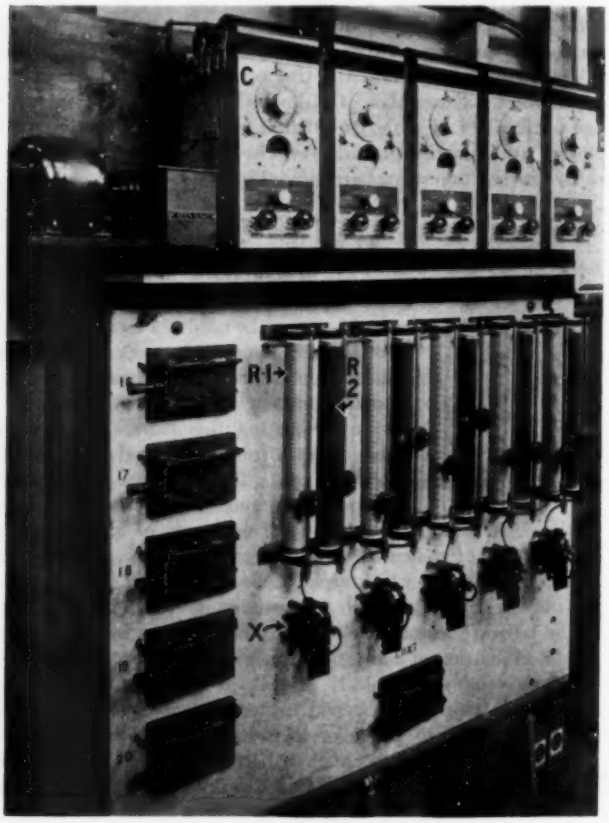

FIG. 2 FURNACE CONTROLS

temperature by a single controller. Rheostats *R*, Fig. 3, are in series with each furnace and compensate for the slight differences in furnace characteristics.

Fig. 4 shows a specimen with the thermocouples attached, the specimen being ready for insertion in the furnace. One thermocouple is connected to the controller and the other to the recorder.

In operation the specimen is given an initial load which is based on previous experience or represents the best guess possible. The application of the load elongates the specimen immediately, after which the rate of elongation decreases, and on a chart in which the elongation is the ordinate and time the abscissa, the curve becomes horizontal, that is, the specimen has ceased to elongate. The load is then increased, and this time a greater period is required before the line becomes horizontal. Increases in loading are continued until the line no longer becomes horizontal but continues to slope upwardly to the right, indicating

a continuous uniform elongation. By properly adjusting the load the rate of elongation can be brought to approximately 1 per cent in 100,000 hr., and after this condition has been established the apparatus is allowed to run from 2000 to 3000 hr. From the elongation which takes place in this 2000- to 3000-hr. period, the actual rate of creep for 100,000 hr. is calculated. In practice two furnaces are used per test, one being set to give a creep of a little over 1 per cent and the other a little less than 1 per cent, so that at the conclusion of the test the 1 per cent point is calculated by interpolation. As a final test a specimen is stressed with the load given by the interpolation, and a check test made for 3000 hr. It can readily be understood that the determination of a complete creep-point curve covering a range of from 900 to 1500 deg. and requiring the determination of at least four points to insure an accurate and smooth curve, occupies a long period of time. For example, assuming 3000 hr. per test, three tests for the determination of each point on the curve, and four points required for a complete curve, a total of 36,000 hr. or 4.1 years would be required to produce this curve if only one machine were available. With twenty-five machines

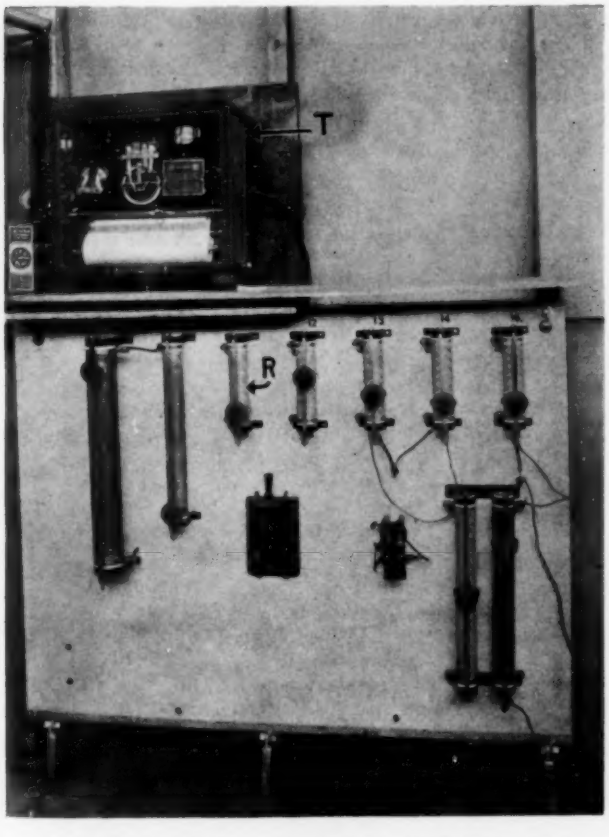

FIG. 3 CONTROL SYSTEM FOR BANK OF FIVE FURNACES

available working in the method outlined above it should be possible to make about six curves per year.

We now have eleven of the furnaces on high chrome-nickel covering the temperature range of from 800 to 1300 deg. in an attempt to correlate the creep limits at 25,000, 50,000, and 100,000 hr. Three machines are on low-carbon steel, six on various chrome steels, and five on special alloys for very high temperatures of from 1800 to 1900 deg. It was mentioned above that an attempt was being made to correlate the creep rates at three different periods; this is being done as the 100,000 hr. is a long time in the oil industry and few indeed are the pieces of equipment which are not scrapped before the end of such a period. One per cent in from five to six years, or, say, 50,000 hr., would appear to be a logical creep limit, as it more nearly represents the life of our equipment.

The full-line curve on Fig. 5 gives the 100,000-hr. creep on KA2S. It extends from 900 to 1300 deg. fahr. The broken-line curve represents one originally supplied by the Babcock & Wilcox Company for Enduro which covers the range from 1000 to 1500 deg. fahr. As these curves are the work of two independent investigators, it is fairly safe to assume that the overlapping portions, at least, may be used for design work. Their close agreement can be noted, in spite of the considerable difference in carbon content: 0.07 per cent for KA2S and 0.43 per cent for Enduro.

Table 1 gives some scattered values for four steels. To date, sufficient points have not been determined to make it possible to draw complete curves.

Following the determination of safe stresses, the next logical step in the solution of the problem was the derivation of a suitable formula with which the actual stresses set up in the tubes could be calculated

The most general case is one in which relatively hot oil is forced through a tube under pump pressure, the tube being located in a suitable furnace whereby heat is imparted through the tube to the oil by radiant brickwork and hot flue gas.

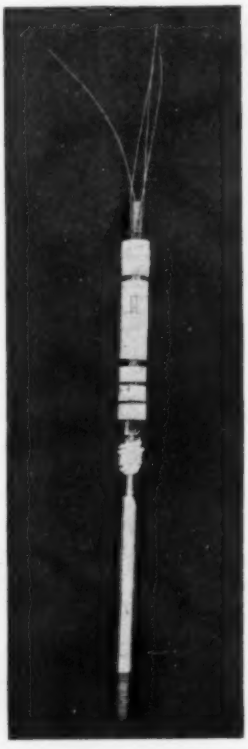

FIG. 4 SPECIMEN WITH THERMOCOUPLES ATTACHED, READY FOR INSERTION IN FURNACE

Under such conditions there should be, according to previous investigators:

1 Stresses accompanying the temperature drop through the tube wall
2 Stresses accompanying the pressure difference between the inside and outside of the tube.

Temperature stresses have been discussed by Lorenz,[2] Dahl,[3] and Orrok.[4] The principal theories of pressure stress are those of Lamé, Barlow, and Clavarino, and are to be found in standard textbooks dealing with this subject.

All the above writers make various assumptions and have worked out many different cases of pressure and temperature stresses. Using their work as a general guide, and starting with the fundamental stress-strain equations, formulas have been

TABLE 1 CREEP VALUES FOR FOUR STEELS

	Lb. per sq. in.	
	800 deg. fahr.	900 deg. fahr.
0.12 to 0.18 per cent carbon steel	15,000	9,500
Low Cr-Ni-Mn	30,000	21,500
KA2S	25,000	20,000

obtained which apply to the conditions in oil-refinery pipe-still and cracking furnaces. The derivation of these is given in Appendix No. 1 of this paper.

When heat flows through the walls of a tube (from the outside to the inside in cracking furnaces), a temperature drop is established. That is to say, any fiber of the material is hotter than the one just inside it. Consequently the thermal expansion of the outer fibers is greater than that of the inner fibers. From this a little consideration will show that the outer fibers are in compression and the inner ones are in tension.

An example may make this clearer. Consider two precisely similar strips of metal, laid one upon the other, with a strip of

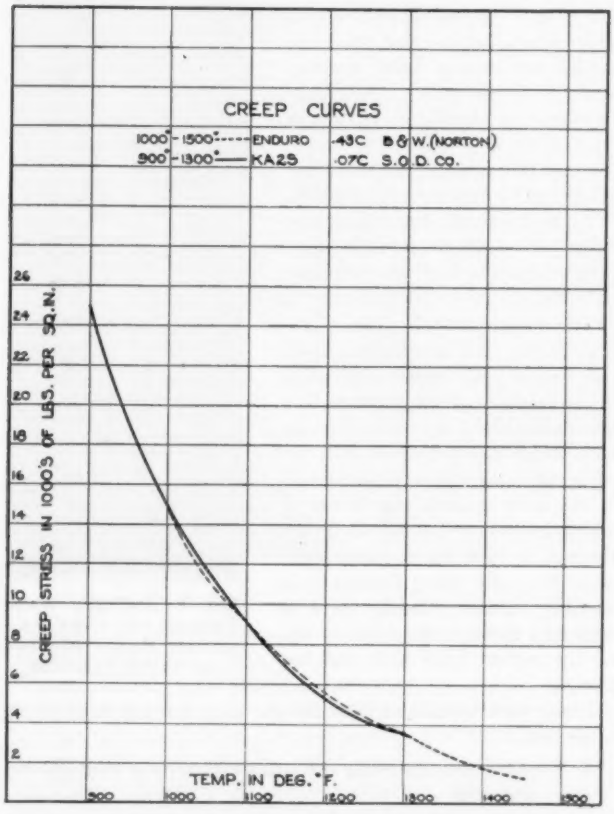

FIG. 5 CREEP CURVES OF TWO ALLOYS

insulating material between them and clamped together. If heat be applied from one side, the exposed strip will tend to become longer. The hotter strip can only expand by stretching the cooler one. The cooler strip is obviously in tension, and its resistance to being stretched produces compression in the hotter strip. If we had a pile of many such insulated strips instead of only two, with a rise in temperature upward from strip to strip, i.e., heat applied from the top, the action described above would take place between adjacent strips. Further than this, any strip in the pile would have all the strips below shortening it and all the strips above stretching it. Strips near the top would be in compression, and those near the bottom would be in tension. This is because a strip close to the top would be acted upon by more strips which tend to shorten it than by strips which tend to elongate it (above it), and vice versa. Finally, there would be a strip somewhere in the pile which would be neither shortened nor elongated, but would remain its original length.

The same remarks apply to the strips considered breadthwise instead of lengthwise. The same stresses are set up, as the strains and temperature changes are identical in the two directions.

Now apply all the above to a set of insulated concentric hoops, forming a laminated ring. We then have a clear conception of what goes on in a metal tube or cylinder with a temperature drop from the outside to the inside. The outside will be in compression, the inside in tension, and one cylindrical surface will remain at its original circumference. This of course applies to the hoop stresses. From the breadth considerations we can see that lengthwise or axial stresses exist in the cylinder.

In the pile of strips, there are no stresses vertically, since in this direction expansion is unrestrained. In the laminated cylinder, however, this is not so. The stretching of the inner hoops and contracting of the outer ones accompany a pressure between them, in a radial direction. There are corresponding distortions affecting the hoop and axial strains. These strains are not now identical, and the hoop and axial stresses are not, in general, equal at any point in the laminated wall. It is, however, obvious that, at the inside and outside surfaces, the radial stress is zero. Here, due to expansion, we should expect the hoop and axial stresses to be equal, and the mathematical analysis given in Appendix No. 1 shows this to be the case.

The principal stresses to be considered are those in the axial and circumferential directions at the inside and outside tube surfaces. They are expressed by the equations (see Appendix No. 1):

Temperature Stresses:

$$[1]\quad f_0 = \frac{m}{2(m-1)}\, aET_0\left(\frac{2}{K^2-1} - \frac{1}{\log_e K}\right)$$ Axial or hoop stress at outer tube surface

$$[2]\quad f_1 = \frac{m}{2(m-1)}\, aET_0\left(\frac{2K^2}{K^2-1} - \frac{1}{\log_e K}\right)$$ Axial or hoop stress at inner tube surface

Pressure Stresses:

$$[3]\quad F_0 = \frac{2P}{K^2-1}$$ Hoop stress at outer tube surface

$$[4]\quad F_1 = P\,\frac{K^2+1}{K^2-1}$$ Hoop stress at inner tube surface

$$[5]\quad F = \frac{P}{K^2-1} = \frac{F_0}{2}$$ Axial stress anywhere

$$[6]\quad T_0 = \frac{\log_e K \times Qr}{k}$$ Temperature drop through tube wall

where a = coefficient of thermal expansion
E = Young's modulus for the material
f_0 = temperature hoop stress at outer surface
f_1 = temperature hoop stress at inner surface
F_0 = pressure hoop stress at outer surface
F_1 = pressure hoop stress at inner surface
K = ratio, outside diameter ÷ inside diameter
k = conductivity
$1/m$ = Poisson's ratio
P = internal pressure
Q_0 = rate of heat input at outside surface
r_0, r_1, r = tube radius, outside, inside, anywhere
T_0 = outside metal temperature — inside metal temperature.

On considering the formulas for temperature stress, we see that they contain the physical quantities a, E, and T_0 in the form of a product. An increase in any or all of them increases the stress.

Taking them in order, an increase in a, the coefficient of thermal expansion, means that the same temperature rise will be accompanied by a greater expansion of the material. The stretching of the cooler portion will then be more, and greater stress will result. A metal of zero thermal expansion would give a zero temperature stress. Such metals are available, but those known lack other essential characteristics.

E, Young's modulus, is defined by the quotient, stress over strain. It is obvious that, for the same strain, an increase in E means an increase in stress.

An increase in T_0, the temperature difference between two points, affects the expansion of the material in the same way as does an increase in a, stress increases for the same reason. T_0 also depends on the conductivity k. For a low k, or small conductivity, a greater temperature difference T is required for the same flow of heat.

From the above considerations, material for tubes should have the following characteristics:

Small expansion due to temperature
Small modulus of elasticity
High conductivity
Great tensile strength at high temperatures.

To facilitate the use of the formulas, Table 2 has been prepared.

Column K gives values of outside diameter ÷ inside diameter

Column A gives values of $\dfrac{2}{K^2-1}$

Column B gives values of $\dfrac{K^2+1}{K^2-1}$

Column C gives values of $\dfrac{2}{K^2-1}-\dfrac{1}{\log_e K}$ (always negative)

Column D gives values of $\dfrac{2K^2}{K^2-1}-\dfrac{1}{\log_e K}$

We then have:

$$\text{Total outside hoop stress} = PA - \frac{maET_0C}{2(m-1)} \quad \ldots\ldots [7]$$

$$\text{Total outside axial stress} = \frac{1}{2}PA - \frac{maET_0C}{2(m-1)} + \text{bending stress} \quad \ldots\ldots [8]$$

TABLE 2 VALUES FOR USE IN FORMULAS

1.23	3.90	4.90	0.933	1.067	1.48	1.68	2.68	0.871	1.129
1.24	3.72	4.72	0.930	1.070	1.49	1.64	2.64	0.869	1.131
1.25	3.56	4.56	0.927	1.073	1.50	1.60	2.60	0.866	1.134

$$\text{Total inside hoop stress} = PB + \frac{maET_0D}{2(m-1)} \quad \ldots\ldots [9]$$

$$\text{Total inside axial stress} = \frac{1}{2}PA + \frac{maET_0D}{2(m-1)} + \text{bending stress} \quad \ldots\ldots [10]$$

The bending stress depends on the manner in which the tube is supported, and is calculated by the usual formulas. The total axial stress is sometimes important, as cases have occurred in which tubes sagged down under the action of the combined axial stresses.

As an example of the use of Table 2, consider a tube 5 in. O.D., 4.2 in. I.D., with a heat input at the outside of 10,000 B.t.u. per sq. ft. per hr. Take P as 1000 lb. per sq. in. Let the material be KA2S, in which, assume

$a = 11.5 \times 10^{-6}$ inches per inch
$E = 24.5 \times 10^6$ lb. per sq. in.
$K = 5 \div 4.2 = 1.19$
$k = 144$ (B.t.u. per sq. ft. per in. of thickness per deg. fahr.)
$m = 3^1/_2$ or $1/m = 0.3$

$$\text{Then } T_0 = \frac{\log_e(1.19) \times 10{,}000 \times 2.5}{144} = 30 \text{ deg. from [6]}$$

$$\frac{maE}{2(m-1)} = \frac{5 \times 11.5 \times 24.5}{7} = 201$$

From Table 2, for $K = 1.19$, $A = 4.81$, $B = 5.81$, $C = 0.942$, $D = 1.058$.

Outside Hoop Stress:

$1000 \times 4.81 = 4810$ from [7]
$-(201 \times 30 \times 0.942) = -5700$
-890

or 890 lb. per sq. in. compression.

Outside Axial Stress:

-5700 from [8]
$+2405$
-3295

or 3295 lb. per sq. in. compression + the bending stress.

Inside Hoop Stress:

$1000 \times 5.81 = 5810$ from [9]
$201 \times 30 \times 1.058 = 6400$
12,210 lb. per sq. in. tension

Inside Axial Stress:

2405 from [10]
6400
8805 lb. per sq. in. tension + bending stress.

It will be seen from the above that the inside hoop stress is the one which governs design, since the bending stresses can be made very small by proper supports. If we take the 5-in. O.D. tube and vary the inside diameter, we can compute Table 3.

From this table, the curves shown in Fig. 6 are plotted. As indicated on the plot, the inside

TABLE 3 HOOP STRESSES, LB. PER SQ. IN.

K	T_0	Inside hoop stress	Outside hoop stress
1.04	6.8	26,900	23,160
1.06	10.1	19,250	13,990
1.08	13.4	15,780	9,400
1.10	16.5	13,950	6,310
1.12	19.7	12,960	4,050
1.14	23.8	12,440	2,100
1.16	25.8	12,240	860
1.18	28.7	12,200	— 350
1.20	31.6	12,300	—1,410
1.22	34.5	12,500	—2,360
1.24	37.4	12,770	—3,280
1.26	40.0	13,050	—4,020
1.28	43.0	13,480	—4,780
1.30	45.5	13,850	—5,450

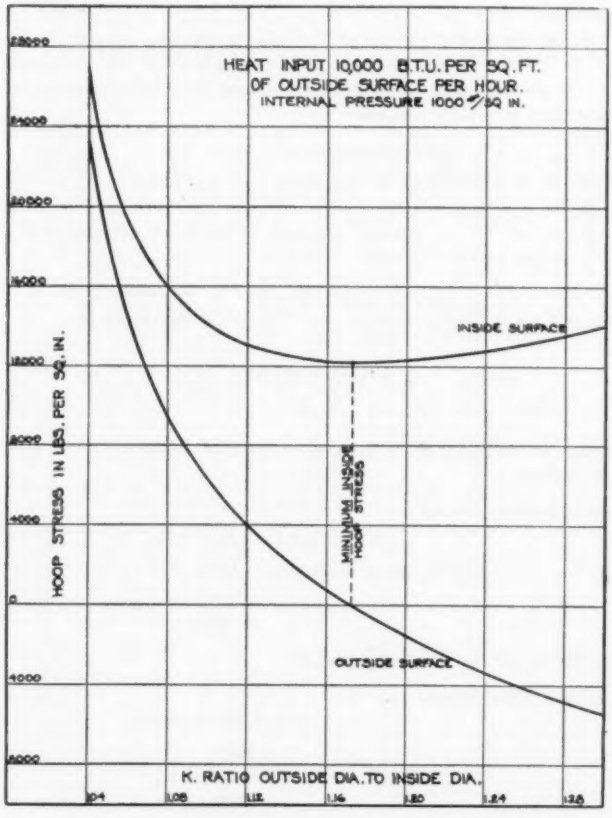

FIG. 6 HOOP STRESSES IN HEATED TUBES UNDER PRESSURE

hoop stress has a minimum value, and for the corresponding value of K the outside hoop stress is zero. As this value occurs at $K = 1.173$, the 5-in. O.D. tube having the lowest inside hoop stress would have an inside diameter of

$$5 \div 1.173 = 4.25 \text{ in.}$$

As pointed out above, the inside hoop stress is the one which governs design. Then by the selection of the proper thickness for the conditions imposed we can secure the minimum hoop stress. This is the optimum tube for the conditions—a tube either thicker or thinner would be weaker. If the inside hoop stress exceeds the safe working stress of the metal, which is usually taken at from 60 to 80 per cent of the 100,000-hr. creep, then the designer must either reduce the metal temperature, the heat input, or the pressure, or else find a metal having a higher creep limit.

For practical calculations, plotting the curves to find the optimum tube involves considerable labor. This can be avoided by the use of Table 4, the mathematical derivation of which is given in Appendix No. 2.

The following example shows its use in the direct calculation of the above-mentioned optimum tube:

$$b = 1.4\,Qr = 1.4 \times 10{,}000 \times 2.5 = 35{,}000 \text{ from [11]}$$

$$2P/b = 2000/35{,}000 = 0.057$$

This lies between $K = 1.16$ and 1.18 in the table. By interpolation,

1.18	0.061	0.057
1.16	0.049	0.049
0.02	0.012	0.008

$$K = 1.16 + 0.02 \times 0.008/0.012$$

$$0.013$$

$$K = 1.173$$

Inside temp. hoop stress =
$35{,}000 \times 1.053 \times \log_e 1.173 = 5900$ from [14]
Inside pressure hoop stress $= 6.30 \times 1000 = 6300$ from [9]

Total inside hoop stress 12,200

Outside temp. hoop stress =
$-35{,}000 \times 0.947 \times \log_e 1.173 = -5300$ from [13]
$5.30 \times 1000 = 5300$ from [7]

Total outside hoop stress 0

These results check with Table 3. It will be noticed that the inside-hoop-stress curve is very flat in the neighborhood of the minimum value. It is therefore quite accurate enough to take K as the nearest value given in Table 4 without resorting to interpolation. This has only been done in the above instance for the sake of completeness.

We might have started with the inside diameter of 4.25 in., to agree with some particular oil velocity. Then for the same total heat input to the tube, we should have had $Q = 10{,}000 \times (5/4.25)$ and b would have been

$$1.4 \times [10{,}000 \times (5/4.25)] \times 2.125 = 35{,}000$$

the same value as before. Then by the use of Table 4, K would have been found to be 1.173, giving an outside diameter of $4.25 \times 1.173 = 5$ in. The table can thus be used to get the optimum tube, if the total heat input, the internal pressure, and either the inside or outside diameter be known. In fact, if any three of these quantities be known, the other can be found for optimum conditions. If we had a tube 5 in. O.D.,

TABLE 4 FOR USE IN SELECTION OF OPTIMUM TUBE

K	$\frac{2P}{b}$	K	$\frac{2P}{b}$

$b = 1.4\,Qr$ for KA2 Eq. [11]
$= 0.47\,Qr$ for steel Eq. [12]

Temperature hoop stresses *for Optimum Conditions:*
Outside: $bC \log_e K$ Eq. [13]
Inside: $bD \log_e K$ Eq. [14]

P = internal pressure
Q = B.t.u. per sq. ft. per hr. through any cylindrical surface of radius r. For a given heat flow into a length of tube, Qr = const.

$4^1/_4$ in. I.D., K would be 1.173, and $2P/b$, by interpolation, would be 0.057; then

$$b = \frac{2P}{0.057} = 1.4\,Qr$$

With P known as 1000,

$$Qr = \frac{2000}{0.057 \times 1.4} = 25{,}000$$

$$Q = \frac{25{,}000}{2.5} = 10{,}000 \text{ at the outside}$$

with Qr known[5] as 25,000,

$$P = \frac{1.4 \times 25{,}000 \times 0.057}{2} = 1000$$

An example is now given, taken from experience, of the occasional importance of axial stresses.

Carbon-steel tube 4 in. O.D., $3^1/_4$ in. I.D., span 18.58 ft.

Weight of tube and contents, 322 lb. P = 400 lb. per sq. in.

Bending moment, $1/8 \times 322 \times 18.58 \times 12 = 8980$ in.-lb.

Section modulus, 3.55 in.^{3}

Compression in top fiber = $8980 \div 3.55 = 2520$ lb. per sq. in.

Tension at low point of inside wall = $2520 \times (3.25/4) = 2050$ lb. per sq. in.

For the existing conditions,

$E = 17.5 \times 10^6$; $a = 11.35 \times 10^{-6}$; $1/m = 0.3$;
$T = 28°$; $K = 1.23$; $m/2(m-1) = {}^5/_7$.

Total outside axial stress:

$-5/7 \times 11.35 \times 17.5 \times 28 \times 0.933$	=	—3700 from [8]
Bending stress	=	—2520
		—6220
$1/2 \times 400 \times 3.9$ = Axial pressure stress	=	780
		—5440

or 5440 lb. per sq. in. compression in upper fiber.

Total inside axial stress:

$5/7 \times 11.35 \times 17.5 \times 28 \times 1.067$	=	4250 from [10]
$1/2 \times 400 \times 3.9$	=	780
Bending stress	=	2050
Tension at low point of inside wall	=	7080 lb. per sq. in.

The creep stress of the material was 6600 lb. per sq. in. at the temperature of the inner wall, and the above tension exceeds it. The tube actually sagged in service. This instance is a demonstration of the existence of high axial stresses due to temperature effects, as the bending stresses are quite insufficient to account for the sagging.

All the foregoing formulas are based on the supposition that the heat input is uniform all over the outside tube surface. In actual tubes this is not so. The heat input is a maximum at points nearest the source of heat and diminishes to a minimum at points furthest from it. This case is being studied by C. O. Rhys. The work done to date appears to show, however, that the inside hoop stress, as calculated above, would still be the governing factor in design.

A study of the formulas shows that the rational design of thick-walled tubes requires a knowledge of a number of physical properties of the material used. The modulus of elasticity, Poisson's ratio, the coefficient of expansion, and the thermal conductivity all enter into the equations either directly or indirectly, and must all be known. The latter two are usually supplied by the manufacturer of the steel or alloy in question; the first two are seldom given. For the determination of the modulus of elasticity, there has recently been set up in our laboratory an Amsler hydraulic testing machine of 60,000 lb. capacity and an Amsler-Martens mirror extensometer with which changes in length of two-millionths of an inch can be measured. Equipment is also available for the determination of the modulus of elasticity at elevated temperatures as well as at atmospheric temperatures. No equipment is available at the moment for the determination of Poisson's ratio; it is planned, however, to install a torsion machine by means of which the modulus of rigidity may be accurately determined at both atmospheric and elevated temperatures. The modulus of rigidity and Young's modulus are all that are necessary to make possible the calculation of Poisson's ratio, and it is felt that this method, particularly at elevated temperatures, is far more feasible than through the determinations of lateral and longitudinal strains. The importance of Poisson's ratio, which is usually given as 0.3, may be judged from the statement that a reduction of this ratio to 0.2, which is the value given by some investigators for certain alloys at high temperatures, reduces the stresses set up by the heat input by 12 per cent.

One other factor is the tube-wall temperature. While it does not enter into the equations, it is of paramount importance. The tube-wall temperature naturally determines the safe working stress which the tube will withstand, as reference to the creep curve of the material will show very clearly. The prediction of tube temperatures could well form the subject of a separate report, but because of the complexity of this problem it can only be briefly touched upon in this paper.

In general, an oil-refinery furnace is designed to raise a given quantity of oil from a known entering temperature to a known final temperature. The heat-input rates are usually well established from past operating conditions, so that the temperature of the oil at points throughout the setting may be readily calculated. From these data the tube-wall temperature is calculated from the drop through the oil film for which numerous formulas have been given by other investigators; however, allowance must be frequently made for surface cracking, boiling, critical temperature conditions, etc., all of which may set up a gas film at the point of contact with the inner tube wall or with the layer of coke in the tube. In case a layer of coke exists in the tube, due allowance must be made for the temperature drop through this layer, which may vary in thickness from $^1/_{32}$ in. to as much as $^3/_4$ in., depending upon the time-temperature relationships, the cracking rate of the oil in question, and the length of time that the unit has been on stream.

These factors seriously affect the tube-wall temperature, and an attempt is now being made to correlate the data secured from recorded tube temperatures with the theoretical drops through the metal, coke, and oil film. For very high mass velocities of 700 lb. per sq. ft. per sec., with little coke formation, the outer tube wall may be only 60 to 80 deg. hotter than the oil for a heat input of 10,000 B.t.u. per sq. ft. per hr., but with mass velocities of 350 to 400, where coke formation is present, the tubes may be 200 deg. or more hotter than the oil.

As pointed out earlier in this report, the question of the existence or non-existence of temperature stresses is controversial.

The final step in the research program outlined in the second paragraph of this paper is the laboratory check of the stress formulas. While we are quite convinced of the existence of temperature stresses, we hold no brief for the theory and would

[5] $\frac{\text{Total heat input to tube, (B.t.u./hr.)} \times r \text{ (in.)}}{\text{Total cylindrical surface (sq. ft.) at radius } r}$

be the first to reject it could conclusive reasons be found for taking this step. Reference to the examples already given will show that with temperature stresses eliminated the remaining stress, i.e., that due to pressure, is approximately one-half of the sum of the two. This would mean that in some cases the use of thinner tubes would be permissible, with a very considerable monetary saving particularly in the case of high-chrome-nickel alloys. In other cases it would allow the employment of greatly increased heat inputs, with a resulting reduction in the cost of the furnace due to the lesser number of tubes required.

To check the mathematical theory of temperature stresses, equipment has been set up which will allow of testing to destruction tubes of various sizes and materials under varying conditions of temperature, pressure, and heat input.

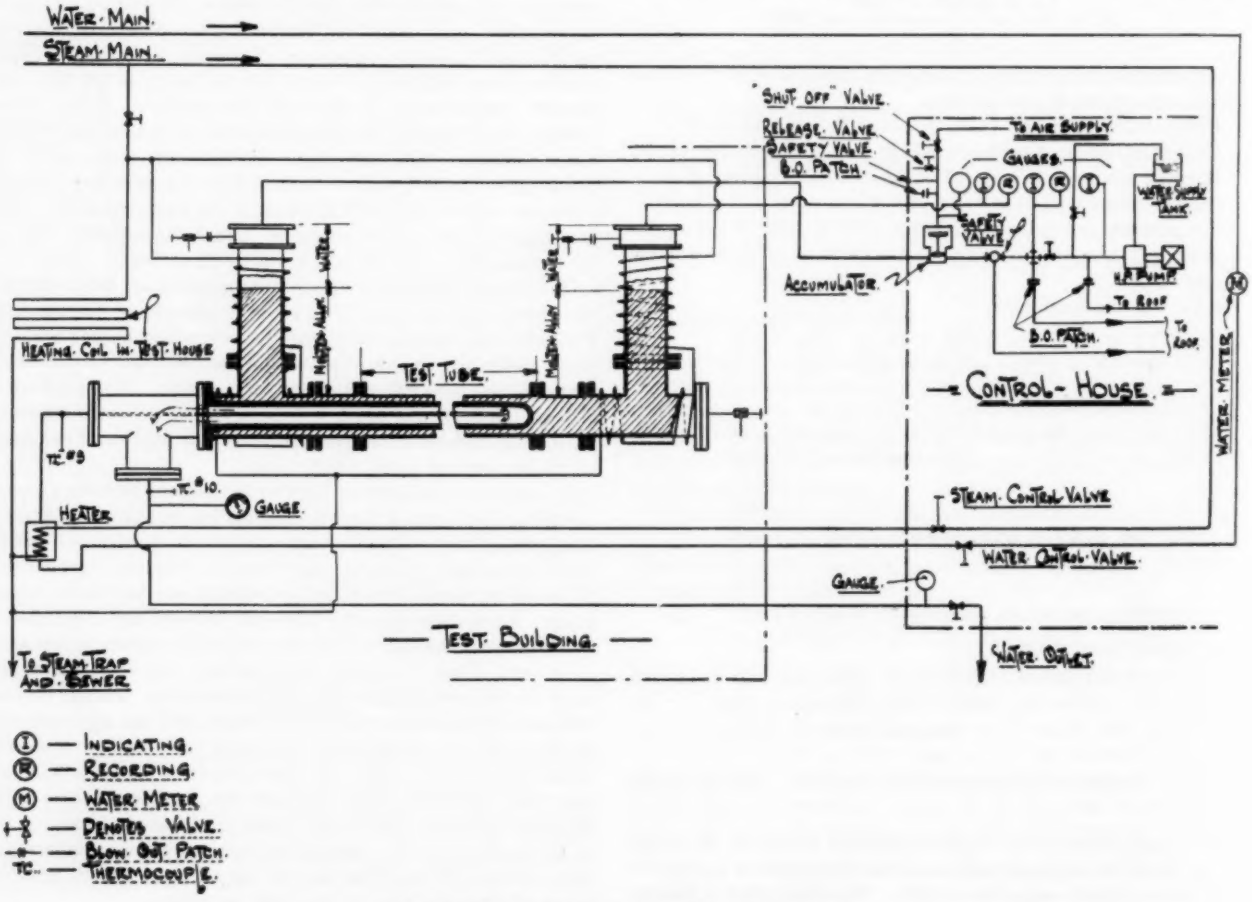

FIG. 7 SCHEMATIC DIAGRAM OF TEST EQUIPMENT

and serves to carry the heat away. Fig. 7 shows a schematic diagram of the test equipment. The pressure medium is a low-melting-point lead-bismuth-cadmium-tin alloy which is contained in the annular space between the test tube and the inner seamless tube, and in two containers which are a part of the high-pressure piping system. This alloy has a melting point of approximately 160 deg. fahr. and is completely liquid at approximately 200 deg. fahr., so that it must be kept hot at all times. For this purpose, the containers are steam jacketed, and a small current can be maintained in the electric-furnace heaters at all times. There are also extra heater plates underneath the fittings to furnish additional heat through the flanges and exposed metal. Pressure is applied on the liquid alloy by means of water from the high-pressure pump, the contact between the water and the metal being in these containers, a second container being used to transmit pressure on the liquid-metal system back through a water medium to gages in the control house. The high-pressure pump is a triplex, motor-driven pump designed for a maximum of 25,000 lb. per sq. in. with a capacity of 250 cu. in. per min. In the system is an air-loaded pressure accumulator with a displacement of approximately 28 cu. in. This system is protected by means of an adjustable 15,000- to 25,000-lb. safety valve as well as by two frangible disks which are now designed to blow at 14,000 lb. The electric furnace consists of nichrome ribbon wound on porcelain insulators, forming a square around the test section. The resistance winding is in four separate sections, the two sides and bottom being connected together in thirds of the furnace length, while the top heater is a separate unit.

The apparatus consists essentially of the test section heated by a radiant electric-resistance heater, with suitable controls and meters, a pressure medium, high-pressure connecting fittings, a cooling system, and a high-pressure pump. The test section is contained in a special reinforced-concrete building, while the pump and all the controls are in a separate building 50 ft. away.

The test section consists of an 8-ft. length of tube of the size under test, mounted in flanges and bolted up to special nickel-chromium alloy fittings designed to operate under a pressure of 3000 lb. at 1200 deg. fahr. under normal working conditions. Supported centrally inside the tube is a one-piece seamless steel tube which is welded closed at one end and flanged on the other end to form a seal between two adjacent fittings. Water circulates inside this tube, being brought in through a $^3/_4$-in. pipe,

Heat is transmitted through the steel tube and through the pressure medium to the inner steel tube, from which the heat is removed by circulating water. The heat flow through the test tube and the temperature of this tube are controlled within certain limits to produce temperature stresses. The outside surface temperatures of the tube are taken by means of eight thermocouples peened in the outer surface. No. 22 Chromel Alumel wire is used to obtain accurate temperature as it is the smallest size considered practicable for use under our particular conditions, and two No. 14 thermocouples are placed alongside two No. 22 to indicate the difference in temperature at the junction due to heat transmission along the thermocouple wires. The No. 14 wire is the size used in our regular service on cracking furnace tubes, and is used in this test merely to check the difference in indicated temperature. The present program covers a series of tests with outside tube temperatures ranging up to 1400 deg. fahr. and with a rate of heat flow through the tube ranging up to 30,000 B.t.u. per hr. per sq. ft. of outside tube surface. The pressure may be carried up to 14,000 lb. per sq. in.

While this equipment will give a rough check on the temperature-stress theory, its greatest value lies in its ability to determine the factor of safety of a tube against rupture. It will show, for example, that a commercial tube operating at temperature T with heat input Q and internal pressure P will not fail until the pressure reaches some multiple of P. It cannot check the equations accurately as these are all based on the elastic properties of the material, whereas this machine will only give bursting conditions.

To check the temperature-stress theory without exceeding the elastic limit of the material, a second testing device is being considered in which a thick tube would be heated from the inside and the strain on the outer wall measured by sensitive extensometers. With such apparatus the temperature stresses could be checked by comparison with those calculated directly from the formulas already derived.

At least part of the discrepancies between results obtained by French and those of the S. O. D. Co. are due to the great differences in the lengths of time in making the tests and the interpretation of the data. In Mr. French's work tests were carried on for 500 hr. or less, while in our own work as long as 6000 hr. was required to obtain the desired result.

Also steel obtained from different sources of supply, and even different heats may produce varying results. In this connection the author quotes from Mr. French's paper the following:

> One important point, which has not been given much consideration in the interpretation of flow tests, is that the numerical values obtained on one bar, lot, or melt of a given alloy may not coincide closely with the values obtained on other bars, lots, or melts. Similar variations in the properties of metals at atmospheric temperatures are well recognized and should likewise be given consideration in the application of flow-test data. The extent of these variations is not now accurately known but it has been shown that the differences in load-carrying ability, from heat to heat of steel, may be large. Without additional data, it is not safe to assume that the reported values represent the average, maximum, or minimum of the range characteristic of a given metal, and safety factors must still be employed.

In the work by Norton, he states that the creep loads may be relied upon to within ±25 per cent, and that relative values should be somewhat closer. Results obtained in our own laboratory may differ from those of other investigators by appreciable amounts and still be as accurate as it is possible to determine at the present time. This is because of the reasons given above.

With a full knowledge of safe stresses, well-defined values for the modulus of elasticity, Poisson's ratio, thermal conductivity, and coefficient of expansion, and laboratory-checked formulas for the calculation of stresses, the designer could proceed with the assurance that his designs were not only safe but economical as well. The program outlined is still far from completion, and for this reason the data contained in this report should be considered as preliminary as the report is not presented as a final one. Until the theory is disproved, however, it seems advisable to accept the existence of temperature stresses, as this is the safer procedure to follow if human life is to be safeguarded and damage to equipment reduced to a minimum.

ACKNOWLEDGMENT

To Mr. C. O. Rhys of the Process Division belongs entire credit for the mathematics given in the appendices to this paper. The derivation of the equations given are an abridgment and simplification of a more complete solution developed by Mr. Rhys during 1929, by which the stresses at any point in a tube may be determined. Mr. R. L. Duff in charge of the Metallurgical Division and his assistants supplied the description of the creep-point equipment and the test results secured with this equipment. Mr. A. J. Ely in charge of the Testing Division supplied the information on the equipment being developed for checking the mathematical theory.

Appendix No. 1—Derivation of Formulas for Temperature and Pressure Stresses in Tubes

TAKE a cross-section near the middle of a long circular tube. Let the temperature at any point be called T. At the inside surface $T = 0$, and at the outside surface $T = T_0$. There is thus a temperature drop through the tube from the outside to the inside. Also let there be an internal fluid pressure P.

Radial Strain. Before the temperature drop is established, let the radius to any point in the wall be called r. When the temperature drop exists, let this radius become $r + u$. Then an element of material, of radial dimension dr will change by du. If a be the coefficient of thermal expansion, and e the radial strain, the radial change of the element will be

$$a\,T\,dr + e\,dr$$

and we can write

$$du = a\,T\,dr + e\,dr$$

or

$$e = \frac{du}{dr} - aT$$

Hoop Strain. When r increases to $r + u$, the circumference, $2\pi r$ increases by $2\pi raT + 2\pi rf$, where f is the circumferential, or hoop strain. We thus have

$$u = raT + rf$$

or

$$f = \frac{u}{r} - aT$$

Axial Strain. When two similar insulated strips are first fastened together and then one of them is heated, compression sets up in one and tension in the other, with consequent bending of the strips. When such strips are replaced by long, thin, concentric tubes (strip length corresponds with tube-axis length) such bending cannot occur, and all fibers stretch axially by the same amount. If therefore v = axial displacement and z = axial length from some origin, it appears that dv/dz would be constant. Calling the axial strain g, we should have, as above,

$$g = \frac{dv}{dz} - aT$$

Strain and Stress Equations. Collecting from above,

$$e = \frac{du}{dr} - aT \quad \text{(Radial strain)}$$

$$f = \frac{u}{r} - aT \quad \text{(Hoop strain)}$$

$$g = \frac{dv}{dz} - aT \quad \text{(Axial strain)}$$

These are the strains in the three directions at right angles to each other. The dilatation is given by $D' = \frac{du}{dr} + \frac{u}{r} + \frac{dv}{dz} - 3aT$ (Love, "Mathematical Theory of Elasticity," p. 61), and the usual stress strain relations of the form

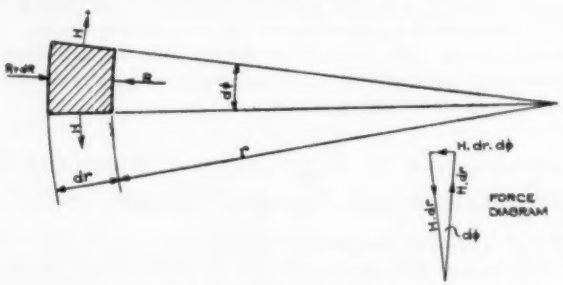

FIG. 8 ELEMENT OF TUBE WALL
(1 in. in length at right angles to section shown.)

$$R = \frac{2GD'}{m-2} + 2Ge$$

$$H = \frac{2GD'}{m-2} + 2Gf$$

$$Z = \frac{2GD'}{m-2} + 2Gg$$

can be written

$$\left.\begin{aligned} R &= \frac{2G}{m-2}\left[(m-1)\frac{du}{dr} + \frac{u}{r} + \frac{dv}{dz} - (m+1)aT\right] \\ H &= \frac{2G}{m-2}\left[\frac{du}{dr} + (m-1)\frac{u}{r} + \frac{dv}{dz} - (m+1)aT\right] \\ Z &= \frac{2G}{m-2}\left[\frac{du}{dr} + \frac{u}{r} + (m-1)\frac{dv}{dz} - (m+1)aT\right] \end{aligned}\right\} \quad [15]$$

where R, H, and Z are the radial, hoop, and axial stresses. G is the modulus of rigidity, or shearing modulus, and $1/m$ is Poisson's ratio.

Equations of Equilibrium. If we take an element of the tube wall as shown in Fig. 8, its equilibrium, in the plane of the paper, is given by

$$(R + dR)(r + dr)d\phi - Rrd\phi = Hdrd\phi$$

or

$$H - R = r\frac{dR}{dr} \quad [16]$$

Radial Displacement. From [15] and [16] we then have, remembering that dv/dz is a constant,

$$\frac{u}{r^2} - \frac{1}{r}\frac{du}{dr} = \frac{1}{m-2}\left[(m-1)\frac{d^2u}{dr^2} + \frac{1}{r}\frac{du}{dr} - \frac{u}{r^2} - (m+1)a\frac{dT}{dr}\right]$$

$$\frac{d^2u}{dr^2} + \frac{1}{r}\frac{du}{dr} - \frac{u}{r^2} = \frac{m+1}{m-1}a\frac{dT}{dr}$$

$$\frac{d}{dr}\left[\frac{1}{r}\frac{d}{dr}(ur)\right] = \frac{m+1}{m-1}a\frac{dT}{dr} \quad [17]$$

To integrate this, T must be expressed in terms of r. For cracking-coil work we require the "steady-state" relation, which is expressed by the well-known heat-conductivity equation

$$\frac{d^2T}{dr^2} + \frac{1}{r}\frac{dT}{dr} = 0$$

of which the solution is, for the boundary conditions

$$r = r_0, \quad T = T_0 \text{ (outside)} \quad r = r_1, \quad T = 0 \text{ (inside)}$$

$$T = \frac{T_0}{\log_e K}\log_e\frac{r}{r_1}, \qquad K = r_0/r_1$$

and

$$\frac{dT}{dr} = \frac{T_0}{\log_e K}\frac{1}{r} \quad [18]$$

This is sometimes called the temperature gradient.

Inserting [18] in [17] we have,

$$\frac{d}{dr}\left[\frac{1}{r}\frac{d}{dr}(ur)\right] = \frac{m+1}{m-1}\frac{aT_0}{\log_e K}\frac{1}{r}$$

$$\frac{d}{dr}(ur) = \frac{m+1}{m-1}\frac{aT_0}{\log_e K}r\log_e\frac{r}{r_1} + C_0r$$

$$u = \frac{m+1}{m-1}\frac{aT_0}{\log_e K}\frac{r}{2}\left(\log_e\frac{r}{r_1} - \frac{1}{2}\right) + \frac{C_1}{r} + C_0r \quad [19]$$

from which

$$\frac{du}{dr} = \frac{m+1}{m-1}\frac{aT_0}{\log_e K}\frac{1}{2}\left(\log\frac{r}{r_1} + \frac{1}{2}\right) - \frac{C_1}{r^2} + C_0 \quad [20]$$

and

$$\frac{u}{r} = \frac{m+1}{m-1}\frac{aT_0}{\log_e K}\frac{1}{2}\left(\log_e\frac{r}{r_1} - \frac{1}{2}\right) + \frac{C_1}{r^2} + C_0 \quad [21]$$

Evaluation of Constant C_1. By inserting [20] and [21] in the first of [15] and simplifying, we have, for the radial stress,

$$R = \frac{2G}{m-2}\left\{\frac{aT_0}{2\log_e K}\frac{m+1}{m-1}\left[m\left(\log_e\frac{r}{r_1} + \frac{1}{2}\right) - 1\right] + mC_0 + \frac{dv}{dz} - (m-2)\frac{C_1}{r^2} - \frac{(m+1)aT_0}{\log_e K}\log_e\frac{r}{r_1}\right\}$$

This is $-P$ (compression) at $r = r_1$, and 0 when $r = r_0$ so that we have, making these substitutions and subtracting:

$$P = \frac{2G}{m-2}\left[\frac{aT_0}{2}\frac{m+1}{m-1}m - (m-2)C_1\left(\frac{1}{r_0^2} - \frac{1}{r_1^2}\right) - (m+1)aT_0\right]$$

$$= 2G\left(C_1\frac{K^2-1}{r_0^2} - \frac{m+1}{m-1}\frac{1}{2}aT_0\right)$$

$$C_1 = \frac{r_0^2}{K^2-1}\left(\frac{P}{2G} + \frac{m+1}{m-1}\frac{1}{2}aT_0\right) \quad [22]$$

Hoop Stress at Outside. At the outside surface we have from [15]:

$$0 = \frac{2G}{m-2}\left[(m-1)\frac{du}{dr} + \frac{u}{r} + \frac{dv}{dz} - (m+1)aT\right]$$

$$H_0 = \frac{2G}{m-2}\left[\frac{du}{dr} + (m-1)\frac{u}{r} + \frac{dv}{dz} - (m+1)aT\right]$$

Subtracting,

$$H_0 = \frac{2G}{m-2}\left[-(m-2)\frac{du}{dr} + (m-2)\frac{u}{r}\right]$$

$$= 2G\left(\frac{u}{r} - \frac{du}{dr}\right)$$

Substituting in this from [20] and [21], putting $r = r_0$,

$$H_0 = 2G\left(\frac{2C_1}{r_0^2} - \frac{m+1}{m-1}\frac{aT_0}{2\log_e K}\right)$$

Inserting the value of C_1 from [22],

$$H_0 = 2G\left(\frac{1}{K^2-1}\frac{m+1}{m-1}aT_0 - \frac{m+1}{m-1}\frac{aT_0}{2\log_e K}\right) + \frac{2P}{K^2-1}$$

$$= G\frac{m+1}{m-1}aT_0\left(\frac{2}{K^2-1} - \frac{1}{\log_e K}\right) + \frac{2P}{K^2-1} \quad \ldots [23]$$

the outside hoop stress.

The term in P is due to pressure only, and the other part of temperature only. We call these F_0 and f_0, respectively.

Hoop Stress at Inside. At the inside surface the radial stress is a compression equal to the internal pressure. We can write

$$-P = \frac{2G}{m-2}\left[(m-1)\frac{du}{dr} + \frac{u}{r} + \frac{dv}{dz} - (m+1)aT\right]$$

$$H_1 = \frac{2G}{m-2}\left[\frac{du}{dr} + (m-1)\frac{u}{r} + \frac{dv}{dz} - (m+1)aT\right]$$

Subtracting,

$$H_1 = \frac{2G}{m-2}\left[(m-2)\frac{u}{r} - (m-2)\frac{du}{dr}\right] - P$$

$$= 2G\left(\frac{u}{r} - \frac{du}{dr}\right) - P$$

Substituting in this from [20] and [21], putting $r = r_1$,

$$H_1 = 2G\left(\frac{2C_1}{r_1^2} - \frac{m+1}{m-1}\frac{aT_0}{2\log_e K}\right) - P$$

Inserting value of C_1 from [22],

$$H_1 = 2G\left(\frac{2K^2}{K^2-1}\frac{m+1}{m-1}\frac{aT_0}{2} - \frac{m+1}{m-1}\frac{aT_0}{2\log_e K}\right) + \frac{2K^2P}{K^2-1} - P$$

$$= GaT_0\frac{m+1}{m-1}\left(\frac{2K^2}{K^2-1} - \frac{1}{\log_e K}\right) + P\frac{K^2+1}{K^2-1} \quad \ldots [24]$$

(the inside hoop stress.) The term in P is due to pressure only, and the other part to temperature only. We call these F_1 and f_1, respectively.

Axial Stresses. By the usual stress-strain equations, we can write the axial strain at the outside and inside surfaces. Consider temperature stresses only, or $P = 0$.

$$\left.\begin{aligned}\frac{dv}{dz} &= \frac{Z_0}{E} - \frac{H_0}{mE} + aT_0\\ \frac{dv}{dz} &= \frac{Z_1}{E} - \frac{H_1}{mE}\end{aligned}\right\} \quad \ldots [25]$$

Subtracting and transposing, since dv/dz is constant,

$$Z_1 - Z_0 = \frac{1}{m}(H_1 - H_0) + EaT_0 \quad \ldots [26]$$

From [23] and [24],

$$H_1 - H_0 = 2GaT_0\frac{m+1}{m-1} \quad \ldots [27]$$

Inserting this in [26], noting that $E = \frac{2G(m+1)}{m}$,

$$Z_1 - Z_0 = 2GaT_0\frac{m+1}{m(m-1)} + 2GaT_0\frac{m+1}{m}$$

$$= 2GaT_0\frac{m+1}{m}\left(\frac{1}{m-1} + 1\right)$$

$$= 2GaT_0\frac{m+1}{m+1}$$

$$Z_1 - Z_0 = H_1 - H_0 \text{ from [27].}$$

This last relation shows us by [26] that Z_1, Z_0, can be interchanged with H_1, H_0 in [25], or $Z_1 = H_1$ and $Z_0 = H_0$, or the temperature parts of the hoop and axial stresses are the same at the inside and outside surfaces.

The axial stress due to pressure in a tube closed at the ends is

$$\frac{P\pi r_1^2}{\pi(r_0^2 - r_1^2)} = \frac{P}{K^2-1}$$

Summary. Collecting from the above, we can write the equations for the stress in terms of E, Young's modulus, instead of G, the shearing modulus.

$$H_1 = \frac{maET_0}{2(m-1)}\left(\frac{2K^2}{K^2-1} - \frac{1}{\log_e K}\right) + P\frac{K^2+1}{K^2-1} \quad \text{(Inside hoop stress)}$$

$$H_0 = \frac{maET_0}{2(m-1)}\left(\frac{2}{K^2-1} - \frac{1}{\log_e K}\right) + \frac{2P}{K^2-1} \quad \text{(Outside hoop stress)}$$

$$Z_1 = \frac{maET_0}{2(m-1)}\left(\frac{2K^2}{K^2-1} - \frac{1}{\log_e K}\right) + \frac{P}{K^2-1} \quad \text{(Inside axial stress)}$$

$$Z_0 = \frac{maET_0}{2(m-1)}\left(\frac{2}{K^2-1} - \frac{1}{\log_e K}\right) + \frac{P}{K^2-1} \quad \text{(Outside axial stress)}$$

$$R_1 = -P \quad \text{(Inside radial stress)}$$

$$R_0 = 0 \quad \text{(Outside radial stress)}$$

In the above, the formulas for temperature and pressure stresses are those of Lorenz and Lamé, respectively.

Appendix No. 2—Derivation of Formulas for Calculating the Optimum Tube

THE heat input through a unit area is given by the temperature gradient multiplied by the coefficient of heat conductivity k.

Calling the heat input Q, and taking the temperature gradient from Equation [18], Appendix No. 1,

$$Q = \frac{kT_0}{\log_e K}\frac{1}{r}$$

or

$$T_0 = \frac{Qr \log_e K}{k}$$

For a given total-heat input to a circular tube, Qr is constant. We can then write, for the inside hoop stress (see Summary, Appendix No. 1),

$$H_1 = \frac{maEQr}{2(m-1)}\frac{\log_e K}{k}\left(\frac{2K^2}{K^2-1} - \frac{1}{\log_e K}\right) + P\frac{K^2+1}{K^2-1}$$

$$= \frac{maEQr}{2(m-1)k}\left(\frac{2K^2 \log_e K}{K^2-1} - 1\right) + P\frac{K^2+1}{K^2-1}$$

Differentiating with respect to K,

$$\frac{dH_1}{dK} = \frac{maEQr}{2(m-1)k}\left(\frac{(K^2-1)(4K\log_e K + 2K) - 4K^2\log_e K}{(K^2-1)^2}\right) - \frac{4PK}{(K^2-1)^2}$$

Equating to 0 and simplifying

$$\frac{maEQr}{2(m-1)k}(K^2 - 1 - 2\log_e K) - 2P = 0 \ldots\ldots [28]$$

Putting $\frac{maEQr}{2(m-1)k} = b$, we have the condition for minimum inside hoop stress,

$$\frac{2P}{b} = K^2 - 1 - 2\log_e K \ldots\ldots\ldots\ldots [29]$$

from which Table 4 has been calculated. The following values have been taken for cracking-coil conditions:

	m	a	E	k
	pure	$\frac{1}{\text{deg.}}$		$\frac{\text{B.t.u.} \times \text{in.}}{\text{sq. ft.} \times \text{hr.} \times \text{deg.}}$
Units...	number		lb. per sq. in.	
Steel...	4	10×10^{-6}	23×10^6	330
KA2S..	3½	11.5×10^{-6}	24.5×10	144

which give $b = 0.47\,Qr$ for steel
$b = 1.4\,Qr$ for KA2S.

Since $\frac{Qr}{k} = \frac{T_0}{\log_e K_1}$, we can write [28] as

$$\frac{maET_0}{2(m-1)}\left(\frac{K^2-1}{\log_e K} - 2\right) - 2P = 0$$

or

$$\frac{maET_0}{2(m-1)}\left(\frac{2}{K^2-1} - \frac{1}{\log_e K}\right) + \frac{2P}{K^2-1} = 0$$

or the outside hoop stress = 0 and the outside axial stress reduces to $P/(K^2-1)$, the axial stress due to pressure only. The inside axial stress is readily shown to be $H_1 - PK^2/(K^2-1)$ from the summary, Appendix No. 1. For the optimum tube we thus have:

Inside hoop stress:	$H_1 = bD\log_e K + PB$ (See Table 2)
Outside hoop stress:	$H_0 = 0$
Inside axial stress:	$Z_1 = H_1 - \frac{PK^2}{K^2-1}$
Outside axial stress:	$Z_0 = \frac{P}{K^2-1}$ or $\frac{PA}{2}$
Inside radial stress:	$R = -P$
Outside radial stress:	$R = 0$

or, when H_1 is a minimum, three of the other stresses are less than H_1 and the remaining two are zero.

FSP-53-13

High-Burned Kaolin Refractories

By F. H. NORTON,[1] CAMBRIDGE, MASS.

The development of high-fired kaolin refractories is briefly described. The various products made from kaolin such as brick, tank blocks, light-weight brick, and insulators, are discussed from the point of view of their physical characteristics. Also, the service results obtained with these products in typical installations for the past ten years are outlined. The results as a whole show that kaolin, when burned to a sufficiently high temperature, will make a refractory possessing very desirable qualities.

KAOLIN is the decomposition product of feldspar rock. It can be divided into two main classes, residual and sedimentary. The residual kaolin is found in the same position as the rock which it displaces, and contains, therefore, a considerable amount of undecomposed particles of quartz and other minerals which were present in the original rock. The sedimentary kaolin, however, has been washed out of the previous type of deposit and has settled to form beds in some ancient lake or sea. While this material was being transported, all of the larger particles were left behind, so that the kaolin itself is comparatively pure as found in the best beds and contains few non-clay minerals.

Probably the most important deposits of residual kaolin occur in the southern United States. While some of these deposits are unsatisfactory for making refractories because of a lowered melting point, the majority are remarkably pure and uniform. The deposits generally occur in layers of 10 to 40 ft. in thickness, and usually there is an overburden of 5 to 30 ft. Of course, the deposits with the least overburden are generally the most economical to work. The mining of this kaolin is comparatively simple as it is only necessary to strip off the overburden and take the clay out with steam shovels, the bed being so soft that blasting is unnecessary. It is also unnecessary to do any hand selecting as is the common practice in many fireclay mines, because here the kaolin is of great uniformity.

A typical analysis of a Southern sedimentary kaolin is given in the following table (it will be noted that the amount of fluxing elements is very low):

Silica	51.96
Alumina	45.38
Iron oxide	0.57
Titanium oxide	1.73
Calcium oxide	0.10
Magnesium oxide	0.22
Sulphur trioxide	0.04
Alkalies	0.00

The kaolin itself consists in large part of a clay mineral, but there is associated with it in very small amounts a number of minerals such as quartz and rutile.

The physical properties of this kaolin are also of considerable interest. The melting point is 3200 deg. fahr. in an oxidizing atmosphere. The shrinkage and porosity are given in Fig. 1. To show the comparatively large and continued shrinkage of the kaolin there are also plotted similar curves for a high-grade Pennsylvania fireclay.

The main advantage of the kaolin as a refractory material is its extreme purity and uniformity, which permit the manufacture of a high-grade refractory which will not vary an appreciable amount as received from month to month or year to year. Kaolin, however, has a high shrinkage on firing, which until recently had prevented the use of this material for a high-grade refractory. It was not until the development of practical methods of burning at temperatures around 3000 deg. fahr. that successful high-grade refractories could be made from this material. At present, however, kaolin refractories are being manufactured on a large scale.

Treatment of the Raw Material

The shrinkage of the kaolin is completed by burning it nearly to the melting point, which also reduces the porosity practically to zero. This hard-burned material is then crushed into grog of the proper fineness for the purpose, and is then bonded together with some of the raw kaolin and again burned at a high temperature. Years of experimenting have led to the belief that a good refractory must have a structure which is in equilibrium at all temperatures up to the highest that it would experience in use. This means that the brick to be stable must be made of pure homogeneous material and be fired at a temperature higher than the temperature of use.

Standard Refractory Bricks

The standard brick is made of a rather coarse kaolin grog bonded together to give a well-knitted and continuous structure, but at the same time to allow sufficient flexibility to give good resistance to spalling. The structure is well shown in the photomicrograph in Fig. 2. This brick has been used where temperatures or loads are high, such as in boiler furnaces, reheating and forge furnaces, enamel furnaces, oil stills, kilns, etc. This brick has the advantage over the usual fireclay brick in that furnaces can be run at higher temperatures, higher loads can be supported by the hot refractories, and more insulation can be safely used. Under conditions where the brickwork is subjected to a flowing slag, it has been found in many cases that the kaolin brick does not show as large a margin of superiority over fireclay brick as under other conditions.

As an example of service, the kaolin bricks were installed in the solid front wall of the boilers of a large central power station several years ago, and have since been giving good service. These boilers are fired by underfeed stokers. The life of the kaolin brick is from 15 to 18 months, while fireclay brick averages 2 months, and ventilated silicon-carbide walls average 3 to 4 months.

Similar results were obtained at another large central station

[1] Assistant Professor of Ceramics, Massachusetts Institute of Technology. Professor Norton was graduated from Massachusetts Institute of Technology in 1918. He was Assistant Physicist and Chief Physicist for the National Advisory Committee for Aeronautics until 1923. He then joined the Babcock & Wilcox Company for research and development work in ceramics. In 1929 he was appointed to his present position. Professor Norton is a member of the American Ceramic Society and a Fellow of the American Physical Society. He has published a number of papers dealing with refractories.

Presented at the French Lick Meeting, French Lick, Ind., October 13 to 15, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

with underfeed stokers, the kaolin brick being operated 18 months with no trouble, while other refractories have given trouble by the adhering slag tearing off the surface. The kaolin brick has found wide use in oil-fired stationary boilers, and gives on an average of three to five times the life of first-class fireclay brick. Fig. 3 shows the bridge wall of an oil-fired boiler made of kaolin bricks after 4600 hours of service.

A large majority of all the American ships with oil-fired water-tube boilers use the kaolin brick because of the comparatively long life and freedom from shutdowns.

The high load capacity of this brick is illustrated by its wide use in enameling furnace piers. A large proportion of the continuous enameling furnaces in this country use kaolin brick in the piers. In one periodic enameling furnace this brick has given good service in the piers for over seven years.

The kaolin bricks find considerable use in reheat and forge furnaces because they allow a higher furnace temperature, and therefore an increased capacity for a given furnace. They also permit considerable insulation of the walls and crown, which in turn means a considerable fuel saving. In the case of kilns for burning refractories, terra cotta, etc. the kaolin brick has been found to give good service in fireboxes, piers, floors, and lower walls. In general they give a life of three to four times the life of the average firebrick without distortion or spalling.

Tank Blocks

The structure of the tank blocks made from kaolin is somewhat different from that of the standard brick as shown in the photomicrograph of Fig. 4. Here the porosity is reduced and

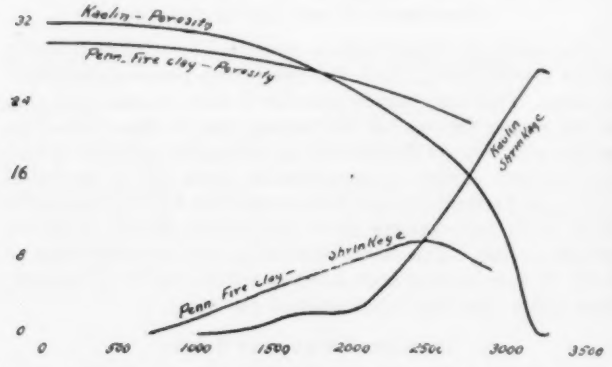

Fig. 1 Chart Showing Shrinkage and Porosity of Kaolins and Fireclays

the grog grains are completely knitted together to form a continuous structure. However, enough pores remain to give a slight amount of flexibility to the structure, so that there is no danger of cracking the blocks when heating up the tank. This structure is unique in being homogeneous and yet not too sensitive to spalling and cracking. The homogeneous structure has the great advantage of permitting the block to wear down with a smooth and even surface. No pits or grooves are formed, as is usually the case with most fireclay blocks, and because of this, seeds and cords are eliminated from the glass.

Some of these blocks were used in a tank making flint glass. The results showed that the kaolin blocks give a life of three to five times that of good fireclay blocks. Another set of kaolin blocks was used with boro-silicate glass in a small tank, and these are still giving good service. These blocks after one month's service are shown in Fig. 5; the freedom from cracks and grooves is noticeable.

Other blocks have been used with opal glass, and have shown a life of about one and one-half times the best of any of the other

Fig. 2 Photomicrograph of Thin Section of Kaolin Brick. ×60, Crossed Nicol Prisms

(The clear black areas are voids. The mottled appearance of the fired particles is due to the formation of very fine mullite crystals, which crystallize with the same orientation as the original kaolinite particles.)

Fig. 3 Boiler Bridge Wall of Kaolin Bricks After 4600 Steaming Hours

blocks. It was particularly interesting to note that they showed no cracks and no grooving, as indicated in Fig. 6, which shows a tank after a 33-week run.

Light-Weight Brick

There is a considerable demand for a brick that will withstand the severe conditions of oil-burning boilers, and yet be light in order to reduce the weight of the propulsive equipment of ships. A kaolin brick of this type has been developed which weighs not more than 5¼ lb., as compared with the 7 lb. for the average firebrick. This brick has a high porosity, but is strongly bonded and will give service equal to or better than the average fireclay brick. Some of these light-weight brick have been in service 18 months in destroyer boilers and are still in good condition. A kaolin-base cement is used to coat the surface of the wall in order to close the pores and prevent penetration of the oil slag into the brick.

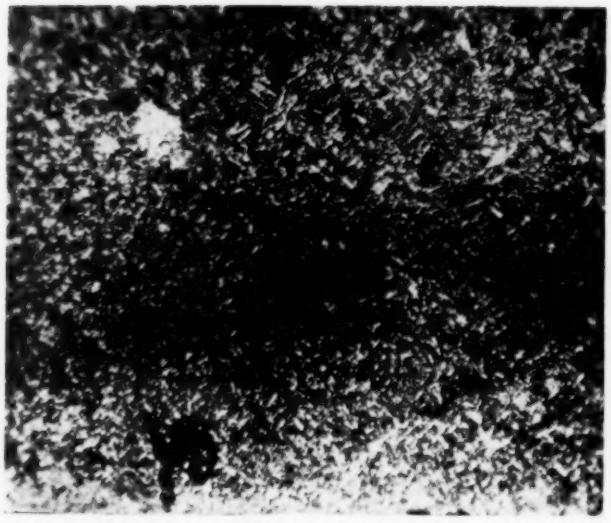

FIG. 4 PHOTOMICROGRAPH OF THIN SECTION OF KAOLIN GLASS TANK BLOCK. ×60, CROSSED NICOL PRISMS

(The structure is much denser than that of Fig. 2, and the mullite crystals are much larger. The light-colored particle is a small bleb of corundum.)

FIG. 5 EXPERIMENTAL TANK WITH THREE KAOLIN BLOCKS

(After one month's service with boro-silicate glass.)

INSULATING BRICK

An insulating brick has been developed using kaolin, which, though still somewhat in the experimental stage of manufacture, has been thoroughly tried out. When this brick is used in furnaces, it takes the place of the refractory and at the same time has a high degree of insulating value. This unique property limits the high-temperature zone close to the inner surface and permits unusual furnace efficiencies. Two small furnaces were made up exactly alike, one with fireclay brick and one with the kaolin insulator. With the same burner the first one reached the maximum temperature of 1900 deg. fahr., and the second a temperature of 2600 deg. fahr. Some of these bricks have been used in furnaces which were suddenly heated and cooled as much as 200 times, with maximum temperatures ranging from 2000 to 2900 deg. fahr., with no signs of cracking or deterioration. It should be clearly understood, however, that these bricks will not withstand slag. This condition would of course be expected from their high porosity.

CRUCIBLES

Carbon-free crucibles are being manufactured of kaolin for melting glass, enamels, and metals. A fine-grained, dense structure is used with about 8 per cent porosity, but the flexibility is kept high enough to prevent cracking, even on rapid heating. These crucibles will withstand reheating many times without cracking, and may be used for melting glass, enamels, or metals without danger of contaminating the melt. In melting alloy steel in high-frequency furnaces as many as 250 heats have been obtained from one crucible by lining the crucible with kaolin cement and relining at intervals whenever the cement became thin.

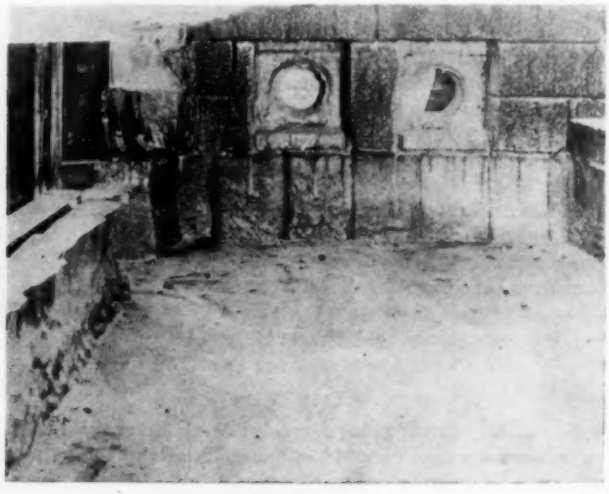

FIG. 6 A COMPLETE TANK OF KAOLIN

(After 33 weeks' run on opal glass.)

TABLE 1 PHYSICAL PROPERTIES OF VARIOUS TYPES OF KAOLIN REFRACTORY

Property	Kaolin tank block	Standard kaolin brick	Light weight kaolin brick	Kaolin insulating refractory	Average of three first-quality Pennsylvania bricks
Weight of standard brick, lb.	8.4	7.3	5.25	1.6	7.0
Density, lb. per cu. ft.	145	126	95	27.5	1.30
Porosity, per cent	10	25	40	85	28
Start of deformation under load of 25 lb. per sq. in., deg. fahr.	2825	2750	2450	....	2100
Deformation of 10 per cent under load of 25 lb. per sq. in., deg. fahr.	3000	2900	2620	....	2725
Start of permanent volume change without load, deg. fahr.	3000	2900	2900	2700	2300
Mean coefficient of expansion per deg. fahr.	0.0000024	0.0000024	0.0000024	0.0000024	0.0000028
Cycles in 2900 deg. fahr. air-spalling test	....	20	...	...	14
Melting point, deg. fahr.	3200	3200	3200	3200	3065
Corresponding cone	35+	35+	35+	35+	31
Thermal conductivity at 1000 deg. fahr.	16	12	...	1.9	9
Thermal conductivity at 2000 deg. fahr.	19	13	...	3.1	11

CEMENTS

A number of types of cement have been developed with a kaolin base. These cements include high-temperature cements with a kaolin bond, a low-vitrifying cement with a low-vitrifying clay bond, air-setting cement, and patching cement with a low fire shrinkage.

FSP-53-14

Comparative Physical Properties of Chromium-Nickel, Chromium-Manganese, and Manganese Steels

By C. L. CLARK[1] and A. E. WHITE,[2] ANN ARBOR, MICH.

This paper gives the results of short-time tensile tests at 75 and 1000 deg. fahr., and creep tests at 1000 deg. fahr., on certain selected steels. The steels investigated belong to either the chromium-nickel, the chromium-manganese, or the manganese series. Certain other alloying elements as silicon and tungsten were also present. The chromium-nickel steel specimens were taken from both bar and tube stock, and certain of them were tested in both the hot-rolled and water-quenched conditions.

The results indicate that the substitution of manganese for nickel in chromium-nickel steels is detrimental, at least in so far as the load-carrying ability of the alloy is concerned. Also that while the creep resistance of the manganese and manganese-tungsten steel at 1000 deg. fahr. is superior to that of many pearlitic steels, it is not equal to that of the Enduro KA2 type of alloy.

WITH the advancing trend in operating temperatures in many industries, the need for metals to successfully withstand not only the necessary stresses but also the oxidizing atmosphere is becoming more pronounced. For temperatures up to a certain maximum, 1000 or 1100 deg. fahr., the so-called pearlitic steels may be successfully used. Certain of them, when in the proper heat-treated condition, possess remarkable strength at the higher temperatures and are able to resist to the necessary extent the corrosive action of the gases with which they are in contact.

C. L. Clark

For temperatures much above 1000 deg. fahr. the effect of any beneficial heat treatment is largely lost, and the strength of all pearlitic steels decreases rapidly. In this temperature range the austenitic steels display superior characteristics both in regard to load-carrying ability and resistance to oxidation. The dividing line between these two zones is not definitely marked, and in certain applications pearlitic steels can be used above 1000 deg. fahr., and in many, austenitic steels are used below 1000 deg. fahr.

The types of austenitic steels commonly used for high-temperature service are not diversified, commercial practice confining itself almost completely to those chromium-nickel steels known as Enduro KA2. On the basis of our present knowledge, the confinement to this particular series of steels is not unwarranted, for they do possess the outstanding properties for the majority of applications. These steels, however, also possess certain undesirable characteristics, and substitute steels, free from these disadvantages and yet possessing the valuable properties of Enduro KA2, would be highly welcomed. Whether or not certain other austenitic steels would fulfil these conditions is unknown, at least from the information available in the literature.

A. E. White

The work reported in this paper was undertaken to determine the effect of certain changes in composition upon the physical properties of steels of the Enduro KA2 type. Also in order to ascertain the truth of the statement sometimes made that all austenitic steels should exhibit nearly the same properties at high temperatures, regardless of the alloying elements present, the investigation was extended to include a straight 14 per cent manganese steel, and a 14 per cent manganese, 1.0 per cent tungsten steel.

MATERIALS

The alloys investigated belong to either the chromium-nickel, the chromium-nickel-silicon, the chromium-manganese-silicon, the manganese, or the manganese-tungsten series. Their compositions and the condition in which they were tested are given in Table 1.

The first four steels in the table were secured from commercial sources, while the remaining four were made at the University of Michigan laboratories. Those designated as KA2 and RS were received in 1-in. and $^3/_4$-in. round bars, respectively, while KA2S-H and KA2S-R were obtained in the form of a 5-in.-diameter tube having a wall thickness of approximately $^3/_4$ in. As shown in the table, one section of this tube was water quenched and pickled, while the remaining was hot rolled.

The steels prepared in the U. of M. laboratories were made in a 35-lb. Ajax high-frequency induction furnace. The melts were cast into tapered ingots approximately $2^1/_2$ in. square at the top, and these were forged into $^3/_4$ in. round bars by the Atlas Drop Forge Company. In order to maintain the carbon content as low as possible, Armco iron was used as a base in melting.

PROCEDURE

The two temperatures chosen for the comparison of the ten-

sile characteristics of these steels were room temperature (75 deg.) and 1000 deg. fahr. The experimental work consisted of short-time tensile tests at each of these temperatures, and long-time creep tests at 1000 deg. fahr.

The method used for the determination of the short-time tensile properties was the same as that described in previous papers by the authors.[3,4] The deformation produced by each increment of stress is measured by Ames dials reading to one-ten-thousandth (0.0001) of an inch.

The apparatus employed in the creep tests is shown in Fig. 1. This is fully described in a paper presented at the Semi-Annual Meeting of The American Society of Mechanical Engineers at Detroit[5] last June. The deformation produced by a fixed load is measured by the rotation of two mirrors mounted on rollers. Readings to 2.8 millionths (0.0000028) of an inch are possible.

In performing the creep tests, a fixed load is applied and maintained constant until either the flow comes to a complete stop or until it has reached a steady state. The load is then either increased or decreased, depending on the magnitude of the rate of deformation under the previous load.

RESULTS

Short-Time Tensile Tests

The short-time tensile properties of these steels were determined at 75 and 1000 deg. fahr. The results are given in Tables 2 and 3.

Tests at 75 Deg. Fahr. The results of the tests at 75 deg. fahr. are given in Table 2.

TABLE 2 TENSILE PROPERTIES OF SELECTED STEELS AT 75 DEG. FAHR.

Designation	Type composition	Tensile strength, lb. per sq. in.	Proportional limit, lb. per sq. in.	Elongation in 2 in., per cent	Reduction of area, per cent
KA2	0.05 C, 18 Cr, 8 Ni	100,000	25,000	60.0	63.0
KA2S-H	0.05 C, 18 Cr, 8 Ni	82,275	16,250	67.5	72.3
KA2S-R	0.05 C, 18 Cr, 8 Ni	82,300	17,500	43.5	68.0
A1	0.05 C, 18 Cr, 6 Mn, 3 Si	92,200	54,000	22.5	44.0

A4	0.05 C, 14 Mn	84,850	9,000	[a]	[a]
A5	0.05 C, 14 Mn, 1 W	77,750	8,000	[a]	[a]

[a] Specimen broke outside of gage marks.

The KA2 bar material possesses higher strength properties than does the steel of similar composition, but with a lower carbon content, taken from tubes. With the ductility values the converse is true. These differences are partly due to the variation in carbon content and to the manner in which the metal was fabricated.

The effect of heat treatment on the properties of the chromium-nickel alloys is obtained from a comparison of specimens KA2S-H and KA2S-R. The hot-rolled material possesses slightly higher strength characteristics, but its ductility is considerably lower than that of the water-quenched material. Especially is this true of the percentage of elongation in 2 in.

Steels A1 and B1, which differ from KA2 mainly in that the nickel has been replaced by 6.32 and 9.78 per cent of manganese, respectively, show this substitution to have resulted in increased strength and decreased ductility, with the latter being the more pronounced. As is the case with lower-alloyed steels, increasing the manganese from 6.32 to 9.78 per cent resulted in increased tensile-strength values, but in a decrease in the proportional limit. No consistent variation was obtained in the ductility, the higher-manganese steel showing the maximum elongation and the minimum reduction of area values.

Steels A4 and A5 differ from the preceding ones in that their principal alloying constituent is manganese. These steels possess a tensile strength comparable to that of the low-carbon Enduro KA2, but their remaining physical properties are much lower. Their ductility was so low that in each case fracture was obtained in the fillet of the specimen.

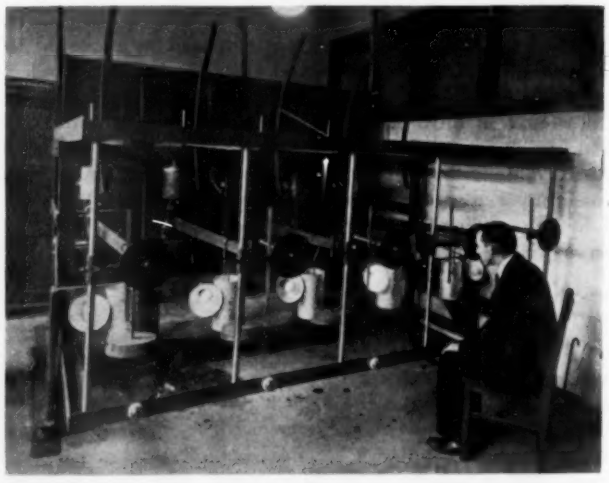

Fig. 1 Apparatus for Determining Rate of Creep of Metal

Tests at 1000 Deg. Fahr. The results of the tests at 1000 deg. fahr. are given in Table 3.

As at atmospheric temperature the higher-carbon bar stock KA2 has greater strength and lower ductility than the lower-carbon tube stock, these differences are the most marked in the case of the proportional-limit and percentage-of-elongation values. Also, as before, the quenched and hot-rolled materials differ from one another mainly in that the quenched material possesses the greater ductility, which is most noticeable in the percentage of elongation values.

TABLE 3 TENSILE PROPERTIES OF SELECTED STEELS AT 1000 DEG. FAHR.

Designation	Type composition	Tensile strength, lb. per sq. in.	Proportional limit, lb. per sq. in.	Elongation in 2 in., per cent	Reduction of area, per cent

steels in that it contains a higher amount of silicon, possesses the highest strength characteristics at this temperature of any of the steels considered. As would be expected, its ductility is somewhat lower.

The replacement of nickel of the chromium-nickel steels with 6.32 per cent of manganese resulted in decreased tensile strength and percentage of elongation values, but produced no marked effect in either the proportional limit or percentage reduction of area. Increasing the manganese content to 9.78 per cent, steel B1, raised the tensile strength but caused a marked lowering in the remaining physical properties.

The 14 per cent manganese steel, A4, has properties comparable to those of the low-carbon Enduro KA2 in the hot-rolled state. Its tensile strength is somewhat lower, but the remaining values are nearly identical. The addition of 1.23 per cent tungsten to this steel slightly increased the strength and lowered the ductility.

Creep Characteristics at 1000 Deg. Fahr.

Creep tests were conducted at 1000 deg. fahr. on all of these steels with the exception of the bar stock KA2 and the manganese-chromium-silicon steel, A1. The results are given in Figs. 2, 3, and 4, and in Tables 4 and 5.

Figs. 2 and 3 give the time-elongation curves of the chromium-nickel and manganese steels, respectively. In each of these tests a fixed load was applied and maintained constant until either the flow came to a stop or until it remained at a constant rate for at least 200 hours. Then the load was either increased or decreased, depending on the magnitude of the flow previously obtained.

Numerical results taken from these two figures are given in Table 4. The first three columns of this table are self-explanatory. The fourth gives the deformation occurring in what is commonly known as the first period of creep. This includes both elastic and plastic deformation, and also any elongation involved in the specimen's adjusting itself to the applied load. It does not include the relatively large amount of elastic deformation obtained immediately upon application of the load. The fifth column records the period of time required for this creep, while the sixth, which is obtained by dividing the figures in the fourth column by those in the fifth, gives the average rate of creep during this period. This value has no practical significance as the rate of creep is constantly diminishing. It is, however, a measure of the metal's strain-hardening ability.

The figures in the seventh column are of greatest importance, for they show at what rate the metal will deform when subjected to the given condition. These figures are obtained from the slope of the curves in Figs. 2 and 3 after a steady state of flow has been obtained.

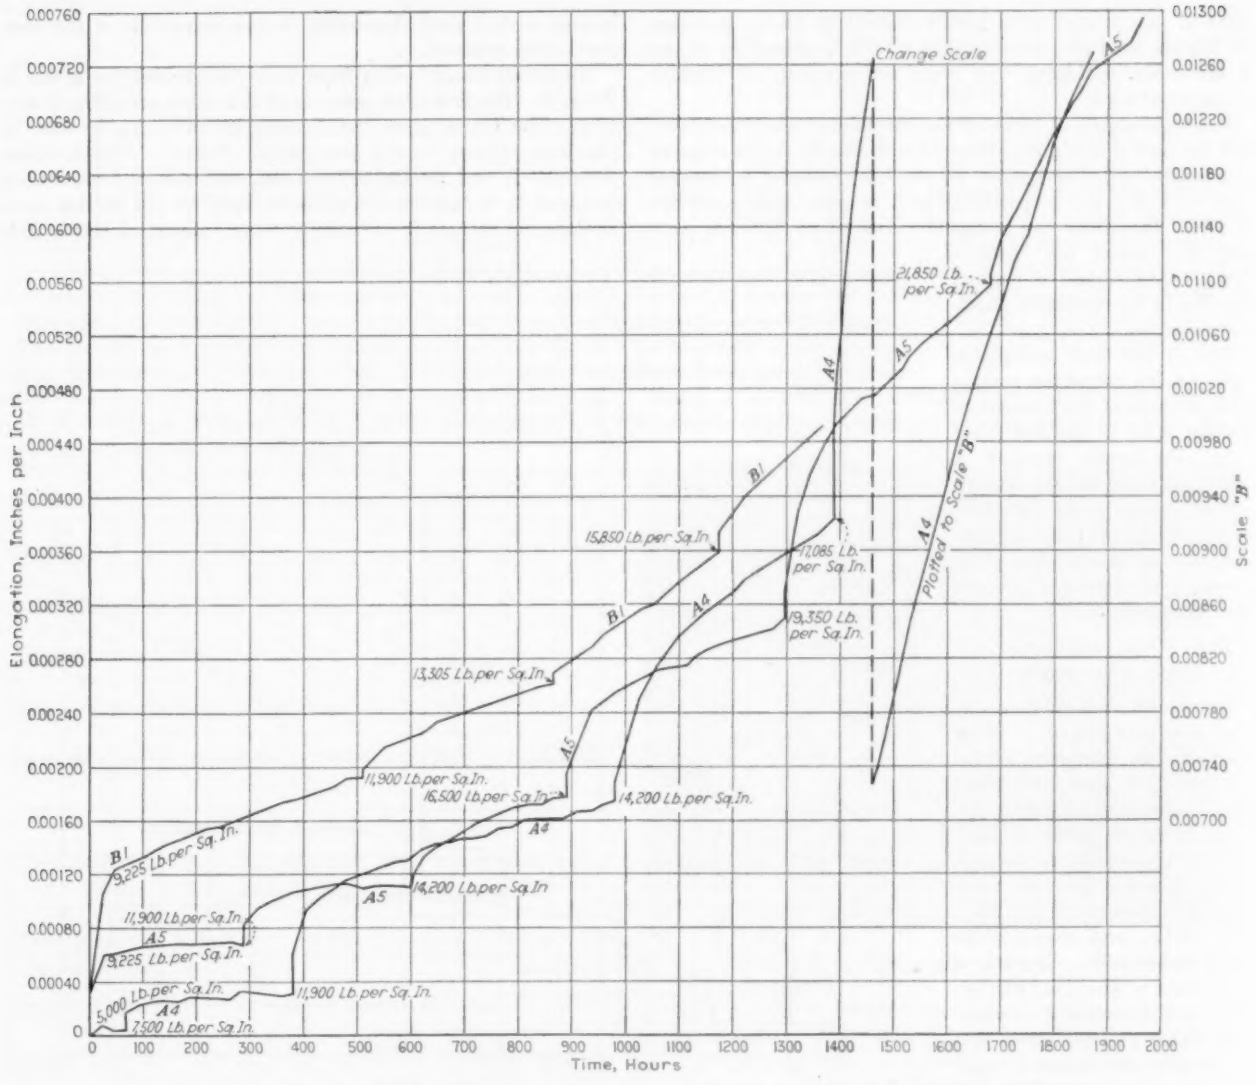

FIG. 3 CREEP CHARACTERISTICS OF MANGANESE AUSTENITIC STEELS AT 1000 DEG. FAHR.

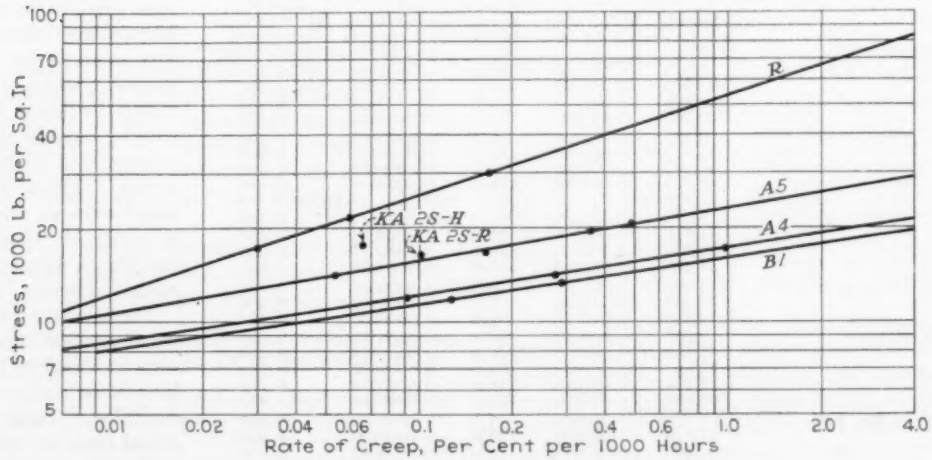

FIG. 4 LOGARITHM OF RATE OF CREEP VERSUS LOGARITHM OF STRESS

Previous work of several investigators has shown that if the logarithm of the rate of deformation be plotted against the logarithm of the stress producing the deformation, a straight-line relationship will be obtained under certain conditions. Fig. 4 shows the values plotted in this manner. It will be observed that practically straight lines are obtained in nearly all cases.

This type of chart is useful for two reasons: First, it allows various steels to be readily compared in so far as their load-carrying ability is concerned; and second, if the amount of allowable deformation is known, then the maximum stress to which a metal can be subjected is easily determined.

Considering the relative merits of the steels being investigated, the chromium-nickel alloys are seen to exhibit the greatest load-carrying ability at this temperature. The alloy of this type containing 2.35 per cent of silicon is superior to the specimens taken from tube stock. Results to date also indicate the water-quenched material to be somewhat superior to that in the hot-rolled conditions.

Replacing the nickel in Enduro KA2 with 9.78 per cent of manganese, steel B1, has resulted in a marked lowering of the metal's ability to withstand continuous loads at 1000 deg. fahr. The straight 14 per cent manganese steel, A4, is slightly superior to B1, while the addition of 1.23 per cent of tungsten has noticeably improved the load-carrying ability of the manganese steel. In fact, the properties of the manganese-tungsten alloy are comparable to those of the hot-rolled KA2 tube stock.

In Table 5 are given values taken from Fig. 4, showing the stresses required to produce deformation at the rate of 0.01, 0.10, and 1.0 per cent per 1000 hours. Values are not given for steels KA2S-H and KA2S-R as the tests on those are not as yet completed.

TABLE 5 STRESSES REQUIRED TO PRODUCE DESIGNATED RATES OF CREEP IN SELECTED STEELS AT 1000 DEG. FAHR.

Designation	Type	Per cent per 1000 hr. 0.01	0.10	1.0
		Lb. per sq. in.		
RS	0.05 C, 18 Cr, 8 Ni, 3 Si	12,000	25,000	56,000
B1	0.05 C, 18 Cr, 10 Mn, 3 Si	8,000	11,250	16,000
A4	0.05 C, 14 Mn	8,600	12,100	17,000
A5	0.05 C, 14 Mn, 1 W	10,600	15,750	23,000

The load of 12,000 lb. per sq. in. required to produce flow at the rate of 0.01 per cent per 1000 hours with the low-carbon high-silicon chromium-nickel alloy is comparable to the value of 15,000 lb. previously reported for Enduro KA2.

CONCLUSIONS

The results obtained from the short-time tensile and long-time creep tests allow certain conclusions to be drawn regarding the effect of composition, fabrication, and heat treatment on the high-temperature characteristics of the selected steels.

In so far as the short-time tensile properties at room temperature are concerned, the substitution of manganese for the nickel in the Enduro KA2 type of alloy results in a slightly increased strength and greatly decreased ductility. The tensile strength increases with the manganese content while the proportional limit decreases. Specimens of the chromium-nickel alloy taken from tube stock display less strength and greater ductility than those from the bar material. Whether or not this material is water-quenched or hot-rolled makes no appreciable difference in the strength properties, but does greatly affect its ductility as shown in the percentage of elongation, the quenched material possessing much higher values. The manganese steels proved to be extremely brittle.

The short-time tensile properties of the material at 1000 deg. fahr. arrange themselves in approximately the same order as at room temperature. The two straight manganese steels possess a good degree of ductility at this temperature, in fact, superior to that of the chromium-manganese alloys and comparable to that of the hot-rolled KA2.

The creep results at 1000 deg. fahr. indicate that the chromium-nickel alloy from the bar stock has greater load-carrying ability than those from tube stock, and that the water-quenched material is slightly superior to the hot-rolled material. Also that the substitution of the nickel with manganese has produced a marked lowering in the material's ability to withstand continuous stress. The 14 per cent manganese steels possess properties comparable to those of the chromium-manganese steel, while the addition of tungsten was found to increase its resistance to a marked degree.

Discussion

F. H. NORTON.[6] Professors Clark and White have given valuable and interesting data in their paper. On the whole their results verify the statement the writer made some time ago that all austenitic steels were in a separate class in regard to resistance to creep at high temperatures. At that time tests were available only on the nickel-chromium austenites, and these new data on manganese and manganese-tungsten steels are very welcome.

The authors show that all of these steels have a creep resistance of 8000 to 12,000 lb. per sq. in. for a 1 per cent elongation in 100,000 hours at 1000 deg. fahr., which may be compared with a resistance, under the same conditions, of only 3000 or 4000 lb. for carbon steel. At higher temperatures this difference would be even more marked. It would appear that the small differences found between the various austenitic steels tested for this paper might almost be within the experimental error, as the specimens were held at one load for only 300 hours.

The authors have plotted their results on logarithmic paper, and it is interesting to notice that their points, in all cases, fall on a straight line and that the average slope is 1 in 5, which is an excellent confirmation of the 5th power flow regime which the writer recently called attention to.

It would be most interesting if the authors continued the work on these steels up to higher temperatures, to determine whether the various austenitic steels showed the same similarity.

J. J. KANTER.[7] The authors report tension test values for 75 deg. fahr. and 1000 deg. fahr. These values afford an intercomparison of several austenitic alloys, several of the nickel-chromium alloys studied giving results comparable with those obtained at Crane Company laboratories. As is noted from the accompanying table (see Table 6), the results of the two laboratories are in fairly good agreement on similar grades and conditions of materials. There is a notable peculiarity brought out very clearly in the Crane Company results that bears emphasis. The proportional limits shown by the water-quenched material in general are considerably less than those given by the hot-rolled and hard-rolled conditions. That proportional limit at high temperatures cannot be taken as a criterion of long-time strength in this instance is demonstrated by the fact that creep stresses obtained on water-quenched KA2S are equal to those for the smaller-grained hot-rolled metal. Elsewhere[8] it has been shown that at higher temperatures than 1000 deg. fahr. creep stresses for water-quenched KA2S are considerably higher than those shown by the metal as it cools from rolling.

Even at 1000 deg. fahr., the extreme case of fine grain size inferiority is brought out by creep results on hard-rolled KA2 as compared with hot forged KA2. A very high elastic ratio is

[b] Estimated from Fig. 4 (Clark and White).

exhibited by the hard-rolled material at both atmospheric and 1000 deg. fahr. This high elasticity in short-time tests is reflected by the creep stresses representative of high rates of deformation (1 per cent in 1000 hours). When minute creep is observed, however, the high-tensile KA2 is found to suffer a drastic reduction in its ability to withstand slight deformation.

The tensile properties of austenitic steels, in the various conditions and treatments to which they are responsive, apparently obey the same rules which have been found to apply to other types of steel. Fine grain size at the lower temperatures is conducive to high strength and elasticity. At extremely elevated temperatures large grain promotes creep resistance.

N. B. Pilling.[9] Manganese and nickel have a number of similarities in the way they behave in iron alloys, but they also have some points of dissimilarity, and it is not very safe to venture predictions regarding the qualities of one series based upon the nature of the other. The authors have pointed out a difference in strength properties at high temperatures between the chrome-manganese and chrome-nickel steels. While this is significant, the question is potentially one of so much importance to users and producers of metals for high-temperature service that it may be urged, without the slightest reflection upon the authors' research, as one deserving careful and independent verification.

While the paper is of course limited to a discussion of strength properties, it has doubtless come under the observation of the authors and would be interesting to know what comparison can be made between the chrome-manganese and chrome-nickel steels with respect to their corrosion by oxidation or other agencies at high temperatures.

Authors' Closure

The authors appreciate the comments of the people who have discussed this paper and are pleased to know that the results reported by them are in accord with those obtained by other investigators.

In regard to the comments of Professor Norton, the authors agree that austenitic steels possess the greatest creep resistance at the more elevated temperatures, but do not believe that such is necessarily the case at 1000 deg. fahr. They are aware of steels of the pearlitic type which possess, at 1000 deg. fahr., creep characteristics above the austenitic steels herein discussed or those of the chromium-nickel type.

The authors also agree that for each metal there is perhaps a temperature range in which the creep results, when plotted on logarithmic paper, fall on straight lines and that the average slope is 1 in 5. They feel, however, that at temperatures below this range, if the results fall on straight lines, the lines have decidedly different slopes.

They are also aware of many cases, in the lower temperature ranges, in which this type of plotting does not yield straight lines.

Concerning Mr. Pilling's remarks, the authors did not intend to convey the impression that the chromium-manganese steels were not worthy of additional study, and they are looking forward to the publication of additional data on these steels.

The authors are also in agreement with Mr. Kanter in that fine-grained materials possess the maximum creep resistance at temperatures below the "equicohesive" temperature range, while coarse-grained materials possess the maximum values at temperatures above.

They also wish to thank Mr. Kanter for the confirmatory data he has presented.

FSP-53-15

Properties of Non-Ferrous Alloys at Elevated Temperatures

By C. L. CLARK[1] AND A. E. WHITE,[2] ANN ARBOR, MICH.

This paper gives the results of an investigation of the properties of certain non-ferrous alloys at elevated temperatures as determined by short-time tensile and long-time creep tests. The alloys considered are of four groups: the nickel-copper, nickel-cobalt-titanium, copper-zinc, and copper-zinc-tin series. The alloys are tested at temperatures both above and below their lowest temperature of recrystallization.

Results indicate a superiority of the nickel-base alloys over the entire temperature range. The outstanding member of this group is Konel metal, which has short-time tensile properties at 1000 deg. fahr. comparable to Enduro KA2, and the greatest creep resistance at this temperature of any alloy of which the authors are aware. Monel metal retains its properties well up to 800 deg. fahr.

Of the copper-zinc alloys, those containing 70 per cent or more copper are superior to those with 60 per cent of this element. None of these alloys can be used at temperatures much above 400 deg. fahr., and for those containing lower amounts of copper, 300 deg. fahr. is believed to be the maximum working temperature if stresses of appreciable magnitude must be considered.

THE question of the behavior of metals when subjected to sustained loads at elevated temperatures is one that is receiving a great deal of attention at the present time. To date, however, a large share of the published work has been concerned with the behavior of ferrous alloys, or of non-ferrous alloys of the chromium-nickel type. This present paper records the results obtained from non-ferrous alloys of the copper-zinc, the copper-zinc-tin, the nickel-copper, and the nickel-cobalt-titanium series.

C. L. CLARK

A. E. WHITE

The work on these alloys was undertaken as it was felt a great need existed for this type of information. Many of these alloys find wide use at slightly elevated temperatures in such applications as valve fittings, while others are used in tubular form at even higher temperatures. Each will render satisfactory service at temperatures up to a certain maximum, provided the proper balance is maintained between temperature and stress. The information herein given is hoped to be of great value in properly defining these conditions.

MATERIALS

The alloys investigated belong to either the copper-zinc, the copper-zinc-tin, the nickel-copper, or the nickel-cobalt-titanium series. Their composition, the condition in which they were tested, and the source from which they were obtained are given in Table 1.

Ambrac metal differs chemically from Monel mainly in that the relative percentages of copper and nickel are interchanged and an appreciable amount of zinc added. The metal designated as K is the material known as Konel metal, which was developed at the Westinghouse Company and is claimed to have outstanding high-temperature properties. It differs from Monel metal in that the amount of nickel has been increased, the copper replaced with cobalt, and titanium added.

The amount of copper in the copper-zinc alloys varies from 85.0 to 69.5 per cent, while in the copper-zinc-tin alloys it ranges from 77.3 to 58.8 per cent.

The materials were received in $^3/_4$-in. round bars and were all in the hot-rolled condition except three, designated as C, A, and B in the table. In each of these cases the bars were given a final $^1/_8$-in. cold-draw.

PROCEDURE

The experimental work in this investigation consisted of short-time tensile tests at normal and elevated temperatures, determination of lowest temperature of recrystallization by means of hardness tests, and metallographic examination and long-time creep tests at selected elevated temperatures.

The method used for the determination of the short-time tensile properties was the same as that described in previous papers by the authors.[3,4] The specimen is maintained at the desired temperature by means of an electric furnace inserted in a screw type of tensile machine. The furnace is calibrated so that the temperature distribution over its entire length is known. The load is applied in increments up to the proportional limit, and the amount of deformation produced by each is determined by two Ames dials reading to one ten-thousandth (0.0001) of an inch.

The apparatus and procedure used in the long-time creep or flow tests was described at the 1930 Semi-Annual Meeting

of The American Society of Mechanical Engineers in Detroit.[5] The apparatus is of the single-lever type, having a lever ratio of 24 to 1. A fixed load is applied and the resulting deformation measured by two mirrors fastened to rollers which are rotated by any change in length of the specimen. The sensitivity of the measuring system is such that readings accurate to 2.8 millionths (0.000028) of an inch are obtainable.

In performing this test a fixed load is applied and maintained constant until either the flow comes to a complete stop, at least in so far as it is measurably within the limits of sensitivity of the apparatus employed, or until it has assumed a steady rate for at least 200 hours. Then the load is either increased or decreased, depending on the magnitude of the deformation previously obtained.

For the determination of the lowest temperature of recrystallization, specimens of each alloy were severely cold worked, after which they were subjected to tempering at various temperatures. They were maintained at temperature five hours, hardness readings being taken before and after the heating operations. The temperature at which a sharp decrease in hardness was obtained was designated as the lowest temperature of recrystallization. The location of this recrystallization temperature was also checked by metallographic means.

RESULTS

Lowest Temperature of Recrystallization

The temperature of recrystallization of each of these alloys was determined by hardness tests and metallographic means. In this particular case an accurate determination of this temperature was not felt necessary and a recrystallization range rather than definite temperature was determined. The results are given in Table 2.

On the basis of the recrystallization temperature the alloys may be divided into three groups. In one group, this temperature lies above 800 deg. fahr., in another, between 400 and 600 deg. fahr., and in the third, below 400 deg. fahr.

The alloys containing large amounts of nickel fall in the first group. The Konel metal retained at temperatures as high as 1000 deg. fahr. all of the hardness given it through cold working, while the Monel metal did not undergo a loss in hardness at temperatures up to 800 deg. fahr. This indicates their respective temperatures of recrystallization to be over 1000 and 800 deg. fahr. Since these alloys differ mainly in that the copper in the Monel metal has been replaced by cobalt, it is evident that this replacement has resulted in the recrystallization range being raised 200 deg. fahr. Cobalt of course melts at a much higher temperature than does copper, and this may account for the increase.

The copper-zinc and copper-zinc-tin alloys containing 70 per cent or more of copper fall in the second group, that is, their lowest temperature of recrystallization lies over 400 and under 600 deg. fahr. The alloys of these two series containing 60 per cent copper recrystallize at temperatures below 400 deg. fahr. Thus they belong to the third group. The lowering of this tem-

perature with increasing amounts of zinc should be expected, as zinc itself possesses a much lower recrystallization temperature than does copper, being 70 deg. fahr. as compared to 392 deg. fahr.

Short-Time Tensile Tests

The short-time tensile properties of each of these alloys were determined at room and selected elevated temperatures. The results are given in Tables 3 to 6 and Figs. 1 to 4, inclusive.

Fig. 1 and Table 3 show the effect of composition, mechanical working, and temperature on the tensile strength of these alloys. Three of the alloys, designated as A, B, and C, were in the cold-worked condition and the remainder were hot-rolled.

Again the high-nickel alloys display the maximum properties throughout the entire temperature range investigated. Konel

metal was tested only at 1000 deg. fahr., but at this temperature it was much superior to the remainder. Its strength is comparable to that of Enduro-KA2, a chromium-nickel steel widely used at elevated temperatures. The Ambrac alloy displayed

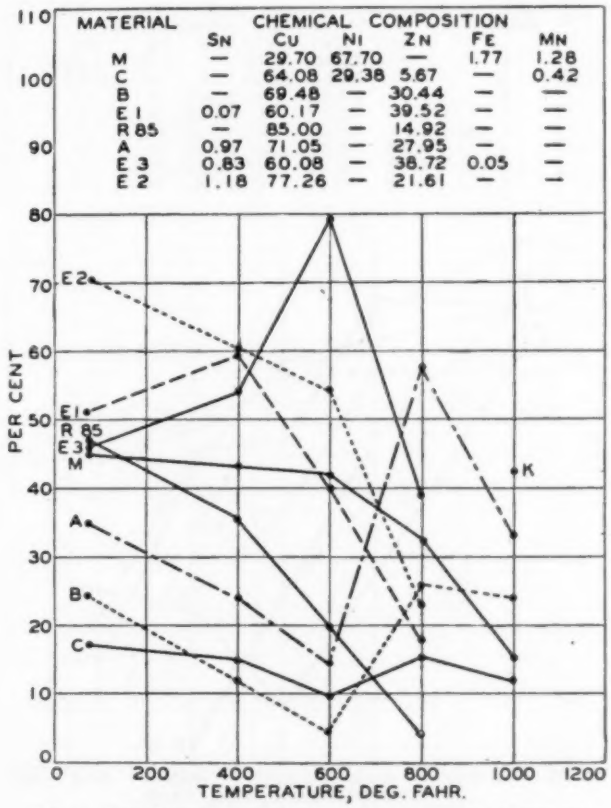

Fig. 3 Per Cent Elongation of Non-Ferrous Alloys at Elevated Temperatures

slightly higher values than did Monel, but it is to be remembered that the Ambrac was cold-rolled while the Monel metal was hot-rolled. Initial treatment greatly affects the short-time tensile properties, and if the Monel had been cold worked it would have displayed a much higher strength.

With the copper-zinc-base alloys, the two cold-worked materials possess the greatest strength. With increasing temperatures their superiority diminishes, and at the lowest temperature at which marked recrystallization occurs under the condition of the test, their strength is nearly identical to that of the other alloys containing 70 per cent or more of copper. The two alloys containing 60 per cent of copper lose their strength rapidly at temperatures above their lowest temperature of recrystallization, about 400 deg. fahr.

These figures emphasize the need of knowing the initial condition of the metal. From Fig. 1 it appears as if the 70-30 brass has a strength at the lower temperatures much superior to that of the 85-15 alloy. This is without doubt due to the lower-copper alloy being in the cold-worked and the 85-15 brass in the hot-rolled condition. If

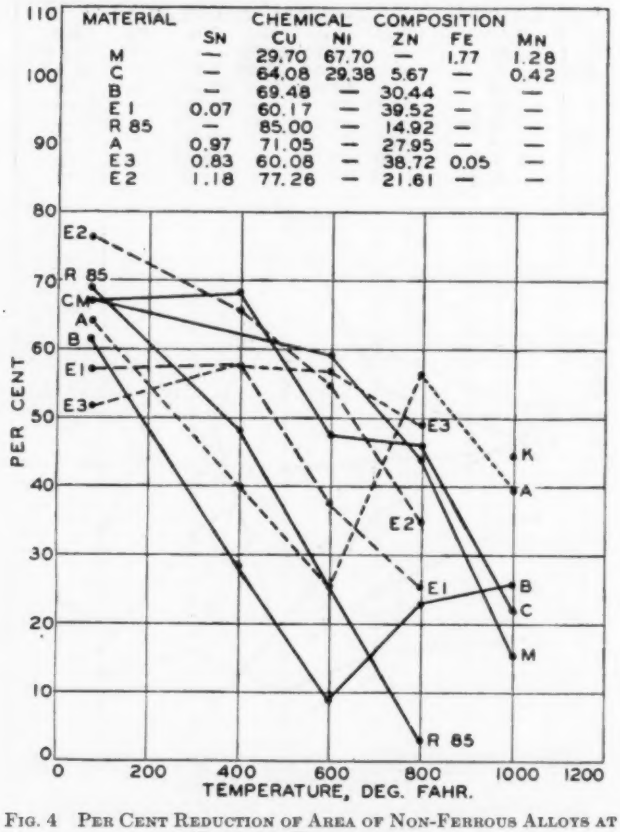

FIG. 4 PER CENT REDUCTION OF AREA OF NON-FERROUS ALLOYS AT ELEVATED TEMPERATURES

the two were placed in the same initial condition, it is probable that the 85-15 brass would have the greatest strength.

Fig. 2 and Table 4 show the variations in proportional limits under the same conditions. The alloys high in nickel have the maximum values at practically all temperatures. At 70 deg. and 400 deg. fahr. the cold-worked Admiralty metal has greater strength than the hot-rolled Monel, but this is because of the initial condition of the two materials. The Konel metal is much superior at the only temperature it was tested, 1000 deg. fahr., again having a value comparable to that of Enduro KA2. The cold-worked Ambrac has greater values at the lower temperatures than the Monel, but above 800 deg. fahr. the case is reversed. This is again due to the initial condition of the alloys.

The two cold-worked alloys of the copper-base series are superior to the remaining alloys at the lower temperatures, but at 800 deg. fahr. their strength is comparable to that of the materials containing 70 per cent or more of copper. Those containing 60 per cent of copper lose their strength rapidly at temperatures above 400 deg. fahr., which is approximately their lowest temperature of recrystallization.

Again the importance of knowing the initial condition of the metal should be emphasized, for while the 70-30 brass possessed values superior to those of the 85-15 alloy, this is believed to be due to their initial treatment and not to the composition.

The variation in the percentage of elongation values are given in Fig. 3 and Table 5, while those of the percentage of reduction of area are given in Fig. 4 and Table 6. These all indicate that the ductility of these alloys tends to decrease with increasing temperature. In the case of the cold-worked materials, however, this decrease is interrupted at the temperature at which recrystallization can occur, and a sharp increase in ductility is obtained. With increasing temperatures, the ductility of these cold-worked alloys again decreases.

The only exceptions to the above statements appear to be the materials containing 60 per cent of copper. The ductility of these alloys is increased with the first rise in temperature, the decrease not beginning until temperatures of 400 to 600 deg. fahr are attained. These alloys differ for the other copper-base alloys studied in that they are not homogeneous solid solutions, and the presence of the additional constituent may account for their difference in behavior.

LONG-TIME CREEP TESTS

Long-time creep tests were conducted on the majority of these non-ferrous alloys at temperatures both above and below their lowest temperature of recrystallization. The results are given in Figs. 5 through 8 and Table 7.

While a large number of time-elongation curves have been collected showing the behavior of these materials when subjected to continuous stresses for long periods of time, only one typical example is included. That, designated as Fig. 5, gives the creep characteristics of Monel metal at 600 and 800 deg. fahr. In obtaining these data, a fixed load is applied and the deformation of the specimen recorded at daily intervals. As soon as it is evident that flow has either come to a complete stop, at least within the limits of sensitivity of the apparatus employed, or has assumed a steady state for 200 hours, the load is either increased or decreased.

It is seen that in this particular case the Monel metal at 600 deg. fahr. was able to withstand loads as great as 22,000 lb. per sq. in. without undergoing continuous deformation with time. When the load was increased to 27,500 lb., however, continuous flow did take place but only at the rate of 0.028 per cent per 1000 hours. This same material at 800 deg. fahr. can withstand stresses at least as great as 15,850 lb. without continuous flow.

Attention should be called to the apparent downward slope of the line representing the behavior of Monel metal at 600 deg. fahr. under a load of 17,000 lb. Closer inspection will show that the line does not have a continuous slope, but is composed of two practically horizontal lines, with one displaced downward with respect to the other. This displacement is without doubt due to an external factor, such as a sudden jar on the apparatus, and should be considered as such.

When continuous flow is obtained, its magnitude is determined mathematically from the slope of the curves shown in Fig. 5. It may, of course, be expressed in any variety of unit desired, but the authors have found that of percentage per 1000 hours to be convenient.

Previous work has shown that, if the logarithm of the rate of creep be plotted against the logarithm of the stress producing that deformation, a straight-line relationship will be obtained under certain conditions. This has been done and the results are shown in Figs. 6 to 8, inclusive. It is seen that not only are straight lines obtained in nearly all cases, but also that a majority of the lines are nearly parallel to one another.

Charts of the above type are valuable, for they not only allow the relative merits of the various alloys to be compared but they also furnish a rapid means of calculating allowable working stresses, provided the amount of permissible deformation is known. Certain values of this type have been taken from the charts and are given in Table 7.

Table 7 briefly summarizes the results obtained from the creep tests, and places them in a form so they may be readily used. It also gives certain other information such as the short-time proportional limit at the various temperatures, and the recrystallization range.

From Table 7 it is seen that the Konel metal possesses the greatest creep resistance of any of the alloys. At 1000 deg. fahr. it was able to withstand a stress of 43,920 lb. per sq. in. without suffering continuous deformation. Although its short-time tensile properties were comparable to those of Enduro KA2, its creep resistance is vastly superior.

Of the remaining materials, the Monel metal is the superior and retains its creep resistance well at temperatures up to 800 deg. fahr. At 1000 deg. fahr. a sharp break occurs, a load of 1650 lb. being sufficient to produce continuous deformation at the rate of 0.01 per cent per 1000 hours.

The copper-base alloys possess good creep resistance at 400 deg. fahr., but have little load-carrying ability at 600 deg. fahr. The cold-worked brass and Admiralty metal have the greatest resistance of any alloys of these series at 400 deg. fahr., and their values are nearly equal. At 600 deg. fahr. the Admiralty is slightly superior to brass, but

60-40	Over 300 Under 400	400	8,000	...	...	...	...	...
59-40-1	Over 300 Under 400	400	16,000	...	3,500	5,700	9,400	..

neither has sufficient strength to allow its use commercially at this temperature. Both were tested at 800 deg. fahr. and while values are included for the Admiralty metal, the brass deformed so rapidly that the rate of creep was not constant but continuously increasing. Consequently they cannot be included in a chart of this type.

The 85-15 brass is inferior to the 70-30 alloy in its ability to resist creep at 400 deg. fahr., but this may be due to the initial condition of the two materials. The 77-22-1 alloy was much superior to the 59-40-1 material, but inferior to the 70-29-1 Admiralty metal.

The values in the table show the creep characteristics of the alloys to be dependent on their lowest temperatures of recrystallization. In every case at the temperatures below this critical one the alloy was able to withstand loads of considerable magnitude without continuous deformation, while, at temperatures above this critical point, continuous

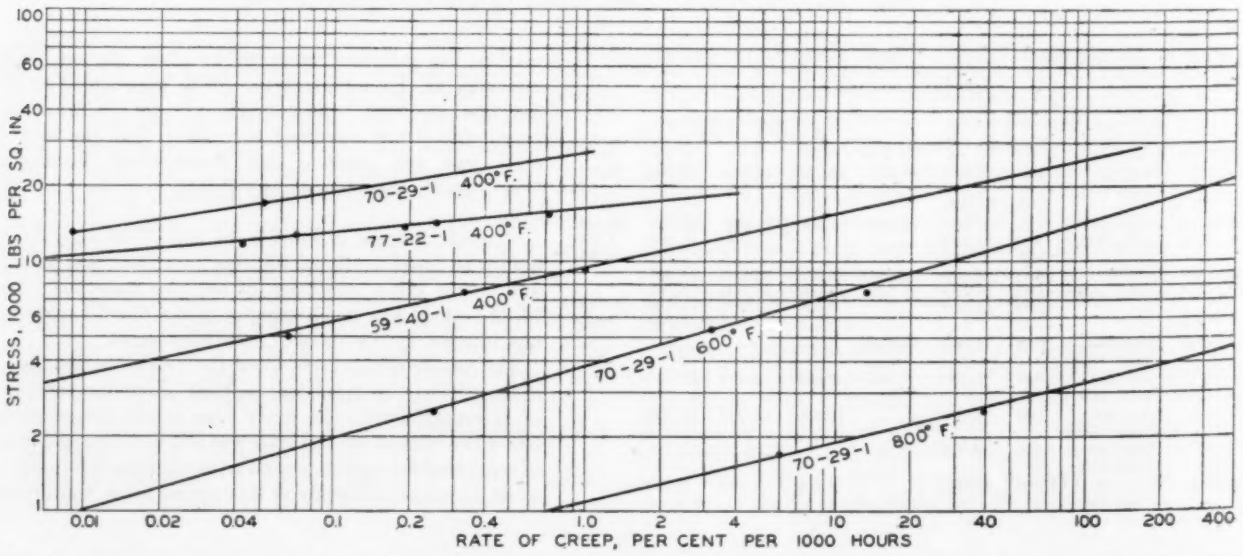

FIG. 8 LOGARITHM OF RATE OF CREEP VERSUS LOGARITHM OF STRESS FOR COPPER-ZINC-TIN ALLOYS AT INDICATED TEMPERATURES

creep was obtained with any load, no matter how small.

It is regretted that at the present time there are no results on similar alloys available in the literature so that a comparison can be made. More confidence is placed in results which may be checked by those from other sources. Until additional information does appear, these figures must be taken at face value.

CONCLUSIONS

The results obtained allow certain conclusions to be drawn regarding the effect of temperature, mechanical working, and chemical composition upon the short-time tensile and creep characteristics of certain non-ferrous alloys. The effect of chemical composition and the temperature of recrystallization was also determined.

In so far as the temperature of recrystallization is concerned, the alloy series arrange themselves in the order of decreasing temperature as nickel-cobalt-titanium, nickel-copper, and copper-zinc alloys. Of the copper-zinc alloys, those containing 70 per cent or more of copper have a higher range than those containing 60 per cent.

The short-time tensile tests show the high-nickel alloys to possess the maximum strength over the entire temperature range, with the Konel metal being the outstanding member of this group. With the remaining alloys, the cold-worked materials possess the greatest strength at the lower temperatures, but their superiority decreases with increasing temperature, and at temperatures at which marked recrystallization can occur, their properties are comparable to those of the hot-rolled alloys. The strength of the alloys containing 60 per cent of copper falls off at a more rapid rate with increasing temperature than do those containing 70 per cent or more of copper.

The ductility of each of the alloys tends to decrease with increasing temperature. In the case of the cold-worked materials, however, this decrease is interrupted at the temperature of recrystallization. At this point a sharp increase occurs, which is again followed by a decrease with rising temperature.

The creep results again show the high-nickel alloys to possess the maximum load-carrying ability at all temperatures and to be capable of use at higher temperatures than the copper-base alloys. The Konel metal possesses the greatest load-carrying ability at 1000 deg. fahr. of any material of which the authors are aware.

On the basis of these results the maximum safe working temperature for certain of the alloys when appreciable stresses must be withstood are believed to be as follows: Konel, at least 1000 deg. fahr.; Monel, 800 deg. fahr.; copper-zinc-base alloys with 70 per cent of copper, 400 deg. fahr.; copper-zinc alloys with 60 per cent of copper, 300 deg. fahr.

Concerning the relationship between the lowest temperature of recrystallization and creep characteristics, it is observed that at temperatures below the lowest temperature of recrystallization loads of appreciable magnitude do not produce continuous flow, while at temperatures above, continuous flow is obtained with any load regardless of its magnitude.

The authors wish to express their appreciation to The Detroit Edison Company for the financial aid given to this work, and to C. F. Hirshfeld, Chief of Research for The Detroit Edison Company, for his kindly interest and advice.

Discussion

J. J. KANTER.[6] The field of long-time tests on non-ferrous metals is one which as yet has been but little touched. Contributions in this direction fulfil an urgent need.

In regard to rolled Monel metal, it should be of interest to note that much higher strength and elasticity at elevated temperatures than the authors report can be obtained on cold-drawn material. If the object of using Monel metal under temperature is high strength, these results should recommend it. (See Table 8.)

The strength of cold-drawn Monel, nearly 60,000 lb. per sq. in. at 1000 deg. fahr., is second only to the Monel result reported by the authors. The reduced elongation and reduction of area which characterize these nickel alloys are shown by the Crane Company tests to occur also in pure nickel. This tendency toward brittleness, however, is greatly alleviated at 1200 deg. fahr., indicating that minimum points on the ductility-temperature curves occur in the vicinity of 1000 deg. fahr.

An important aspect of tensile properties of wrought brasses and bronzes is their change during fabrication. When hot-rolled and extruded stock is forged or hot-stamped, it invariably is found to have undergone drastic softening. The difference in hardness between the "as received" stock and the formed parts corresponds approximately to the loss sustained through a dead anneal. In order to properly evaluate high-temperature tensile properties representative of hot-worked articles, it is imperative that the test specimen be prepared from either hot-forged or annealed stock. A number of non-ferrous alloys have been tested under temperature in both the "received" and annealed conditions at Crane Company laboratories. These tests show that annealed materials are inferior to the hot-rolled and extruded in proportional limit at temperatures up to 500 deg. fahr., to the order of 50 to 75 per cent. Tensile-strength values likewise undergo an appreciable reduction of from 15 to 30 per cent.

The proportional limits of dead-annealed brasses, while small in value at temperatures from 75 to 400 deg. fahr., persist in measurable values at temperatures above those for which this constant has practically vanished in the case of hot-rolled and extruded material. At 600 deg. fahr., a temperature for which the authors report 1500 and 1750 lb. per sq. in. proportional limit for hot-rolled yellow brass, it can be shown that the same material, when annealed at 1500 deg. fahr., retains a proportional limit of 7000 to 12,000 lb. per sq. in. Creep tests on the annealed brass show a rapid decline of load-carrying ability in the vicinity of 400 deg. fahr., as has been reported by the authors for hot-rolled brasses. The red bronzes (not covered in the Clark and White report) are found

[6] Crane Company, Chicago, Ill.

in Crane Company tests to resist creep up to about 600 deg. fahr., a margin of 200 deg. fahr. superiority to yellow brass.

It is of interest to note the types of fracture which are obtained on high-temperature tensile-test specimens, particularly nonferrous metals and alloys. Normally, at atmospheric temperature, wrought brasses and bronzes rupture with cup-like fractures of a silky contour. Fractures of this kind persist up 300 or 400 deg. fahr., where they commence to take on a more irregular or heterogeneous appearance. At 500 deg. fahr. and above, the breaks are characterized by jagged contours and complete disappearance of cup. In the case of Monel metal and other nickel-base alloys, similar transitions occur between 800 and 1000 deg. fahr. For carbon and low-alloy steels a similar change is usually found between 800 and 900 deg. fahr. Highly tempered alloy steels that give a star-like or radially cracked fracture when cold, usually pass through a temperature range giving cup fractures before reaching irregular rupture. Austenitic irons and steels do not completely transform from silky to irregular rupture until they reach 1200 deg. fahr.

These transformations in fracture type are usually interpreted as being due to change from rupture through the grains to rupture by separation of grains along their boundaries. This temperature or range of temperature has come to be called the "equicohesive" on the assumption that it represents a state in which the grain boundary strength is equivalent to the crystalline cohesive force. Long-time test results indicate that it is in this critical range that metals start to creep at small loads. The temperature of recrystallization determined by the authors for the various alloys they considered are all well within the range where the fracture type usually changes. May it be suggested that the value of Table 2 would be greatly enhanced if it were correlated with descriptions of the fractures obtained in the tensile investigations.

W. B. Price.[7] In support of the authors' statement that "Results indicate a superiority of the nickel-base alloys over the entire temperature range," the writer would like to record the results of some short-time tensile tests carried out some six years ago on Adnic. Adnic is a copper-nickel-tin alloy of the following composition: copper, 70 per cent; nickel, 29 per cent; and tin, 1 per cent. Its recrystallization temperature would be over 1100 deg. fahr. and under 1200 deg. fahr. Tests conducted on $^{3}/_{16}$-in. cold-drawn material gave the following results:

Temperature of tests, deg. fahr.	Tensile strength, lb. per sq. in.
70	94,000
387	82,900
557	81,000
769	70,600
957	59,300

If these results are plotted on Fig. 1 of the paper, it will be noted that the curve is above the curve for Ambrac and Monel metal.

The proportional-limit results over the same temperature range were as follows:

Temperature of tests, deg. fahr.	Tensile strength, lb. per sq. in.
70	60,000
387	58,500
557	60,000
769	46,300
957	31,300

These results plotted on Fig. 2 of the paper show them to be very much superior to any of the other alloys, even Konel.

In the November, 1927, issue of *Mining and Metallurgy* there was an article by the writer on "The Physical Properties of Adnic." In that paper, in Fig. 1, a comparison of the physical properties of Monel metal and Admiralty nickel (Adnic) are shown in which the tests were carried up to 1500 deg. which is 500 deg. higher than the temperature used by the authors. Note the high proportional limit and tensile-strength values at elevated temperatures exhibited by Adnic when compared with Monel.

P. G. McVetty.[8] It is indeed interesting to see the results of independent tests of one of the Konel alloys which have been developed in the Westinghouse Research Laboratories. The first knowledge that the authors were investigating this material came when the paper was received.

In Tables 2, 4, 5, and 6, the condition of the test specimens is given as "unknown." The company is not acquainted with the history of this particular bar, but has obtained similar test results after heating at 900 deg. cent. (1652 deg. fahr.) for two hours and cooling in the furnace.

To supplement the data given in the paper, Table 9 gives physical properties at 24, 400, 500, and 600 deg. cent., corresponding, respectively, to 75, 752, 932, and 1112 deg. fahr. These values were all obtained after annealing two hours at 900 deg. cent. (1652 deg. fahr.).

TABLE 9 PHYSICAL PROPERTIES OF KONEL

	51.6	45.4	..	..

The analysis referred to in the paper is one of a series of alloys. By variations in the constituents, it has been found possible to improve the alloy to meet various service conditions. A comprehensive investigation of the system has been in process for about three years, and the writer expects to present a paper on the subject before the A.I.M.E. in February.

Arthur J. Herschmann.[9] This is an exceedngly interesting paper which has given much information and many ideas. In view of the statement that one of the main objectives of these investigations is the application of results to benefit central-station practice and construction for highest pressure in conjunction with highest temperature, it may be pertinent to tell of one instance of highest pressure and temperature where carbon steel has thus far been satisfactory.

The Loeffler boiler, which the writer represents, operates on 1900 lb. and 950 deg. total temperature. Drums and tubes have been in constant operation on slightly lower pressure and temperature for over three years, and no creep or change of

[7] Chief Chemist and Metallurgist, Scovill Manufacturing Company, Waterbury, Conn.

physical properties has been observed with testing equipment at disposal. It may be stated that these high-pressure drums, which are now about 44 in. diameter each and about 26 ft. long, are out of the fire. They are $2^{5}/_{8}$ in. thick. The superheater tubes are of 45 carbon steel, there being no rolled joints; everything is welded. There is now a slight addition of molybdenum, but only because it is relatively cheap and its increased cost is offset by the obvious advantages of consequently thinner tubes. The reason why this company can use 950 deg. total temperature is that its system precludes an accidental rise of such total temperature in the superheaters during operation, owing to the pump of the Loeffler system which invariably cools these tubes with ample steam. Loeffler boilers are built for 50 and 75 tons of steam per hour, on steel as stated.

The 2500-hp. Loeffler locomotive of the German Reichsbahn has a high-pressure drum of nickel-chromium steel owing to the desirability of obtaining the lowest possible weight.

Answering the statement that ordinary carbon steel could not very well serve a much higher combination of pressure and temperature than the foregoing, the writer would repeat that the circulating pump of the Loeffler design enables the working in these limits with considerable safety. Professor Loeffler could see no advantage in going above such pressure and temperature.

Authors' Closure

The authors appreciate the discussion which has been offered to this paper and are pleased to find their work in agreement with that of other investigators. They wish to thank Mr. Kanter for his comments and additional data showing the affect of heat treatment and methods of fabrication on the resulting physical properties of these non-ferrous alloys. They are well aware that the initial condition of these alloys greatly affects their properties, but time has not as yet allowed the long-time creep tests to be conducted on each of these alloys in all possible conditions of fabrication and heat treatment.

In regard to Mr. Price's comment, it should be understood, of course, that when the authors made the statement, "Results indicate a superiority of the nickel-base alloys over the entire temperature range," they were referring only to the alloys considered in this paper.

They have not as yet conducted any tests on Adnic, but are hoping to be able to investigate this interesting alloy at a later date.

The authors are also gratified for Mr. McVetty's comments and additional data concerning Konel metal and to Mr. Herschmann for his comments as to operating temperatures and pressures in the Loeffler boiler.

Fractures in Boiler Metal

By A. E. WHITE[1] and R. SCHNEIDEWIND,[2] ANN ARBOR, MICH.

During the past several years many specimens of failed boiler materials have been brought to the authors' attention with questions as to the mechanism and probable cause of the failures. In some cases the pieces consisted of fractured portions of tubes, blow-off pads, saddles, plates, rivets, and similar boiler parts. The examinations, which were to a large extent metallographic in nature, have led to some generalizations and classification of cracks and fractures as related to the causes of failure. This paper classifies the types of failure and gives their metallographic characteristics. The material presented consists of a short review of the literature on boiler-metal failures, a detailed description of fractures in boiler metal due to known causes, and a description of actual failures in service.

FROM a study of the literature the causes for failures in boiler materials may be divided roughly under three general headings: defects due to the composition of steel or to steel-mill practice, defects due to methods of boiler construction, and defects developing as a result of conditions of operation of the equipment. These divisions are not entirely clear-cut due to the close interrelationship of these factors.

High sulphur and especially high phosphorus contents in steel have been mentioned as contributing causes of brittleness by Fowler[3] and by Law.[4] Houghton[5] believed that the combined contents of phosphorus and arsenic determined to a large extent the satisfactoriness of boiler steel.

Segregation of constituents[6,7,8] and other non-homogeneities such as are revealed by macroscopic etching, a Rosenhain etch,[9] or by sulphur prints[10] are commonly found near fractures. In many cases, however, segregations do not constitute a serious defect.

Pipes, blow holes, seams, and inclusions constitute defects of a serious nature. In order to improve the quality of boiler plate, Houghton[5] suggested that not more than 45 per cent of the ingot be used for this purpose. It is general practice, however, according to McKnight and Humpton,[11] with rimming carbon steel to utilize about 70 per cent for boiler plate, and with nickel steels about 60 per cent. In order to improve the physical properties much of the boiler steel is being supplied in the normalized condition.

Many failures have been traced to serious strains induced by careless riveting[12,13,14,15] in the process of constructing the boiler. Sharply bent flanges[16] if not properly heat-treated are quite apt to suffer from aging and become brittle or they are liable to fail by corrosion. Boiler-making methods have been improved greatly by drilling instead of punching the rivet holes, by more careful calking, and in general by improving the fit of the various parts of the boiler so that undue stresses are not set up in the seams.[17] Many of the defects enumerated thus far can be detected by good inspection methods.

A large share of failures occur from defects which although they may have their inception in the streases or flaws present when the boiler went into service do not, however, make their appearance until after the boiler has been in service for some time. Cracking sometimes occurs in stressed parts due to a phenomenon known as blue brittleness. If a piece of low carbon steel is deformed and heated to from 300 to 450 deg. cent., the material becomes brittle, and the fractured steel has a bluish tinge. Nickel and especially chromium raise the temperature at which such embrittling takes place. Brittleness[18] is also developed on aging. It was observed that some boiler plate which was known to be ductile when the boiler was built became markedly less ductile after several years' use.

Age-hardening after cold drawing is due to the carbon according to Pfeil.[19] Carbon-free iron does not age, but as little as 0.0025

per cent of carbon will permit aging. Iron oxide acts similarly.

Cracking has been ascribed by some writers to pure physical stresses.[3,20,21] Wolff[22] describes some transcrystalline cracks and suggests that fatigue is an important factor contributing to the failure. Similarly Rosenhain and Hanson[23,24] believed that cracking might occur in mild carbon steels through prolonged tensile stressing. However, upon loading steel containing 0.10 per cent carbon with stresses up to $^2/_3$ of the normal ultimate strength for over five years and maintaining a temperature of 300 deg. cent., no fracture took place.

Cracking in boiler metals has also been considered a corrosion phenomenon. Körber and Pomp[25] demonstrated by means of etching agents containing copper that locally strained areas were present and that corrosion and cracking took place along these lines or directions of high stress.

Cracking due to brittleness and strain is in general through the grain. A large number of boiler cracks are intercrystalline and start at points of high localized stresses. This phenomenon has been termed by some caustic embrittlement. Parr and Straub[17,26] in a series of carefully controlled tests showed that intercrystalline cracking such as is often found in boiler plate could be reproduced in the laboratory at operating boiler temperatures by maintaining a piece of steel in tension under a stress near the elastic limit in contact with a solution containing no less than 100 grams per liter of sodium hydroxide. They point out that high stresses may occur in the vicinity of riveted joints, and that in small cracks or fissures acting as capillaries a high concentration of salts can be formed. Careful control of the boiler-water composition and the addition of sodium sulphate will materially decrease chances of embrittlement. Suggestions of other possible mechanisms of intercrystalline cracking have been made, notably that of corrosion-fatigue by MacAdam.[27] Pfeil[28] has showed that occluded hydrogen always weakens the grain boundaries so that intercrystalline cracks are formed. In many cases intercrystalline cracks have developed in the presence of stress and a corroding medium. For example, low carbon-steel pans used in evaporating sodium-nitrate solutions cracked where the metal was bent sharply. Solutions of other nitrates and alkalies acted in the same manner on stressed steels.

The water in the boilers if not properly controlled[29] as to its pH, oxygen, and carbon-dioxide content may cause corrosion and pitting of the steel. Woodvine and Roberts[30] showed that segregation of constituents in the metal also affected the pitting and corrosion in boiler tubes. If the process of water softening is not adequate, scale will form in the tubes and permit overheating which may lead to bulges and even ruptures of the tubes.

Characteristic Fractures Due to Known Causes

In order to present more or less ideal type failures, boiler-tube material was caused to fail by bending, compression, tension, impact, fatigue, and by caustic embrittlement. The characteristics of each type of failure were noted and were later compared with those of failures actually met with in boiler materials.

The material used in this study was ordinary boiler tubing having the following analysis:

Carbon	0.14 per cent
Manganese	0.48 per cent
Sulphur	0.031 per cent
Phosphorus	0.010 per cent
Silicon	0.14 per cent

It was annealed at 1800 deg. fahr. for four hours and cooled slowly in the furnace in order to produce equiaxed, unstrained crystals of large size. Photomicrographs in Figs. 1 and 2 show the structure of the metal at 100 and 1000 diameters, respectively. At the lower magnification a tendency can be seen for the carbides to be distributed along lines in the direction of working. In general the material is fairly clean, homogeneous, with distinct, straight grain boundaries.

The failures produced in the manners described were in some cases accompanied by deformation of the crystals and in others the crystals were not deformed. The results of the tests are therefore taken up according to that classification.

Failures Accompanied by Deformation of the Crystals

Slip Lines. Upon subjecting a polished and etched section of this steel to a stress by squeezing in a vise, lines corresponding to the crystallographic planes of slip are formed. Typical slip lines are shown in photomicrographs in Figs. 3 and 4 at 100 and 1000 diameters, respectively. Lines of slip are shadows due to differences in level caused by the sliding of different portions of a crystal along gliding planes. In the case of α-iron, this represents the trace of the [111] plane. The stress must be, locally at least, beyond the elastic limit of that crystallographic constituent so that failure or disorganization of a series of unit cells takes place. After repolishing and re-etching the specimen it will be found that the slip lines (or slip bands) have disappeared. This is shown in photomicrographs in Figs. 5 and 6. Repolishing effaces the differences in level and thus eliminates the evidence of slip.

X Lines. A strip of this steel was bent through an angle of 180 deg. and then bent flat again. Photomicrograph in Fig. 7 presents a longitudinal section at 100 diameters through the axis of bending. Bending took place along an axis perpendicular to the edge shown in photomicrograph Fig. 7 and roughly through the middle of the picture. A number of lines can be seen existing in some of the crystals. Since polishing and etching do not completely efface these lines, they must be considered a severer type of slip line or, to use the nomenclature of Howe,[31] they are X lines or X bands. They are found in this steel only in the ferrite; a typical system is shown in photomicrograph Fig. 8 at 1000 diameters. It is to be noted that X lines have formed only in a portion of the crystals, undoubtedly in those crystals only whose orientation favored deformation by stresses applied in the direction in which the force was applied in this case. It is to be noted further that all of the X lines make angles of 45 deg. or less with the axis of bending. It can be inferred that the orientation of the undeformed crystals was such that they resisted deformation sufficiently so that no traces of X lines resulted.

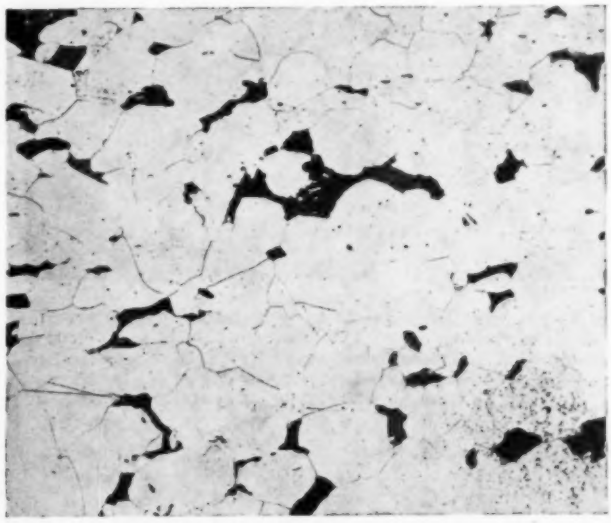

FIG. 5 THE SLIP LINES IN FIG. 3 HAVE BEEN EFFACED BY RE-POLISHING AND RE-ETCHING—PHOTOMICROGRAPH AT 100 DIAMETERS

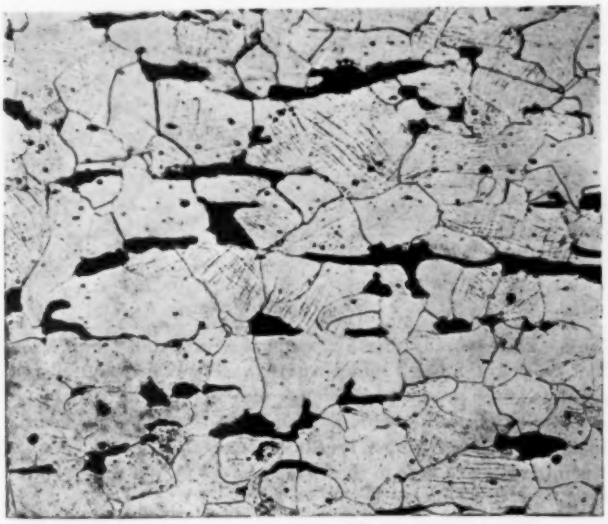

FIG. 3 SLIP LINES PRODUCED BY SQUEEZING SPECIMEN—AT 100 DIAMETERS

FIG. 6 SAME AS FIG. 5 BUT AT 1000 DIAMETERS

Whereas a slip line may be a phenomenon affecting material in a section having a thickness equal to a few unit lengths of the space lattice, several Angstroms wide, an X line embraces a section of metal at least 0.0001 in. wide.

It is generally accepted that etching effects in crystal aggregates are due to differences in the solubility of the various constituents. In pure substances or in solid solutions where the chemical composition is uniform, differences in appearance noted under the microscope are due to the differences in solubility as a result of orientation. X lines can probably be explained on the basis of one or more of the following hypotheses:

1 They may represent sections of a crystal containing greater

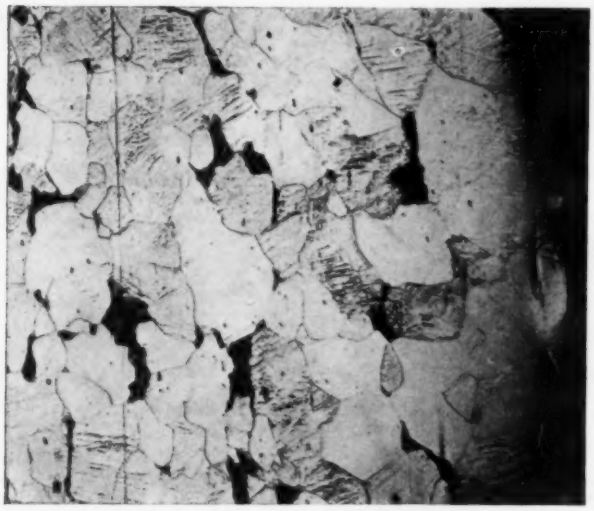

FIG. 7 SECTION THROUGH AXIS OF BENDING AFTER SPECIMEN WAS BENT THROUGH 180 DEGREES AND BACK—THE X LINES FORMED WILL STILL BE THERE AFTER REPOLISHING AND RE-ETCHING—NOTE X LINES MAKE ANGLES LESS THAN PLUS OR MINUS 45 DEGREES WITH AXIS OF BENDING—AT 100 DIAMETERS

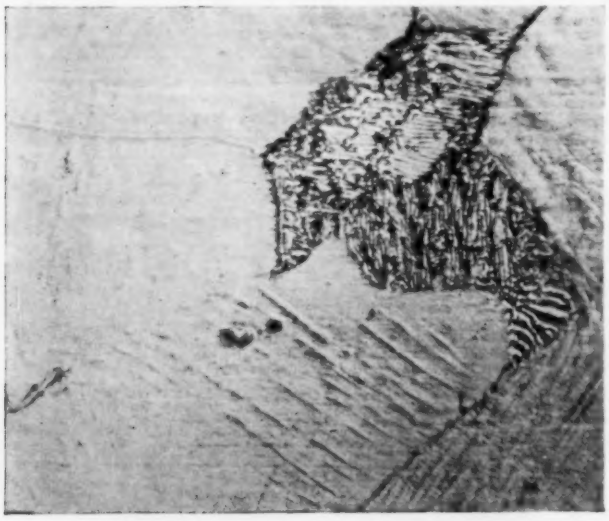

FIG. 8 SAME AS FIG. 7 BUT AT 1000 DIAMETERS

strain and therefore, being at a different electrolytic potential, dissolve at a different rate in the etching medium.

2 They may represent sections of metal having distorted, partially disorganized, or otherwise imperfect unit cells and thus exert a greater solution pressure.

3 They may represent sections of metal, the orientation of whose lattice is slightly different from that of the rest of the crystal. Howe[32] inclines to the last explanation when he says: "Hence these X bands may be twinned layers, or at least layers of different even if not symmetrically different orientation."

Failure by Bending. It was found necessary to bend this steel through 180 deg. and back three times before failure was induced.

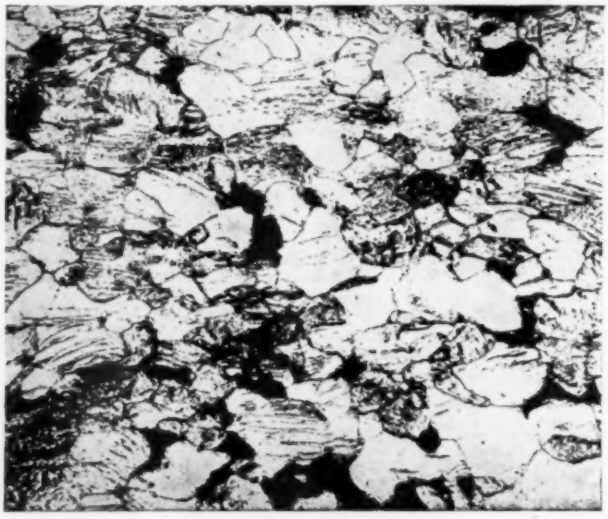

FIG. 9 SPECIMEN WAS BROKEN BY BENDING BACK AND FORTH THROUGH 180 DEGREES THREE TIMES—PHOTOMICROGRAPH AT 100 DIAMETERS SHOWS EDGE OF FRACTURE—NOTE THAT X LINES PARALLEL THE AXIS OF BENDING MUCH MORE CLOSELY THAN IN FIG. 7—IN MOST CASES THE X LINES MAKE ANGLES LESS THAN 10 DEGREES WITH AXIS OF BENDING

FIG. 10 SECTION ONE-HALF INCH BACK FROM BINDING FRACTURE—NOTE BURST GRAIN BOUNDARIES AND CRACKED CRYSTAL—AT 100 DIAMETERS

The stresses naturally were a mixture of tension and compression. Photomicrograph Fig. 9 shows at 100 diameters the fractured edge which had been preserved by copper plating for 36 hr. Although not readily apparent, careful examination will show that the fracture is transcrystalline, that is, it passes through the crystals. It is interesting to note in the vicinity of the failure that, (1) the

crystals are deformed as would be expected, and that (2) a larger portion of the grains exhibit strain lines or X lines than were visible in photomicrograph Fig. 7. Some of the lines are double so that it would not be incorrect to term them X bands. Few

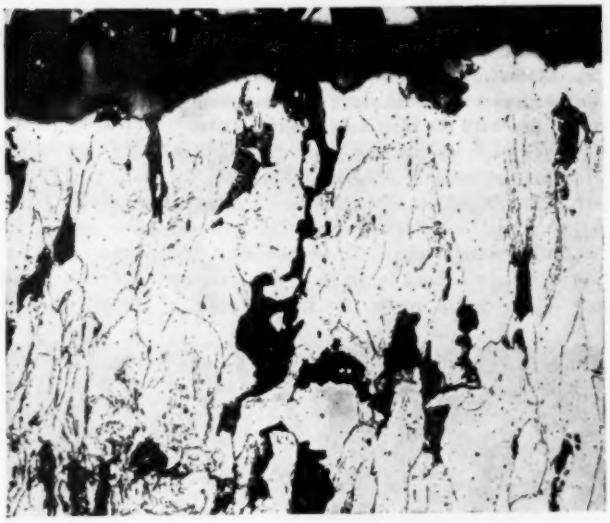

FIG. 19 EDGE OF TENSION FRACTURE—FAILURE IS ACROSS THE GRAIN—AT 100 DIAMETERS

FIG. 21 CRACKING DUE TO TENSION SHOWN AT 1000 DIAMETERS —THIS SECTION WAS ABOUT ONE-HALF INCH BACK FROM THE FRACTURE—CRACKING TOOK PLACE IN THE PEARLITE ALONG A LINE MAKING AN ANGLE OF 45 DEGREES TO THE APPLIED STRESS

of the X lines and X bands, the directions of which are assumed to be indicative of the orientation of the crystals, make angles greater in magnitude than about plus or minus 10 deg. with the axis of bending. Such a condition may well be explained on the basis of movement of the grains in the aggregate approaching as limit a condition of identical orientation.

Photomicrograph Fig. 10, also at 100 diameters, shows an area more remote from the edge of the fracture. Less severe X lines

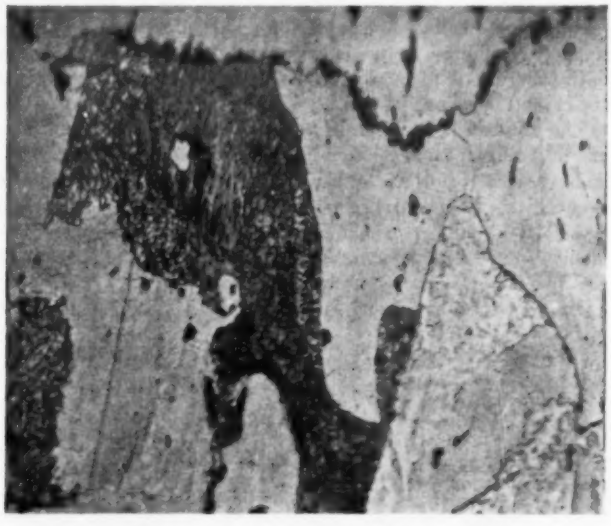

FIG. 20 TENSION FRACTURE AT 500 DIAMETERS—NOTE FRAGMENTATION OF CARBIDES AND ABSENCE OF STRAIN LINES IN ROW OF CRYSTALS ADJOINING FRACTURED EDGE

FIG. 22 PHOTOMICROGRAPH AT 1000 DIAMETERS SHOWING 45 DEGREE SHEAR FAILURES IN PEARLITE DUE TO TENSILE PULL

and a larger portion of undeformed crystals can be seen. Two important points are brought out in this picture. First, some of the crystals seem to have abnormally wide grain boundaries and, second, failure can be seen taking place in some of the grains. Upon examination of the wide boundaries at higher magnification, shown at 500 diameters in photomicrograph Fig. 11, the

boundary around a small grain possessing X lines is seen to be ruptured. The crystals are actually torn apart. This same condition is shown in photomicrograph Fig. 12 also at 500 diameters. In the former the formation of a series of cracks can be seen running across in a direction parallel to the axis of bending and parallel to the X lines in two smaller adjacent crystals. It is not unlikely to suppose that this large crystal also possessed X lines until failure took place which relieved the strains and permitted the crystal to recover elastically.

The presence of burst grain boundaries shows that technically one may think that a bending fracture is sometimes intercrystalline. Actually, however, a bending failure is transcrystalline as shown by the fractured edge in photomicrograph Fig. 9, in cracked crystals in photomicrographs Figs. 10 and 11, and even more convincingly at 1000 diameters in photomicrograph Fig. 13, which clearly shows a long transcrystalline crack.

Failure by Compression. Another strip of this same boiler tube steel was subjected to a compressive stress of about 125,000 lb. per sq. in., which flattened the specimen considerably. After being copper plated for 36 hr. it was polished and etched. Photomicrograph Fig. 14 at 100 diameters shows a condition of flattening of the crystals. The X lines parallel the edge of the specimen fairly well. Failure takes place in two different manners. The softer constituent, the ferrite, distorts along its gliding planes in those crystals which are favorably oriented. Two such crystals can be seen in photomicrograph Fig. 15 at 1000 diameters. Distortion has taken place up to the point of incipient cracking of the crystals. Again it is to be noted that the failures make angles of less than plus or minus 30 deg. with an axis normal to the compressive stress. Such deformation undoubtedly permits less favorably oriented crystals to move by manner of plastic flow until they too are oriented in a direction favorable to distortion by the existing stress.

On the other hand no definite cracking can be observed in the pearlite. The pearlite is elongated in the direction normal to the compressive force as is shown at 1000 diameters in photomicrograph Fig. 16. The pearlite does probably crack, but it cannot be observed readily at this magnification due to the darkness of the constituent. The portions cracked off are then carried along much as logs are floated along on the surface of a stream, and the voids filled with the relatively plastic ferrite.

Since no serious cracking or fracturing occurred, a less ductile steel was then used. A $^3/_4$-in. round bar, 3 in. long of 0.20 per cent carbon steel was subjected to a compressive load of 100,000 lb. Cracking took place along the Lüders lines, planes making 45-deg. angles with the axis of compression. Microscopic examination revealed the fact that no appreciable distortion of the crystals took place except along the Lüders lines. This situation is clearly shown at 100 diameters in photomicrograph Fig. 17, which was taken along a crack. Photomicrograph Fig. 18 at 1000 diameters demonstrates the stringing out of the ferrite and pearlite until the axes of each grain paralleled the axis of failure. Whether the failure goes through or around the grains cannot be unequivocally demonstrated although it is most likely of a transcrystalline nature due to slip.

Failure by Tension. A flat strip of the boiler-tube steel was next caused to fail by a tensile stress. After copper plating to preserve the fracture, the specimen was polished and etched for microscopic examination. Photomicrograph Fig. 19 of the edge of the fracture at 100 diameters shows the elongation of the grains in the direction of the tensile stress. Fracture has taken place across the crystals as is demonstrated even more clearly in

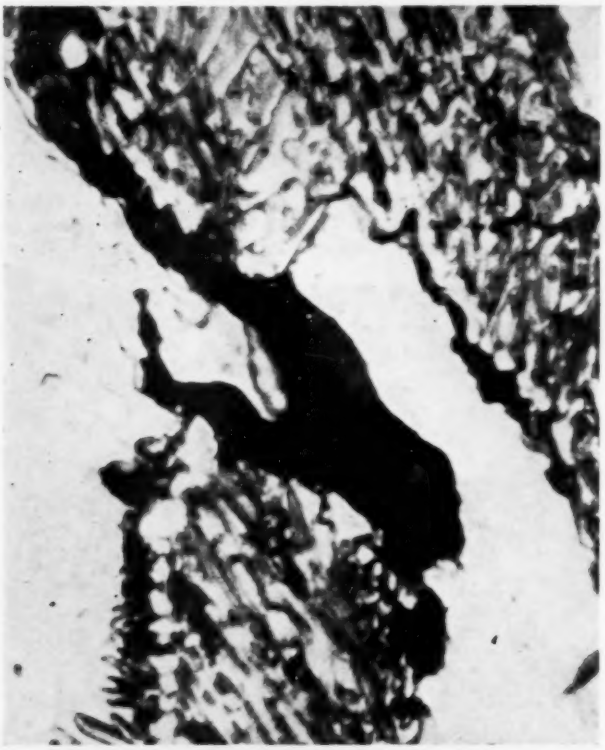

FIG. 23 PHOTOMICROGRAPH AT 3000 DIAMETERS OF A 45-DEGREE FAILURE DUE TO TENSION—THE FLOW OF FERRITE HAS CAUSED ROTATION OF THE LOWER FRAGMENT OF THE PEARLITE GRAIN—NOTE THE FERRITE FLOWING INTO THE VOID AT THE RIGHT SIDE

photomicrograph Fig. 20 at 500 diameters. The latter photomicrograph was taken with vertical lighting and hence does not bring out in full detail the X lines in the crystals. Close examination, however, will reveal the surprising fact that, although evidences of strain other than elongation of the crystals are visible in some grains, those in which fracture took place do not reveal any strain lines whatever. The small particles of dark material in the large ferrite grains are undoubtedly fragments of carbide particles. Those in the copper layer are presumably particles of pearlite which were torn loose in polishing and became embedded in the soft copper.

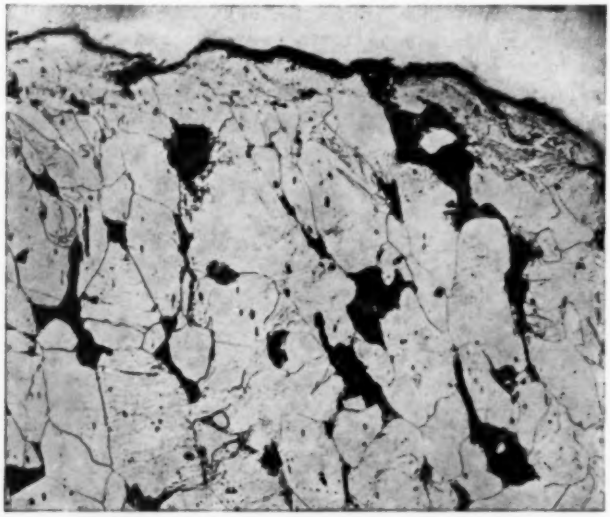

FIG. 25 PHOTOMICROGRAPH AT 100 DIAMETERS OF THE EDGE OF IMPACT FAILURE

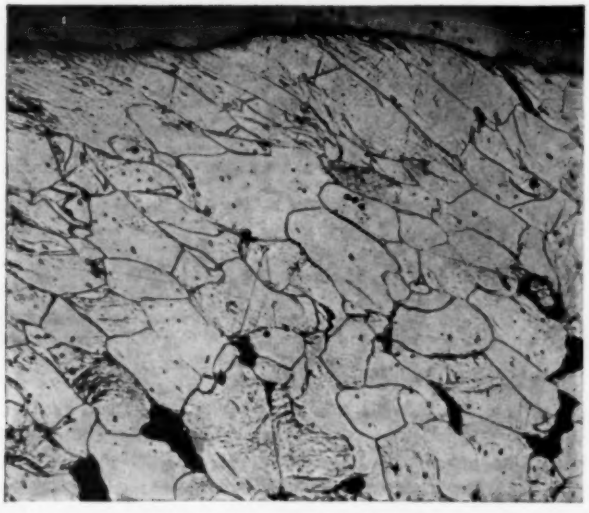

FIG. 26 EDGE OF IMPACT FAILURE AT 100 DIAMETERS—IN THIS SECTION SHEAR WAS AN IMPORTANT FACTOR

Naturally a fracture does not take place suddenly but occurs in stages along a plane which has been weakened by an accumulation of failures in individual crystals. Failure in mild carbon steels through tension seems to start in the relatively strong but brittle pearlite constituent. This was first noted by Rosenhain.[33]

As a tensile stress is applied the ductile ferrite, by elongating and cold working, constantly increases the stress existent in the pearlite which undergoes no appreciable elongation. Evidently the cohesive force between grains is greater than the strength of the pearlite. The pearlite fails not necessarily along any slip plane, but along a shear plane at about 45 deg. to the direction of the tensile stress. Photomicrograph Fig. 21 at 1000 diameters shows a typical failure occurring in a pearlite grain. The fracture cuts across the laminations in the eutectoid; the dark portion between the two halves of the crystal represents a void. The two portions were clearly parts of a single pearlite particle; after shearing along a 45 deg. plane, due to the movement of the ferrite, the two portions appear to be separated about 0.0005 in. Photomicrograph Fig. 22 also at 1000 diameters shows a similar condition except that fracture took place not along an unidirectional line but along several lines the direction of each being plus or minus 45 deg. to the line of stressing.

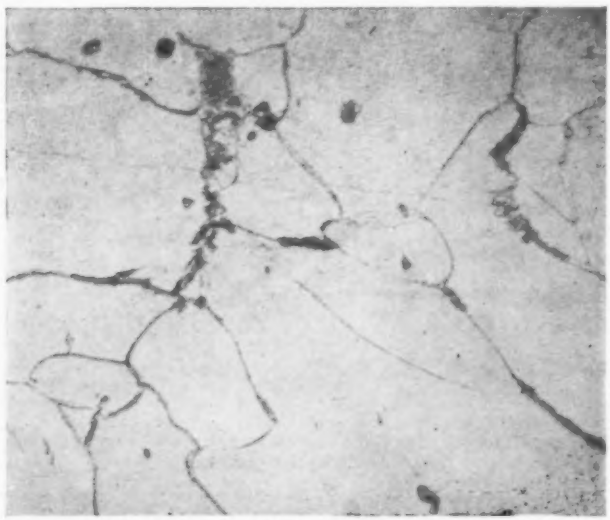

FIG. 27 BURST GRAIN BOUNDARIES DUE TO IMPACT—AT 500 DIAMETERS

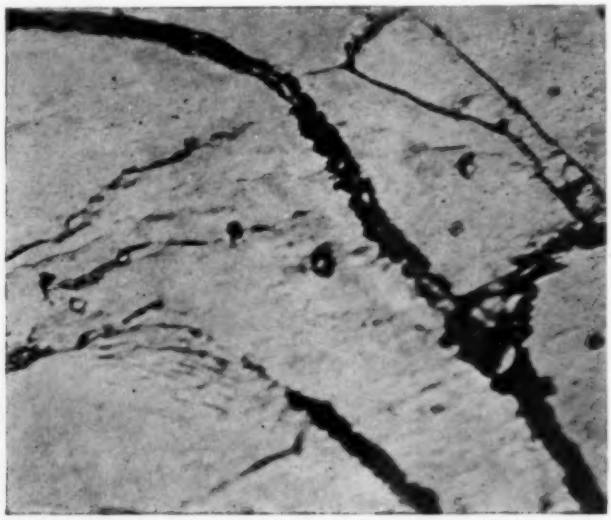

FIG. 28 BURST GRAIN BOUNDARIES AT 1000 DIAMETERS

The next stage in failure by tension is shown at 3000 diameters in photomicrograph Fig. 23. Rotation of the lower fractured portion of the pearlite can be seen to have occurred probably be-

[33] W. Rosenhain, "Deformation and Fracture in Iron and Steel," Jl. Iron and Steel Institute, vol. 70, pp. 189–228, 1906.

cause the long arm at the left of the picture extended outward into the moving stream of ferrite. Rotation was accomplished much as a log floating crosswise in a river and fixed at one end soon tends to assume a position paralleling the direction of flow. A second interesting feature brought out in this picture, tending to illustrate

FIG. 29 BURST GRAIN BOUNDARIES AND STRAIN LINES DUE TO IMPACT—AT 1000 DIAMETERS

FIG. 30 STRAINED AND UNSTRAINED CRYSTALS IN IMPACT SPECIMEN AT 1000 DIAMETERS—NOTE UNEVEN CONTOUR OF METAL—THESE FIGURES ARE PROBABLY THORNS, A TYPE OF NEUMANN BAND

the plastic nature of ferrite under stress is the fact that ferrite is flowing into the right-hand side of the void. It is generally known that if a specimen is left under a condition of stress in excess of the elastic limit for a period of time and then ruptured, the tensile strength proves to be greater than if a tensile-strength measurement had been made in the usual manner. It is not improbable that incipient local failures in the pearlite are healed by the plastic flow of the softer constituent, and that even new atomic bonding may be effected. The completion of this flowing-in process is shown at 1000 diameters in photomicrograph Fig. 24. The slender carbide particle at the right has cracked along 45 deg. shear lines, and the voids created in this manner have been apparently filled by material from the single-ferrite crystal adjoining it on the left. X lines can be seen in some of the ferrite grains in the vicinity. But again, no X lines can be seen in crystals which have been in contact with a crack or a void. Tension failure is undoubtedly a pure shear phenomenon.

Failure by Impact. A specimen of this boiler-tube material was notched and fractured by means of a blow of a hammer. In

FIG. 31 FATIGUE FRACTURE AT 100 DIAMETERS—THE FRACTURE GOES THROUGH THE GRAIN—THERE IS NO DISTORTION OF THE CRYSTALS

so ductile a metal as this, a failure by pure impact can hardly be expected. Although one would expect some of the grains to fail through impact, a large number tend to bend and, hence, to fail by shear. Photomicrograph Fig. 25 shows at 100 diameters a portion of the fracture in which impact played a major role. Strain lines and distorted Neumann bands of the wedge type can be seen. The grains in general are not very severely deformed. Photomicrograph Fig. 26 also at 100 diameters shows that portion of the edge of the fracture which was probably due to shear. The grains seem inclined in the direction of the applied stress. The edge of both of these sections is so indistinct that it is not possible to state definitely whether fracture occurred along the boundaries or through the grains. Photomicrograph Fig. 27 at 500 diameters shows a number of burst grain boundaries and some strain lines roughly paralleling the fracture. The same things are shown at 1000 diameters in photomicrographs Figs. 28 and 29. In these latter two pictures are shown strain lines in the

same crystals which are in contact with voids, a combination less common in the failures due to bending, compression, or tension. Because of the burst grain boundaries, failure by impact must be in part at least an intercrystalline phenomenon.

Some of the grains of ferrite are not distorted at all whereas others are very badly strained. Photomicrograph Fig. 30 shows at 1000 diameters such a case occurring in two adjacent crystals. The short parallel ridges (whose directions make angles of less than 45 deg. with the axis of failure) have been described by Osmond[34] as thorns, a special type of Neumann band.

A Neumann band by definition is a section of a crystal the orientation of whose crystallographic planes is the mirror image of the original crystallographic planes. This reversal of orientation is brought about in ferrite by sudden severe shock. Perhaps if the shock had been more severe than was the case in this sample, rupture would have taken place in shorter time and changes in orientation would have been effected without further deformation of the grain. Thus the usual straight Neumann band might have been produced.

FIG. 32 SAME AS FIG. 31 BUT AT 500 DIAMETERS

Obviously, since a thorn is a structure which is revealed only upon etching, the same possible explanations for their appearance on etching must be true as in the case of X bands. Thorns undoubtedly represent a severe disturbance of the orientation of the crystallographic axis in a portion of a grain. Since it is not possible by X-ray analysis or any other manner to measure the degree of change in orientation, it cannot be determined whether the axes are symmetrically reversed, and hence whether a thorn is a true Neumann band. Thorns might even represent a structure intermediate between a Neumann band and the original crystal.

It has been demonstrated that failures by bending, by compression, by tension, and by impact all occur with deformation of the crystals. The fractures are through the crystals. Impact failures show the presence of burst grain boundaries, but even so one could not accurately classify an impact failure as intercrystalline.

FAILURES NOT ACCOMPANIED BY DEFORMATION OF THE CRYSTALS

Failure in mild steels not accompanied by deformation of the crystals makes up the second general type. In this classification

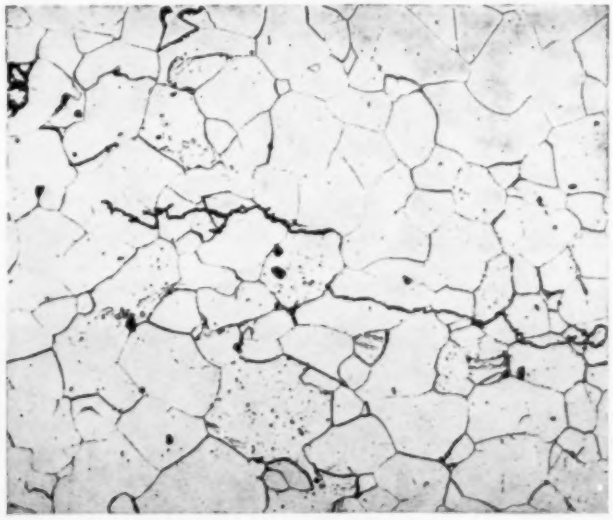

FIG. 33 FATIGUE CRACK IN FERRITE ONE-HALF INCH FROM FRACTURE—AT 100 DIAMETERS

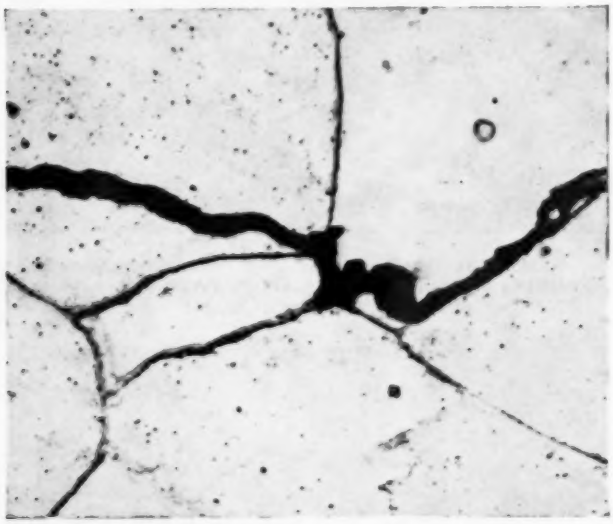

FIG. 34 FATIGUE CRACK AT 1000 DIAMETERS ILLUSTRATING TRANSCRYSTALLINE NATURE OF FAILURE

also the fractures or cracks may be divided into those which are transcrystalline and those which are intercrystalline.

Failure by Fatigue. Fatigue cracks illustrate the first type. A specimen of the boiler-tube material was caused to fail in an Upton Lewis type fatigue machine. After copper plating for 36 hr. photomicrographs Fig. 31 and 32 were taken to show at 100 and 500 diameters respectively the appearance of the fracture which is clearly across the crystals. Photomicrographs Fig. 33 and 34 at 100 and 1000 diameters respectively show a transcrystalline fatigue crack which occurred about $\frac{1}{2}$ in. from the

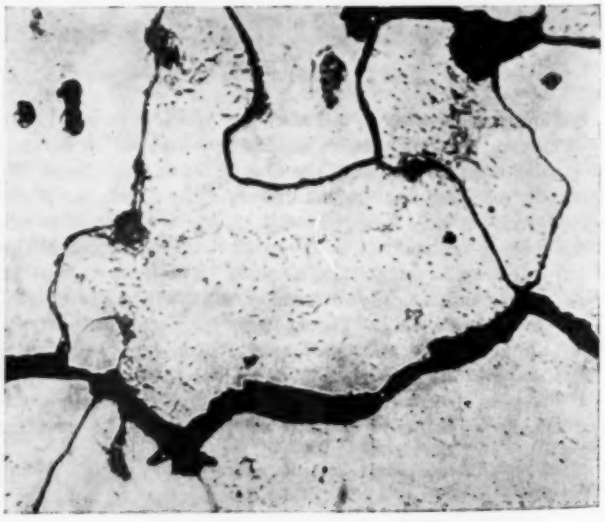

FIG. 40 SAME AS FIG. 39 BUT AT 1000 DIAMETERS

break. The probable mechanism of fatigue cracking is shown at 100 and 1000 diameters in photomicrographs Fig. 35 and 36. Cracking takes place in the ferrite in stages in a manner such that

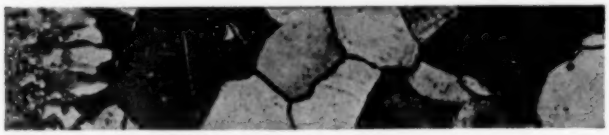

FIG. 41 INTERCRYSTALLINE CRACK IN IRON DUE TO OCCLUSION OF HYDROGEN (PHOTOMICROGRAPH BY PFEIL, PROCEEDINGS OF ROYAL SOCIETY, LONDON)

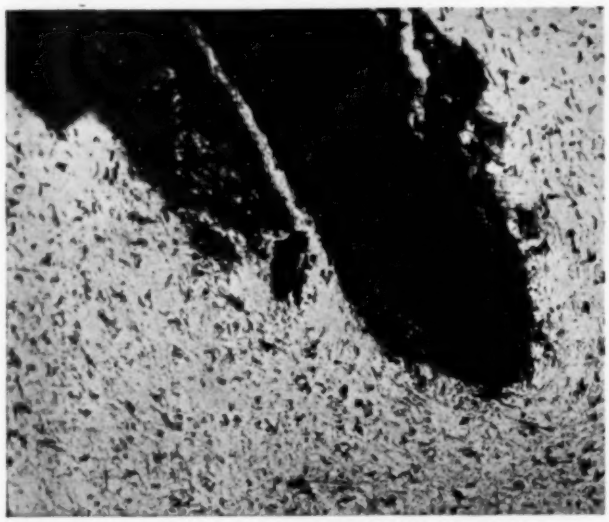

FIG. 42 CRACK IN BOILER TUBE DUE TO BENDING THE TOP PORTION IN REMOVING IT FROM TUBE SHEET—AT 100 DIAMETERS

the crack proceeds by short breaks varying in direction. Cracking does not proceed through the pearlite grains. The pearlite undoubtedly transmits the stresses to the next ferrite grain which will then crack in the usual manner. When actual fracture occurs the pearlite fails because it alone is bearing all the load.

Failure by Caustic Embrittlement. Intercrystalline cracking without deformation of the grains is sometimes brought on through the agency of sodium hydroxide. Photomicrographs Figs. 37 and 38 show at 100 and 1000 diameters an intercrystalline crack in a low-carbon steel tube. This tube had been in service in a vertical-tube caustic-soda evaporator for about one year.

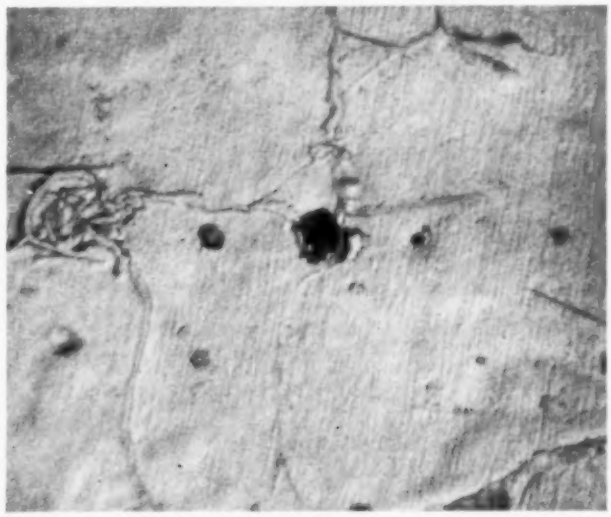

FIG. 44 INCLUSIONS IN BRITTLE BOILER TUBE—SHOWN AT 2000 DIAMETERS—THIS TUBE IS PROBABLY OF BESSEMER STEEL

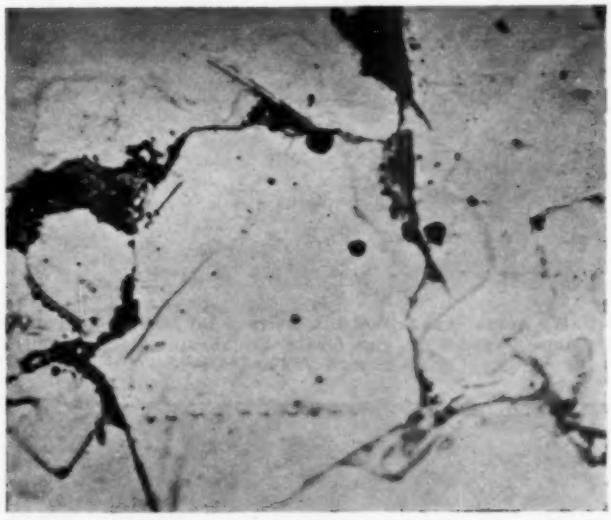

FIG. 45 TYPICAL STRUCTURE OF AGED BOILER TUBE AT 1000 DIAMETERS—NOTE THE DIRTY GRAIN BOUNDARIES AND THE UNEVEN SURFACE OF THE METAL

No stress other than the weight of the tube had been applied. The temperature of operation was 190 deg. fahr., and the crack shown occurred $1^1/_2$ in. below the tube sheet. At the time of removal the tube was exceedingly brittle. Its ductility returned upon being exposed to air for some time. This example is given because it represents a true case of caustic cracking.

Intercrystalline cracking and brittleness can also take place in phosphate solutions. Photomicrographs Figs. 39 and 40 show cracked portions of a wrought-iron hanger strap for a steam coil

from a tank used for dissolving sodium phosphate. This strap did not support any appreciable load. It failed after eight weeks operation at 140 deg. fahr. in a solution containing 55 per cent of commercial trisodium phosphate calculated on the basis of the anhydrous salt. After exposure to the air the original ductility returned to the uncracked portion of the metal.

Pfeil[28] reports similar cracking while cathodically pickling coarse-grained iron in sulphuric acid. Photomicrograph Fig. 41 is a reproduction of an intercrystalline crack produced by him in this manner. He concluded that occluded hydrogen weakens the grain boundaries.

Actual Boiler Metal Failures

Up to this point failures have been discussed which were due to known causes. Failed boiler materials from service are usually not quite so characteristically clean cut as to type and easy to identify as were these more or less ideal cases. A few actual cases falling under the above types will be given.

Methods of Investigation. A few purely routine considerations must be briefly explained because it is only in the light of the results of these that approach can be made to an interpretation of the metallographic study. Before attempting any serious analysis of a failed part, data should be secured regarding the duration and temperature of service, the probable stresses to which the piece was subjected, the manner in which failure manifested itself such as by leaking, cracking, or by complete rupture, and any other facts that might have any bearing on the case.

A chemical examination of boiler steels will show them to fall roughly within the following limits of composition:

Carbon.....	0.10 to 0.30 per cent
Manganese.....	0.30 to 0.60 per cent
Sulphur.....	under 0.050 per cent
Phosphorus.....	under 0.050 per cent
Silicon.....	0.01 to 0.10 per cent

Some boiler tubing has been analyzed and found to contain even less than 0.01 per cent of silicon.

A metallographic examination of sections etched with 4 per cent Nital will reveal the relative grain size, the distribution of the carbides, whether or not the metal has been annealed, condition of working, and the presence of inclusions. Boiler tubing and plate often contain inclusions which if well dispersed rarely cause failure. A Rosenhain etch will reveal the presence of segregations and other non-homogeneities. One must not be over-hasty in ascribing cracks or ruptures solely to the presence of non-homogeneities as revealed by this etch because a large number of boiler tubes which rendered many years of satisfactory service have been examined, and under the Rosenhain etch showed severe ghost lines, phosphorus segregations, and other non-homogeneities. Wrought iron and Bessemer steel have been used widely in the past with fair success, and these as is well known contain many inclusions.

A metallographic examination of the failed area itself will yield the most valuable information. Failure usually manifests itself first through the formation of a crack; as the cracked area increases in size complete rupture of the piece may ultimately take place. The appearance of the fracture and of the metal in its vicinity will vary with the cause.

A study of a large number of boiler-material failures has led to a grouping of fractures under two main headings determined by the metallographic appearance. These are failures accompanied by deformation of the crystals, and failures not accompanied by deformation of the crystals. The principal subclassifications which can be made will distinguish between transcrystalline and intercrystalline fractures.

There is another distinctive type of failure observed when a boiler tube explodes due to overheating the metal. Because of the temperatures involved and the drastic thermal changes to which the metal is subjected, the crystal structure is far from normal, and no data can be obtained regarding the trans- or intercrystalline nature of the failure.

Failure by Bending. In removing a boiler tube a tool was used so that one end of the tube was badly crimped. A cracked surface was noted. It was then desired to know whether these cracks were due to caustic embrittlement, a matter of great concern to the plant from which the tube came, or to other causes. Photomicrograph Fig. 42 shows at 100 diameters a section near one of the cracks. This represents more or less of a tension failure. The metal was bent in one direction, the fiber in the side shown in the picture was in tension. Elongated crystals and the absence of fine secondary cracking can be seen. Undoubtedly this tube was somewhat brittle.

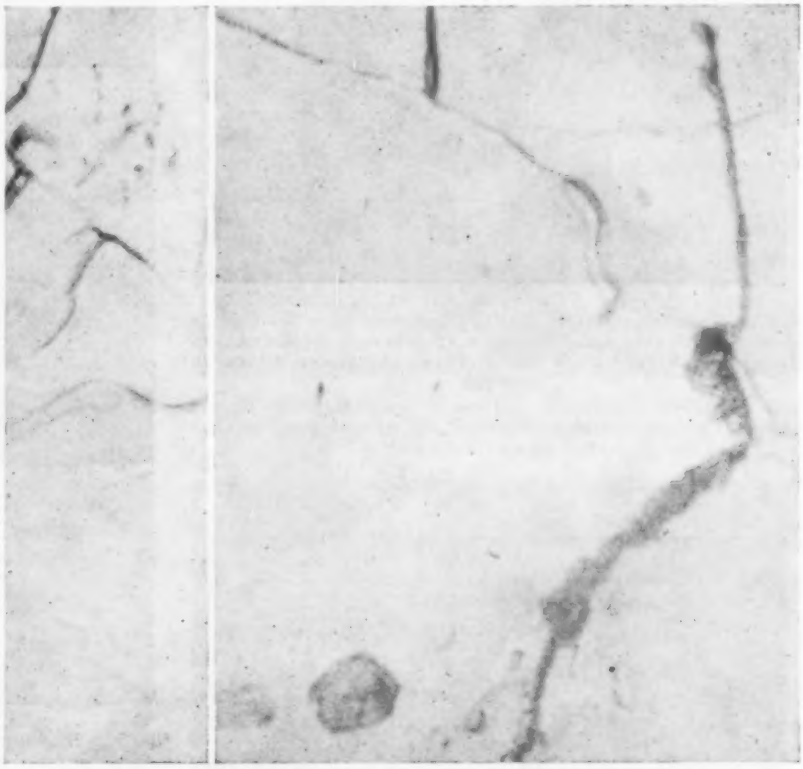

Fig. 52 Transcrystalline Cracks in Age-Embrittled Boiler Tube at 4000 Diameters

Failure by Impact and Aging. In striking, with a small hammer, the end of a boiler tube which had been in service from 1903 until 1928, pieces broke off which were so brittle that they fractured upon being dropped to the floor. Chemical analysis showed the presence of 0.087 per cent sulphur, indicating that it probably was of Bessemer steel. The presence of an exceedingly large number of inclusions is shown in photomicrograph Fig. 43 at 100 diameters and in photomicrograph Fig. 44 at 2000 diameters.

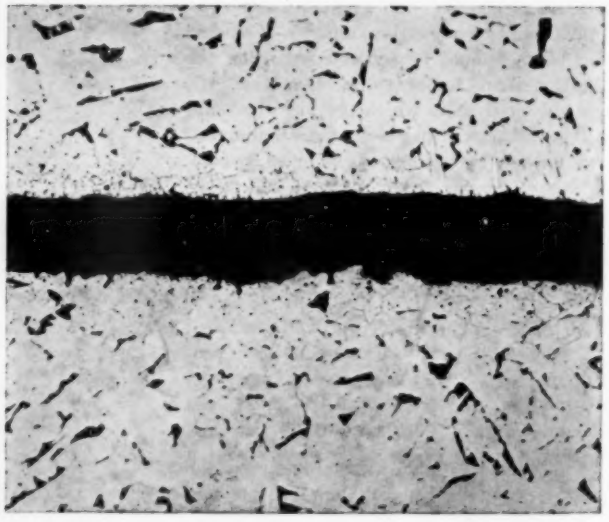

FIG. 56 FORGING LAP IN A BLOW-OFF PAD SHOWN AT 100 DIAMETERS

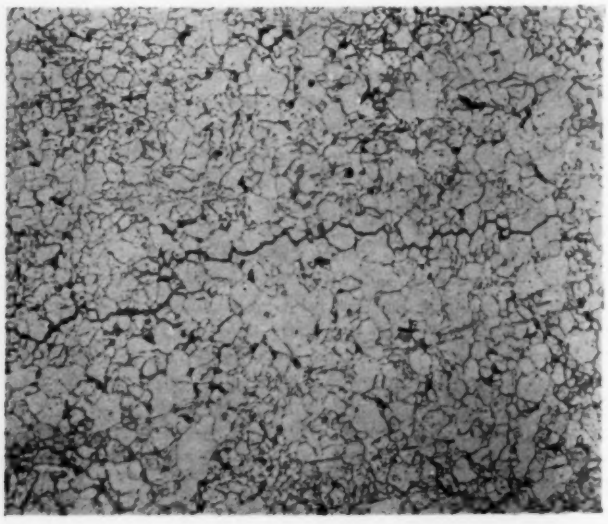

FIG. 57 CRACK IN TOP END OF BOILER TUBE AT 100 DIAMETERS

A study was made to determine the reason for the behavior of this metal. The metallographic appearance of this specimen was unusual. Referring back to photomicrograph Fig. 43 the grain boundaries can be seen to be wavy, indistinct, actually double in some cases. Photomicrograph Fig. 45 at 1000 diameters shows segregation of material at the boundaries. The first clue to the nature of the failure was gained by examination of the section shown at 1000 diameters in photomicrograph Fig. 46. In addition to all the peculiarities shown in the other illustrations, this

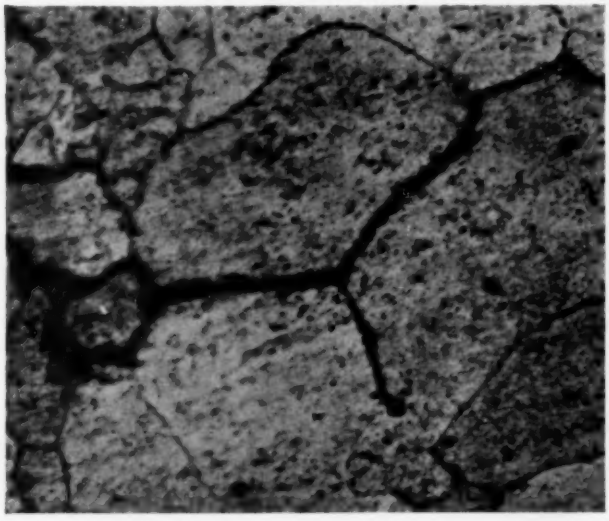

FIG. 58 SAME SECTION AS FIG. 57 BUT AT 1000 DIAMETERS SHOWING INTERCRYSTALLINE NATURE OF CRACK—THIS FAILURE WAS PROBABLY DUE TO CAUSTIC EMBRITTLEMENT

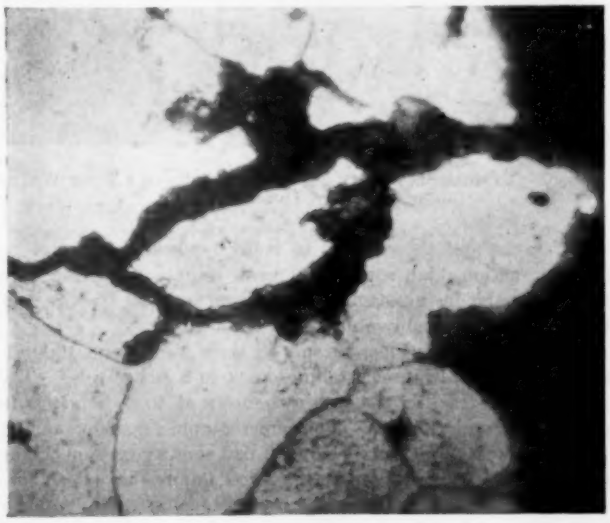

FIG. 59 INTERCRYSTALLINE CRACK DUE TO CAUSTIC EMBRITTLEMENT SHOWN AT 2000 DIAMETERS

section shows a series of fringes or thorns at the grain boundaries and presents an uneven surface giving the appearance of stamped impressions. This structure is identical with that of an impact failure shown in photomicrograph Fig. 30. This steel has undergone what is termed aging and has become embrittled through repeated heating and cooling. The original properties of an aged low-carbon steel can be restored by heating above the A_3 temperature. Photomicrographs Figs. 47 and 48 show a more normal structure after annealing at 1600 deg. fahr.

That this steel was brittle is shown in its manner of fracture. A ductile material will distort by gliding along slip planes; a brittle metal will crack along a plane of stress. Photomicrograph

FIG. 60 PHOTOMICROGRAPH AT 1000 DIAMETERS OF INTERCRYSTALLINE CORROSION IN THE PEARLITE CONSTITUENT IN A CRACKED BOILER BLOW-OFF PAD

FIG. 61 CRACKS IN A BOILER BLOW-OFF PAD AT 100 DIAMETERS—THIS TYPE OF CRACK IS FREQUENTLY MET—THE CRYSTAL STRUCTURE OF THE METAL AND WIDTH OF THE CRACK MAKE IT DIFFICULT TO DETERMINE WHETHER OR NOT IT IS DUE TO CAUSTIC EMBRITTLEMENT

Fig. 49 shows a single crystal which contains within its boundaries short cracks running in various directions. Higher magnifica-

tions reveal faint boundary lines as though this crystal had once been made up of several small ones and was therefore the result of a recrystallization process. Photomicrographs Figs. 50 and 51 at 2000 and 4000 diameters respectively show a crack running into or from a sulphide inclusion. It is very doubtful whether the presence of even this large number of inclusions contributed to the failure of the metal. Cracks appearing in the steel are transcrystalline and run through inclusions only if the inclusion happens to be in its path. This is shown at 4000 diameters in photomicrograph Fig. 52.

Two Failures by Stress and Corrosion. Some rivets taken from service were examined for possible cracking. Photomicrograph Fig. 53 shows at 100 diameters two cracks due to corrosion which occurred at the junction of the rivet head and shank. In the area

FIG. 62 ANOTHER CRACK FROM A BOILER BLOW-OFF PAD AT 100 DIAMETERS

of metal between the two large fissures a small transcrystalline crack proceeding through undeformed crystals can be seen. A similar appearance was presented by the rivet shown at 100 diameters in photomicrograph Fig. 54. In this case, however, the crack is filled with the products of corrosion. The Jevons modification of the Fry etch showed that cracking had occurred in the area of highest local stress. Corrosion not directed by stress will usually proceed uniformly rather than by penetrating the metal in the form of cracks. Stressed areas carry a different electrolytic potential than unstressed areas.

A boiler tube started to leak at a point about an inch below the tube sheet. Examination showed that the tool used to expand the tube in place had been inserted carelessly so that a gouge was cut on the inner surface of the tube. Corrosion started at that point and gradually proceeded through the tube until leakage occurred. Photomicrograph Fig. 55 at 100 diameters shows a section of the crack. The black area represents the crack; the dark gray, products of corrosion; and the remainder is naturally the steel.

Slag, Forging Shuts, and Seams. Another source of failures in boiler materials is due to slag inclusions, forging shuts, and seams. Failure can readily occur due to mechanical causes under these conditions. Such a failure is shown in photomicrograph Fig. 56 at 100 diameters. These types of failure are generally regular in direction.

FAILURE THROUGH INTERCRYSTALLINE CRACKING

Parr and Straub[17] have described a phenomenon in boiler materials which they identify as caustic embrittlement. An accurate description of the effect they produced in the laboratory would be intercrystalline cracking in steel due to local tensile stresses in excess of the elastic limit, and to contact with solutions of caustic soda whose concentrations are in excess of 100 grams per liter. In very carefully controlled experiments they showed that, if the above conditions were met, intercrystalline cracking would take place regardless of the quality or previous thermal treatment of the steel. They pointed out the similarity between

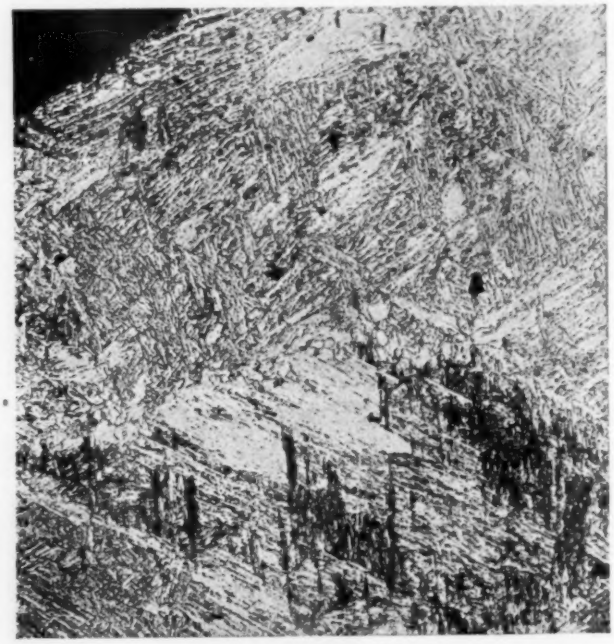

FIG. 63 TYPICAL SECTION AT 100 DIAMETERS FROM A TUBE WHICH BURST DUE TO OVERHEATING

these cracks and those found in boiler materials; that due to capillary action, high concentrations of sodium hydroxide were not improbable in the seams of the boilers, and that stresses near the rivets were probably quite high.

Photomicrographs Figs. 57 and 58 show at 100 and 1000 diameters a typical intercrystalline crack in a boiler tube. The course of the crack in the ferrite is shown at 4000 diameters in photomicrograph Fig. 59. Photomicrograph Fig. 60 taken at 1000 diameters of a cracked blow-off pad shows corrosion taking place in the pearlitic constituent. These failures have been considered due probably to caustic embrittlement. Many boiler failures, however, show cracks such as those presented at 100 diameters in photomicrographs Figs. 61 and 62 which were taken of a cracked blow-off pad. The nature of the failure is not clearly defined because of the peculiar grain structure, and because the cracking takes place both through and around the crystals.

FAILURE BY OVERHEATING AND BURSTING

An entirely different type of structure is exhibited by boiler tubes which have burst in an explosion. Sometimes material lodges in the tube and prevents the circulation of the water or scale formation permits overheating. As the temperature of the

tube increases the tensile strength of the metal diminishes. A point is reached where the pressure exerts stresses in excess of the yield point and failure takes place with explosive violence. Photomicrograph Fig. 63 shows the structure of the metal. It apparently had been heated above 1600 deg. fahr., and was quenched by the rush of steam around it.

Conclusion

The characteristic appearance of failures in boiler metals due to various common causes has been discussed. Bending, compression, tension, and impact according to the conditions described in this paper all produce fractures which are predominantly through the grain. Failure in such cases is accompanied by deformation of the crystals. Impact failures under some conditions may be produced with very little deformation. Fatigue cracks are always transcrystalline without deformation of the grain. Caustic embrittlement, as found in metal which has been in service in alkaline liquors, produces intercrystalline cracks. The actual mechanism of this phenomenon is not completely understood although it would seem that it is a result of the embrittling action which occluded hydrogen exerts upon the grain boundaries of iron. The causes of many actual failures of boiler material can be more or less satisfactorily traced by comparison with fractures produced in the laboratory.

Acknowledgments

This work was done at the suggestion and with the financial assistance of The Detroit Edison Company. Special acknowledgments are due C. F. Hirshfeld, Chief of Research of that company, and J. H. Walker, Assistant Chief of Research, for their friendly interest and their helpful and constructive suggestions.

Discussion

F. G. Straub.[35] In reading this most interesting paper one is impressed with the fact that much time must have been spent by the authors in preparing the material. They are to be congratulated upon their technique in preparing their specimens for micro-examination. The micrographs which they have shown illustrate the points they emphasize in an excellent manner.

This paper should help clear up the confusion which must have resulted from the publication of recent articles which have attempted to place the responsibility of most boiler-metal failures on corrosion fatigue. The authors show very clearly the different types of failure which result from stress, stress and corrosion, and so-called caustic embrittlement.

The writer is of course primarily interested in the intercrystalline cracking which they describe. The results of the work at the University of Illinois agree in almost every detail with the results of the work reported.

Some engineers have the impression that we ascribe all cases of boiler-metal failure to embrittlement caused by caustic. In fact we have, like the authors of this paper, found various types of failures brought about by vari-

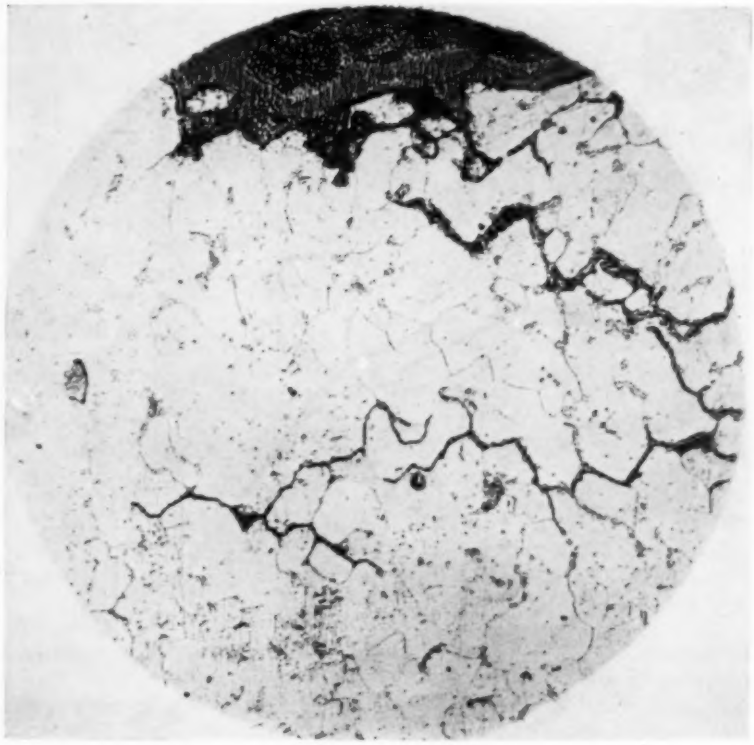

Fig. 64 Intercrystalline Cracks in Superheater Header. × 250

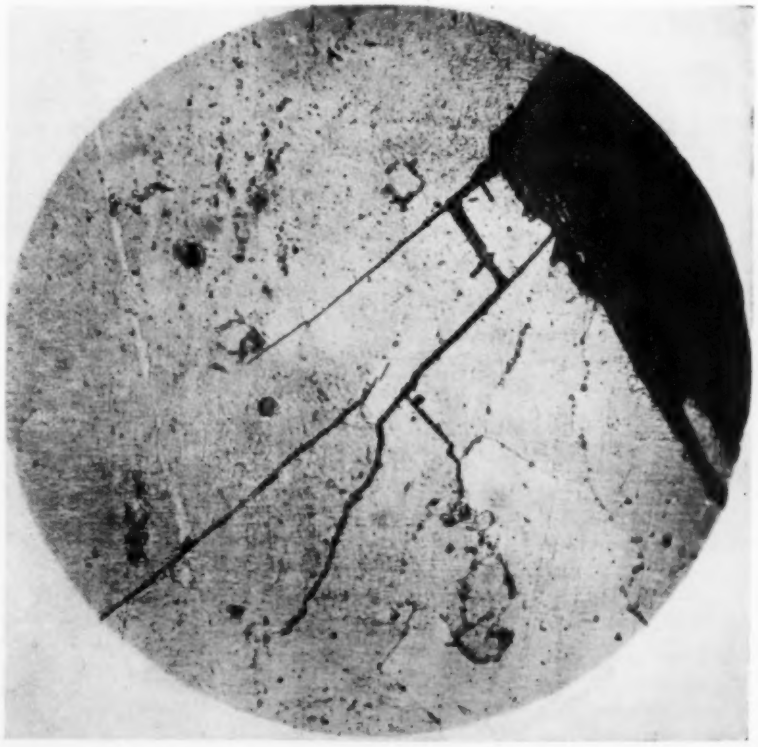

Fig. 65 Cracks in Same Header as Shown in Fig. 64, but Transcrystalline and Following Nitride Needles. × 250

[35] University of Illinois.

ous causes. The writer would like to discuss a few cases of failure which proved very interesting and almost misleading, and which illustrate that to arrive at definite conclusions as to causes one must make a thorough study of all contributing factors, in the same manner as the authors of this paper have done.

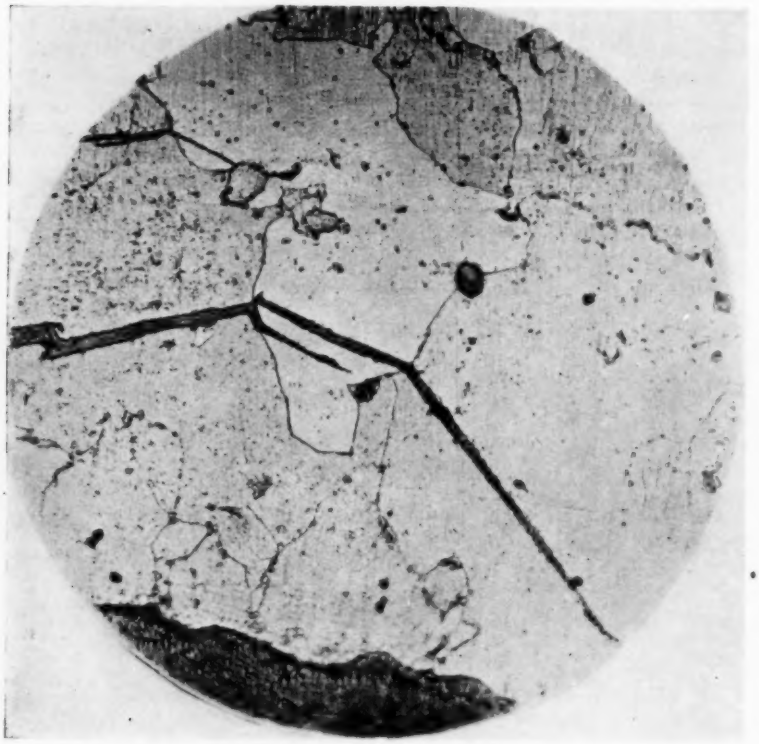

FIG. 66 CRACKS IN SAME HEADER AS SHOWN IN FIG. 64, BUT TRANSCRYSTALLINE AND FOLLOWING NITRIDE NEEDLES. × 250

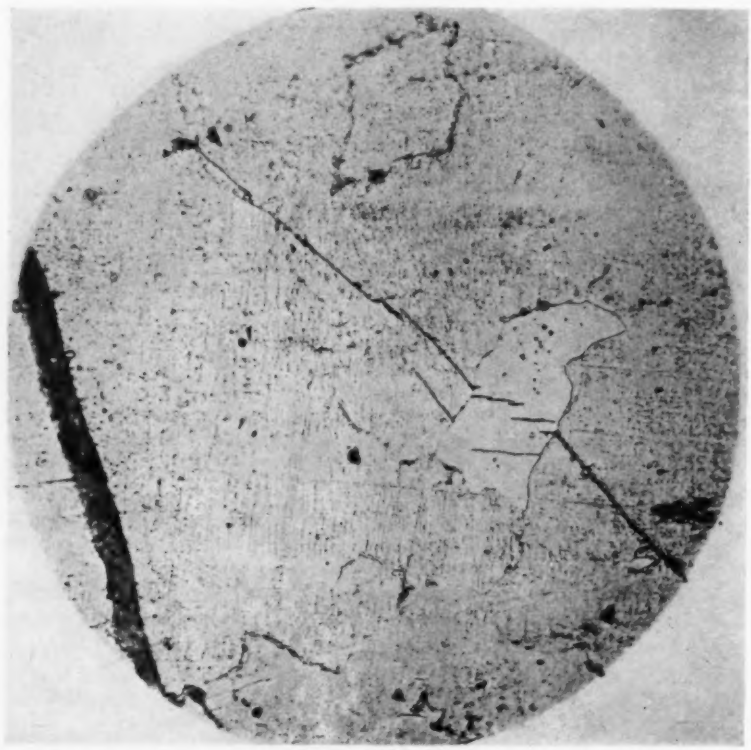

FIG. 67 CRACKS IN SAME HEADER AS SHOWN IN FIG. 64, BUT TRANSCRYSTALLINE AND FOLLOWING NITRIDE NEEDLES. × 250

In a large power plant using an older type of superheater, cracking was encountered in the superheater headers. The cracks were starting from the edge of the handholes. There had been evidence of high caustic concentration in the boilers and carryover to the superheaters. Microexamination of the polished specimen gave the typical intercrystalline crack shown in Fig. 64. The plant operators were ready to attribute their difficulty to caustic embrittlement. A more thorough study of the specimens cut from the cracked header indicated that caustic was not the cause of the cracking. The micrographs taken of these sections are shown in Figs. 64 to 67, inclusive. Further study showed that some of the rods supporting the header had broken, and the header without proper support was bending. The gases striking the metal were between 1200 and 1500 deg. fahr. The conditions of operation were such that this cracking could be readily explained on a basis of high temperature, stress, and high nitride.

The second case involved tube ends that were brittle and appeared to be laminated. The ends would break off. The fracture did not have a bright metallic luster. The tube could be separated into two layers running lengthwise of the tube. Microexamination of one of these tubes gave the result shown in Fig. 68. This indicates that the tubes were burned, apparently during manufacture.

The writer is extremely interested in the statement that the authors make relative to the fact that they have encountered typical intercrystalline cracking in steel which has been in contact with concentrated phosphate solutions. Our research has indicated that small amounts of phosphate tend to retard the embrittling action of caustic soda. It has been known that concentrated nitrate solutions produce this same type of cracking. We have found that small amounts of nitrate introduced in concentrated caustic solutions stop the action of the caustic.

H. C. DINGER.[36] The authors are to be congratulated upon this paper, which presents a mass of definite and useful information upon a very much discussed subject. In giving definite data as to the observed character of the cracks produced by definitely known causes much valuable information can be learned, and this information can then be used in investigation of actual cracks.

The paper, however, has not sufficiently considered the character of the cracks produced by cyclic stress accompanied by corrosion. This is the actual condition that is generally presented to the metal in the boiler. It also seems to be a fact that many if not most of the actual cracks in boilers show some evidence of both transcrystalline and intercrystalline cracking. The evidence presented by the authors seems to indicate that

[36] Captain, U. S. Navy, Officer in Charge, U. S. N. Experiment Station, Annapolis, Md. Mem. A.S.M.E.

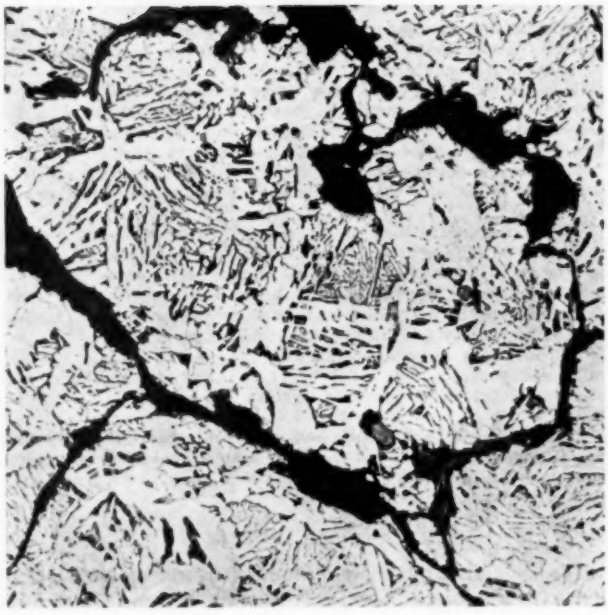

FIG. 68 MICROPHOTOGRAPH OF BURNED TUBE. × 100

true intercrystalline cracks are produced by stress in the presence of very high caustic concentration. In actual boilers these conditions are not produced either in the seams or elsewhere, but we do have variations of cyclic stress in the presence of variable corroding medium. We therefore have some kind of *corrosion fatigue* in all boilers, unless perhaps we could absolutely exclude oxygen from the water. There is some evidence that a caustic condition tends to accelerate the formation of intercrystalline cracks, but we also have many cracks partially intercrystalline where no caustic was present. We must then assume that corrosion tends to intercrystalline failure and stress to transcrystalline, or perhaps slow failure is pro-intercrystalline while rapid failure, due to higher stress, is more likely to be transcrystalline. The amount of oxygen and corroding salts present also, no doubt, accounts for variations.

The authors' deductions as to slippage, deformation, and final failure though crystal cracks present a logical picture of what may take place. This is in entire agreement with the phenomenon of corrosion fatigue. A real explanation of boiler cracks is really not possible unless the varying effects of corrosion accompanied by cyclic stress are con idered.

So-called "caustic embrittlement" appears to be but one of many variations of possible conditions. If we can keep the water in the least destructive condition (this is not yet fully known, but would seem to be deaerated water controlled at about nine pH), we can lessen the effect of corrosion. If we design our pressure parts to avoid stress concentration and cyclic stress as far as possible, we can lessen the destructive effect of cyclic stress. In view of the fact that neither of these can be very easily controlled where uncertainty exists, it is well to have an adequate margin of safety and in the design to consider that both corrosion and fatigue are likely to be present. One thing is fairly well established and it is that it is extremely desirable to keep the water away from the highly stressed metal of a riveted joint. Sealing of joints by inside calking or other means, such as by cements or lasting coatings, is extremely desirable. The coating of the water side of all joints by a durable protective film that will effectively keep the mixture of air and water away from the stressed surface of the metal ought to give some protection.

D. S. MCKINNEY AND MAX HECHT.[37] It may be considered that the contribution the authors have made to the literature on fractures in boiler metal will be of distinct benefit to workers closely associated with plant operation. The comparison of

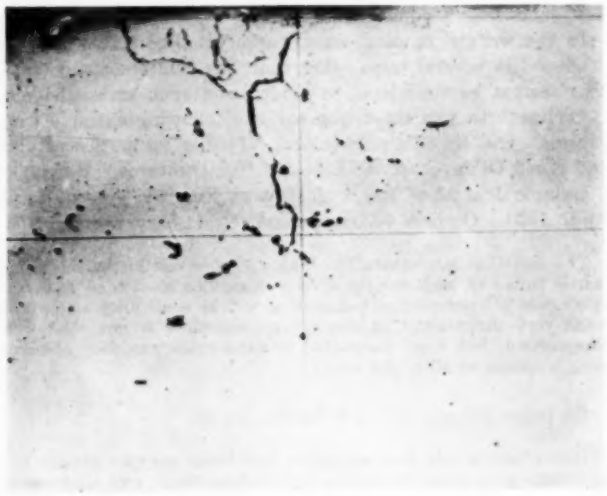

FIG. 69 SPECIMEN AS BURNT, PARTIALLY MELTED, AIR-COOLED, COLD-WORKED, UNETCHED. × 100

photomicrographs of boiler metal failures due to known causes with those found in boilers should produce more exact knowledge of the conditions accompanying boiler metal failure.

Under the heading of "Failures Through Intercrystalline Cracking," the authors refer to Figs. 57 to 62 inclusive. In the writers' opinion, Figs. 61 and 62 exhibit a structure characteristic of severe overheating.

In their own laboratory intercrystalline cracking has been pro-

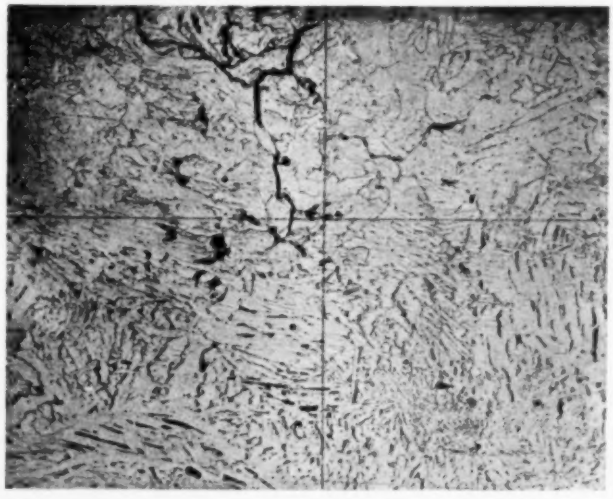

FIG. 70 SAME SPECIMEN, ETCHED WITH 4 PER CENT NITAL. × 100
(Cracks noted in Fig. 69 are intercrystalline.)

duced by abnormal heat-treating and cold-working new boiler metal (a rivet), carbon 0.2 per cent. The photomicrographs given in Figs. 69 and 70 show the cracks before and after etching.

The absence of evidence of overheating or cold-working cannot be taken as conclusive evidence that this abnormal treatment

[37] Duquesne Light Company.

has not been given to the steel, as these evidences may be removed by annealing. However, cracks once formed cannot be healed by annealing.

Freeman and Quick have shown that intercrystalline cracking is found in steel of varying carbon content, including Armco iron, exhibiting "secondary brittleness."

In the writers' opinion, since intercrystalline cracks may be produced in several ways other than "caustic embrittlement," they cannot be considered as evidence of such embrittlement.

Pertinent to this discussion are the following extracts from Freeman and Quick's publication, "Tensile Properties of Rail and Some Other Steels at Elevated Temperatures," Bureau of Standards Journal of Research, Report No. 164, Vol. 4, No. 4, April, 1930. On page 573, it is stated:

> The fact that intercrystalline failure is observed in the secondary brittle range of such widely diverse materials as Armco iron, rail steels, and a 1 per cent carbon steel as well as some alloy steels indicates very definitely that secondary brittleness is not related to composition, but must be related to some grain boundary phenomenon common to all of the steels.

On pages 590 and 591, it is further stated:

> It has been shown that secondary brittleness may be present in a relatively pure iron, rail steels, high-carbon steels, and alloy steels. The low ductility has been shown to be related apparently to a grain boundary condition of the steel as was indicated by the marked intercrystalline shattering found in specimens tested in the secondary brittle range. The cause then must be related to one or more of the following: some structural condition, an element, or nonmetallic inclusions which may be present in steels of widely varying composition. The influence of free cementite has been suggested. The fact that annealing below the Ac_1 transformation affects the degree of secondary brittleness indicates that it may be related to a constituent capable of solid solubility or precipitation at temperatures below the A_1 transformation.
>
> A study has been made of the tensile properties of rail steels and some other steels at elevated temperatures. Special study was made of the tensile properties in the approximate temperature range of 400 to 700 deg. cent. It has been found that the ductility of all rail steels, as measured by percentage elongation, and reduction of area, decreased with increase in temperature over a portion of this temperature range. In some instances the decrease in ductility is very marked, the elongation and reduction of area values becoming less between approximately 500 to 650 deg. cent. than at normal atmospheric temperatures. The same phenomena have been found to exist in Armco iron, a 1 per cent carbon steel, and some alloy steels. This range of temperature in which low ductility becomes manifest has been termed the "secondary brittle" range to distinguish it from the well-known "blue brittle" range occurring at 200 to 300 deg. cent. and the "hot-short" range which is usually associated with the A_3 transformation and high sulphur content. The phenomenon has been termed "secondary brittleness."
>
> The degree of secondary brittleness varies markedly between individual heats, and the temperature of the maximum effect also varies.
>
> The data indicate that the secondary brittleness is not confined to individual rails or ingots, but is apparently a property of the heat as a whole. It has been shown that the degree of secondary brittleness is decreased by annealing at a temperature (700 deg. cent.) slightly below the Ac_1 transformation as well as at the usual annealing temperature above the Ac_3 transformation.
>
> The fact that secondary brittleness is found in other steels than rail steels suggests that other types of unexplained failures, such as internal cracks in ingots or forgings, may be due to secondary brittleness.
>
> The data indicate that equalization of temperature and slow cooling of rails and other steel shapes through their secondary brittle range are desirable procedures to follow in order to prevent formation of shatter cracks.

Authors' Closure

The point raised by Professor Straub on intercrystalline cracking due to overheating or burning is very interesting. Overheating of low-carbon steel, however, cannot be brought about at the temperature of the furnace gases, given as 1200 to 1500 deg. fahr. A temperature of between 2200 and 2400 deg. fahr. is necessary.

The authors were not familiar with "secondary brittleness" which Mr. Hecht mentioned, and have found his comments very interesting.

The authors appreciate the importance of corrosion fatigue as a probable mechanism of boiler cracking, as Captain Dinger points out. Before submitting the paper, they communicated with Mr. D. J. McAdam, Jr., who has done a great deal of work in this line. The authors requested a photomicrograph on a specimen having an intercrystalline crack due to corrosion fatigue. His reply was that up to the present he had no photomicrographs or specimens with intercrystalline cracks due to corrosion fatigue. For this reason the authors did not discuss this phase of failure at greater length.

FSP-53-17

Frictional Resistance and Flexibility of Seamless-Tube Fittings Used in Pipe Welding

By SABIN CROCKER[1] and ARTHUR McCUTCHAN,[2] DETROIT, MICH.

The trend toward the use of welded piping has led to the development of seamless-tube fittings. These fittings are a decided departure from both the cast fittings and long-radius pipe bends heretofore used, and their introduction has occasioned considerable speculation as to their relative merits and correct application. This paper is confined to a discussion of: (a) the relative friction loss in elbows and bends of different radii, and (b) the relative flexibility of pipe lines made up with long-radius bends as distinguished from cast fittings and from seamless-tube fittings having a radius of $1^1/_2$ pipe diameters. The authors have compiled and analyzed the available data on friction loss in elbows and bends, and present a detailed comparison of the flexibility of piping made up with seamless-tube fittings, long-radius bends, and cast fittings. Seamless-tube fittings (R/d — $1^1/_2$) are found to compare to advantage with the older types of construction in both phases considered.

THE application of fusion welding to the fabrication and erection of steel pipe lines has progressed rapidly in recent years both in the extent of use and in new types of construction made possible thereby. A decided improvement in welded construction has been effected through the development of ready-made elbows and returns of a radius comparable to long-radius cast fittings and forged from seamless tubing. For convenience these will be referred to in this paper as seamless-tube fittings.[3] Such fittings are made at the present time in sizes from 1 in. to 18 in., inclusive, in standard iron-pipe size, as shown in Fig. 1, and from sizes $1^1/_2$ in. to 12 in., inclusive, in extra strong. The three standard types, i.e., 45- and 90-deg. ells and the 180-deg. returns, are made, and all fittings are scarfed 45 deg. to facilitate their application. The usual center-line radius of such fittings is $1^1/_2$ internal pipe diameters, although other radii can be obtained.

S. CROCKER

A. McCUTCHAN

Before proceeding with a presentation of the friction loss and flexibility data which constitute the principal subjects of this paper,[4] a few photographs will be introduced to illustrate how seamless-tube fittings are applied in the construction of welded pipe lines. They are adapted readily to the fabrication of branch connections equivalent to tees and the like, as shown in Fig. 3. Where flanges are required, the seamless-tube fitting can be welded on, as shown in Fig. 4(*a*), which compares to advantage with the equivalent piece built up with a screwed elbow and screwed flange, Fig. 4(*b*).

Where welded construction is used, seamless-tube fittings have a decided advantage over the mitered square-corner job made in the field as regards strength, reduced friction loss, and appearance. Typical examples of mitered elbows are shown for comparison with a seamless-tube elbow assembly in Fig. 5. Examination of Fig. 5 indicates that decidedly less field labor is required in cutting and welding in the case of the seamless-tube elbow.

That the assembled product made up with seamless-tube fittings makes a good-looking job and provides easy turns for fluid flow is illustrated in Figs. 6 and 7. The noticeable absence of flanges adds to the appearance of the piping ensemble, and has a decided advantage in the application of covering. The general effect is entirely different from anything that can be obtained with mitered elbows, and should do much toward developing a preference for welding over older types of construction.

It is the purpose of this paper to discuss in some detail the use of seamless-tube fittings from a piping-design standpoint, comparing them with mitered fittings, cast fittings, and long-

radius pipe bends as regards pressure drop and flexibility. In the latter connection a comparison will be made of the elastic properties of piping made up with long-radius pipe bends as distinguished from seamless-tube fittings having a radius of $1^1/_2$ pipe diameters.

I—PRESSURE DROP IN ELBOWS AND BENDS

A misconception is more or less prevalent to the effect that short-radius bends and fittings cause appreciably greater pressure drop than do long-radius bends. This idea is not borne out by published results, provided the mean radius of curvature is from $1^1/_2$ to 2 times the inside pipe diameter. More data on the frictional resistance in bends are available for air and water than for other fluids. Some of the leading references on this subject are quoted in succeeding paragraphs.

Air. Fig. 8, reproduced from "Fan Engineering" of the Buffalo Forge Co., is based on data presented in a paper by Frank L. Busey on "Loss of Pressure Due to Elbows in the Transmission of Air Through Pipes or Ducts," A.S.H. and V.E. Transactions 1913, page 336. The pressure drop in percentage of a velocity head is given for elbows of different radii, the center-line radius being expressed in percentage of the pipe diameter. It is evident from this diagram that very good results are obtained with $R/d = 1^1/_2$, and that almost nothing is to be gained by making R/d greater than 2.

Further data on the flow of air through elbows of different radii are given in an article by William D. Edwards entitled "Pressure Losses in Air Ducts," published in *The Heating and Ventilating Magazine*, Feb., 1928, page 69. Fig. 9, which is reproduced from that article, shows the equivalent resistance of different-radius elbows and bends expressed as the product of a bend constant and pipe diameter. The bend constants serve as indices of the pressure drop through each type of bend, and are plotted in Fig. 10 as Resistance Factor vs. Mean Radius of Bend. Inspection of Fig. 10 indicates that here again no appreciable reduction in pressure drop is shown for a mean radius of bend greater than $1^1/_2$ times the inside pipe diameter. In this instance the nearest approach to a mitered elbow is given a friction loss of between 11 and 12 times that of a bend having a radius of $1^1/_2$ pipe diameters.

Water. That similar relations of pressure drop to bend radius exist for other fluids is shown by the curves of Fig. 11 which give fractional velocity heads lost in screwed elbows and in water-pipe bends of different radii. These curves were plotted from data taken from several sources[a] as indicated. Deduction has been made in each case for the friction loss which would have occurred for a corresponding length of travel through straight pipe, so that the results represent loss which is directly chargeable to the type of bend or fitting. The curves show a rapid decrease in elbow friction as R/d increases from less than one until it reaches $1^1/_2$ or 2. For values of from 2 to 4 the decrease in elbow friction diminishes slightly, and for values of R/d above 5, with the exception of the Weisbach curve, there is a rapid increase in bend friction. A similar tendency to increase at values of R/d greater than $2^1/_2$ was observed in large-diameter pipes by Williams, Hubbel, and Fenkell,[6] who found a point of minimum friction at R/d equal to $2^1/_2$. For values of R/d exceeding 5 or 6 several of these investigators observed fluctuating friction losses which did not appear to bear a definite relation to bend radius. This portion of Fig. 11 has been drawn in as smooth curves which the authors believe should represent average results. The authors of the papers from which these data were taken attributed the increase in friction loss at values of R/d above 4 or 5, to the greater length of pipe travel over which flow disturbance persisted, acting to counterbalance the lesser degree of disturbance produced in longer-radius bends. Or, in other words, they took the view that a long-radius bend tends to maintain the disturbance and attendant high frictional loss over a greater length of travel than does a short-radius bend, hence producing a greater total loss although the loss per unit length of travel is not so great. This fits in with the theory that elbow or bend loss is caused in part by increased turbulence of flow in the bend and beyond, as well as by shock resistance to change in direction. In short-radius fittings or 90-deg. mitered elbows, the predominating loss is that due to shock, while in long-radius bends, where the change in direction is more gradual, the loss is due principally to increased friction. The foregoing leads to the conclusion that medium-radius bends of smooth curvature and full cross-section are preferable from a pressure-drop standpoint to either mitered elbows or long-radius bends.

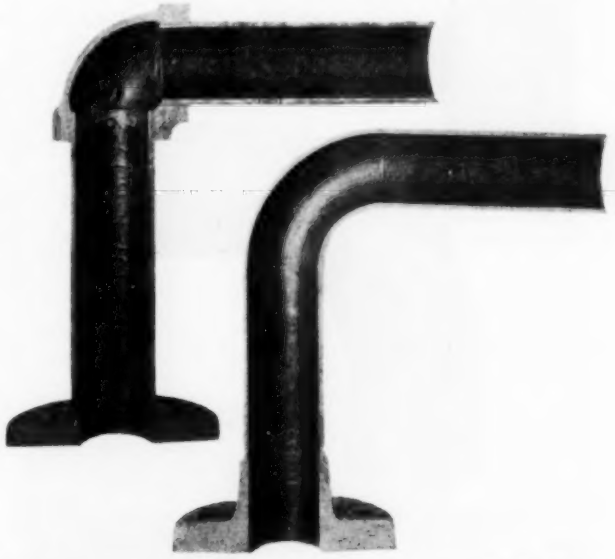

FIG. 4(*a*) FLANGED ASSEMBLY MADE WITH SEAMLESS-TUBE ELBOW AND WELDING NECK FLANGE

FIG. 4(*b*) FLANGED ASSEMBLY MADE WITH SCREWED ELBOW AND SCREWED FLANGE

It will be noted that three of the curves plotted in Fig. 11 refer to a flow velocity of 5 ft. per sec. These writers reported similar observations at other flow velocities ranging from 2 to 15 ft. per sec. in the same and other sizes of pipes, the general shape of the curves being similar, although the fractional velocity heads lost in bend friction varied with the velocity and pipe size. It seems reasonable to suppose that with sufficient data available it would be possible to formulate an equation involving radius of curvature and diameter of pipe, and velocity, density, and viscosity of the fluid, which would be more widely

applicable to the flow of water and other fluids in bends.[7] The curves presented in Fig. 11 are offered merely as typical of conditions in bends of different curvature with a view to illustrating the characteristic tendency for variance in pressure drop with R/d.

Other Fluids. The above data apply to the flow of air and water as noted. The authors have been unable to locate any results of equivalent tests covering the flow of steam and other fluids through bends of different radii, but it is reasonable to

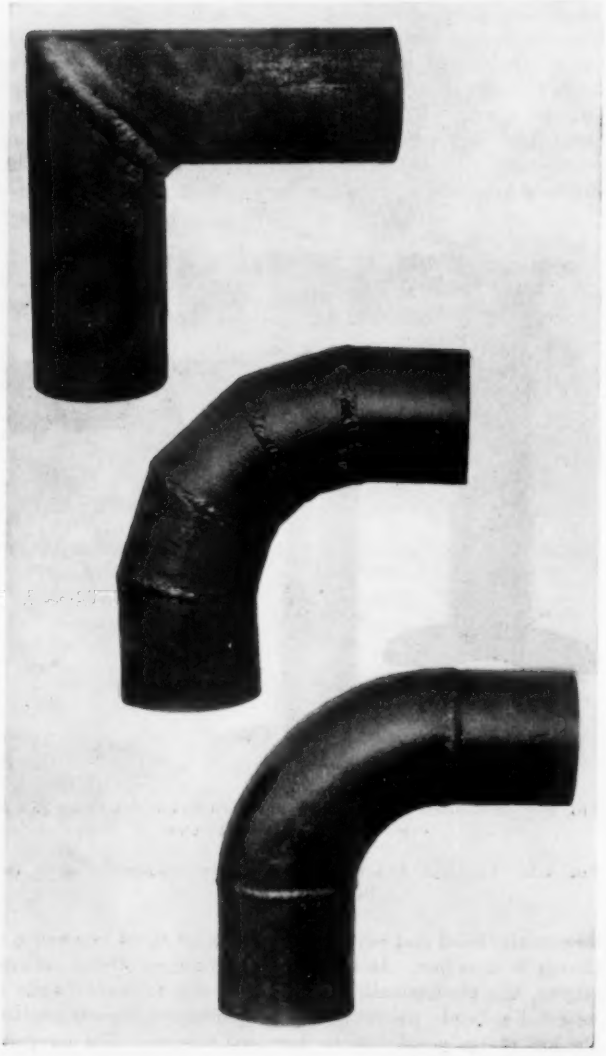

FIG. 5 COMPARISON OF TWO TYPES OF MITERED ELBOWS WITH A SEAMLESS-TUBE ELBOW

assume that such fluids exhibit similar characteristics. In an article by M. Hottinger in *Gesundheits-Ingenieur*, vol. 51, 1928, page 723, dealing with the flow of water through bends and fittings, the following statement is made: "The tests made in the Laboratory for Heating and Ventilating at the Polytechnic Institute, Berlin, concerning pressure losses in different elements

[7] See "Piping Handbook" (McGraw-Hill Book Co., Inc.), by Walker and Crocker, pp. 84 to 99, for description of a rational formula applying to the flow of fluids in general. The authors believe it would be possible to introduce the effect of curvature into such formulas, thus obtaining a widely applicable set-up for dealing with bend friction.

FIG. 6 WELDED PIPE CONSTRUCTION IN A BUILDING, USING TWO SEAMLESS-TUBE ELBOWS

FIG. 7 WELDED PIPE CONSTRUCTION IN A TUNNEL, USING SEAMLESS-TUBE ELBOWS

of a distributing system, gave results showing that the coefficients of resistance are the same for pipes carrying water (cold or hot)[8] and steam of low or high pressure. (See Bulletin No. 5–1913 of this Laboratory.) Therefore my experiments on bends and fittings were made only with cold water from 48 to 54 deg. fahr." While the above statement is somewhat broad

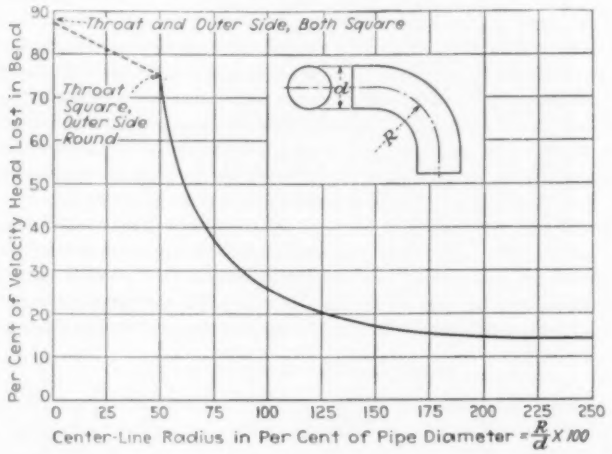

FIG. 8 HEAD LOST IN 90-DEG. BENDS CARRYING AIR

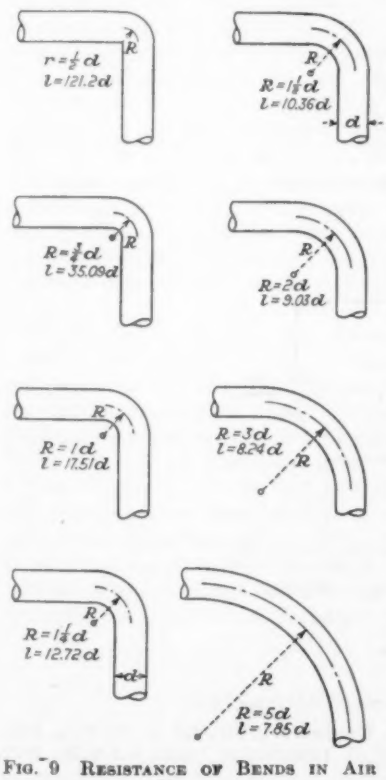

FIG. 9 RESISTANCE OF BENDS IN AIR PIPING

(l = equivalent length of straight pipe expressed in diameters.)

to accept literally, it does tend to support the idea that the relation of bend friction to R/d for steam would plot into a shape similar to those given in Fig. 11 for water.

RADII OF AMERICAN STANDARD CAST-IRON AND STEEL ELBOWS

In view of the relatively high frictional resistance observed in elbows where R/d is less than $1^1/_2$ it is of interest to note the approximate values of this ratio for different classes of American Standard screwed and flanged elbows set down in Table 1. These values were computed on the assumptions that (*a*) the bore of the fitting agrees with the nominal size up to 12 in., and with the corresponding pipe bore for sizes 14 in. and larger; (*b*) the curvature is a circle whose center is determined by lines passing through the back of the flange or through the back of the band in the case of screwed fittings. While these assumptions are not exact in all cases, it is deemed that they approximate actual conditions well enough for the present comparison, as these details will vary to some extent with different manufacturers. Examination of Table 1 indicates that all the screwed fittings lie in the high-pressure-drop range of R/d; that standard

[8] These tests were made at temperatures ranging from 59 to 194 deg. fahr.

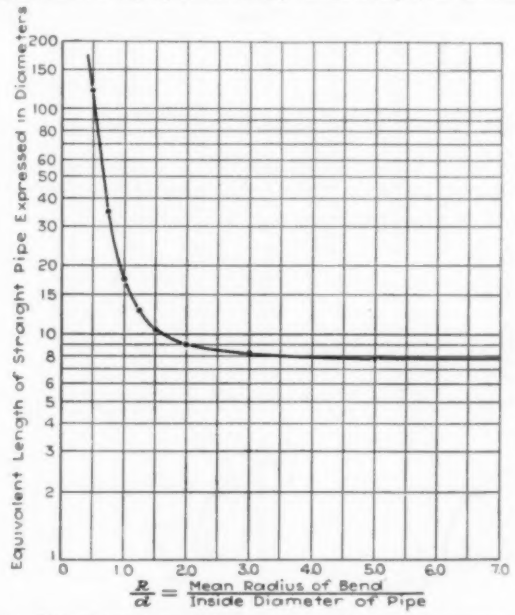

FIG. 10 RESISTANCE OF BENDS IN AIR PIPING—PLOTTED FROM DATA IN FIG. 9

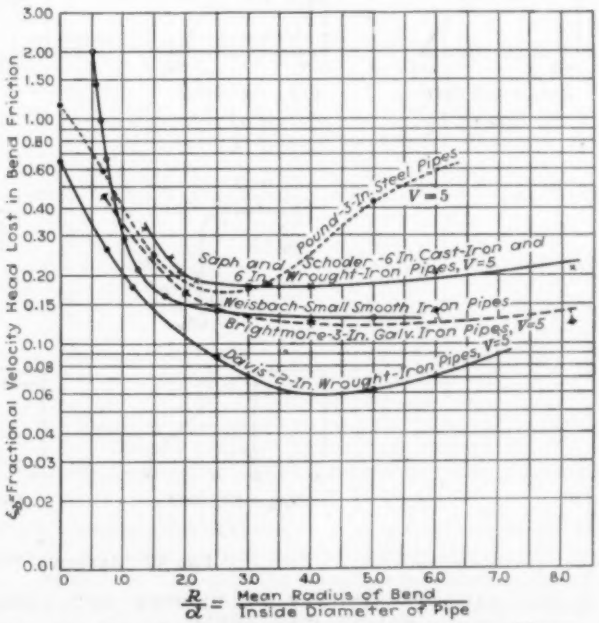

FIG. 11 HEAD LOST IN 90-DEG. BENDS CARRYING WATER

($h_b = \epsilon_b V^2/2g$, where h_b = head lost, ft. of water; ϵ_b = fractional velocity head lost in bend friction above loss in corresponding length of straight pipe; V = water velocity, ft. per sec.; and g = 32.2 ft. per sec. per sec.)

flanged fittings for pressures up to 600 lb. fall in the low- or moderate-pressure-drop range for sizes below 6 in. and in the high-pressure-drop range for larger sizes; that long-radius flanged fittings come almost entirely in the low- and moderate-pressure-drop range. These observations are of interest for comparison with seamless-tube fittings having a uniform R/d ratio of $1^1/_2$, which gives a consistent pressure-drop relation approaching the flat region of the curves.

[1] Approximate values for R/d where R is mean radius of 90-deg. elbow and d is bore of fitting.

593 of the paper by Crocker and Sanford on "Elasticity of Pipe Bends," Trans. A.S.M.E., 1922. At that time the effect of flattening in the circular cross-section of a curved pipe during flexure was not as well understood as at present, and no attempt was made to take it into account in that comparison. The present investigation shows that such flattening of curved pipes during flexure has a decided effect on a comparison of this kind which cannot be ignored in computing either reactions or stresses.

A number of references are available for those who wish to familiarize themselves with the theory of flattening in the circular cross-section of a curved pipe during flexure.[9]

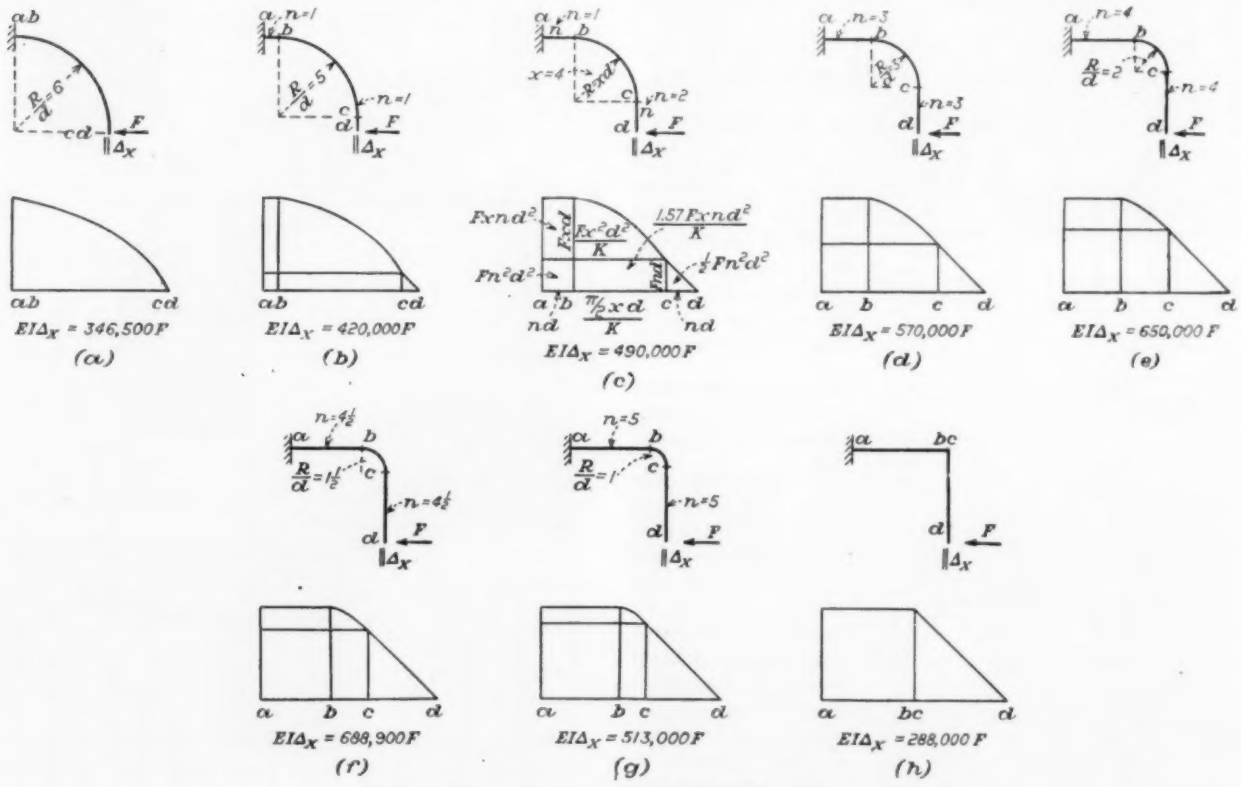

FIG. 12 RELATIVE FLEXIBILITY OF 90-DEG. TURNS

II—RELATIVE FLEXIBILITY OF ELBOWS AND LONG-RADIUS PIPE BENDS

In comparing the merits of different piping layouts applicable to any given job, question frequently is raised as to whether long-radius pipe bends or so-called "square bends" give the greater flexibility. In making such a comparison it is necessary to consider both major phases of flexibility, i.e. (*a*) the relative reactions set up at anchor points; and (*b*) the maximum stress produced at any point in the bend or pipe line. The maximum bending moment produced at any joint also is of interest, since the amount of bending moment obtaining has a bearing on the probability of keeping a joint tight. A comparison of reactions and stresses for four simple types of bends was made on page

e "Piping Handbook," by Walker and Crocker, McGraw-Hill Book Co., Inc., p. 550.

This theory has been well established by rigorous mathematical analysis and extensive tests on actual pipe bends. No derivation of this relation is included here since it is adequately covered in the references listed below. The terms and symbols used in applying the theory in this paper are in agreement with those given in reference 9e, and are defined for convenience in Appendix No. 3.

Several common forms of long-radius pipe bends have been selected as examples for comparison with their equivalent counterparts of the "square bend" variety as made up with seamless-tube fittings ($R/d = 1^1/_2$), American Standard flanged steel fittings and mitered elbows. Enough examples have been worked out to afford some degree of comparison and to indicate how the methods can be applied to other cases. Solution by the area-moment method described in the "Piping Handbook" by Walker and Crocker has been adopted as the one most universally applicable to problems of this sort. Complicated bends and pipe lines in three-dimensional space can be solved by area-moments, although such problems are too complicated for the successful application of analytical solutions.

Flexibility of 90-Deg. Turns

Elements Considered. The fundamental relations between displacement, reaction, and stress obtaining with a simple quarter-bend or 90-deg. turn are the basis of flexibility computations for practically all cases involving curved pipe. It is convenient, therefore, to take up first the case of a quarter-bend anchored at one end and having a force applied at the other end perpendicular to the axis of the pipe and lying in the plane of the bend as shown in Fig. 12. Ten-inch standard-weight pipe has been chosen for this comparison, using as the basis a quarter-bend having a radius of 6 nominal pipe diameters ($R/d = 6$). With this quarter-bend are compared other 90-deg. turns consisting of shorter-radius bends and fittings having sufficient tangent length on each end to give the same center-to-face dimension in each case. The other turns considered are made up with a seamless-tube fitting ($R/d = 1^1/_2$), a 250-lb. American Standard flanged steel elbow ($R/d = 1$), and a 90-deg. miter elbow.

Relation Between Deflection and Force. The relation between deflection and force is obtained by means of the area-moment diagrams shown in connection with Fig. 12. The general bending-moment diagram for a single force acting in the plane of the bend on a quarter-bend with tangents at each end is shown in Fig. 12(c). This diagram involves elements treated as cases II, III, V, and VII of the "Piping Handbook" (reference 9e). The rotations of the elements due to force F acting on the free end of the tangent length of pipe, Fig. 12(c), are represented by the following equations which are simply the areas of the bending-moment diagram to the left of each point indicated. (See Appendix No. 3 for definition of symbols.)

$$\psi_b = (F/EI)\ (xnd^2 + n^2d^2) \qquad \text{clockwise}$$

$$\psi_c = \psi_b + F\left(\frac{x^2d^2}{KEI} + \frac{1.57xnd^2}{KEI}\right) \qquad \text{clockwise}$$

In which $x = \dfrac{R}{d} = \dfrac{\text{mean radius of bend in inches}}{\text{nominal diameter of pipe in inches}}$

$n = \dfrac{l}{d} = \dfrac{\text{length of tangents in inches}}{\text{nominal diameter of pipe in inches}}$

K = rigidity multiplication factor which takes flattening of the cross-section of a curved pipe into account.

The deflections in the direction in which the force acts of the several parts of the bend are given by

$$EI\,\Delta x_c = \Sigma\psi_b xd \qquad \text{left}$$

$$\psi_F\,0.7854R = \frac{Fx^2d^2}{K}\,0.7854xd \qquad \text{left}$$

$$\psi_M 0.637\,R = \frac{1.57Fxnd^2}{K}\,0.637xd \qquad \text{left}$$

$$EI\,\Delta x_d = \Sigma\psi_c nd \qquad \text{left}$$

$$\psi_F{}^2/_3 l = {}^1/_2 Fn^2d^2/_3 nd \qquad \text{left}$$

90-Deg. Bend ($R/d = 6$). Where the radius of the bend is 6 times the diameter of the pipe ($R/d = 6$), the center-to-face dimension was chosen so that the force acts directly on the bend

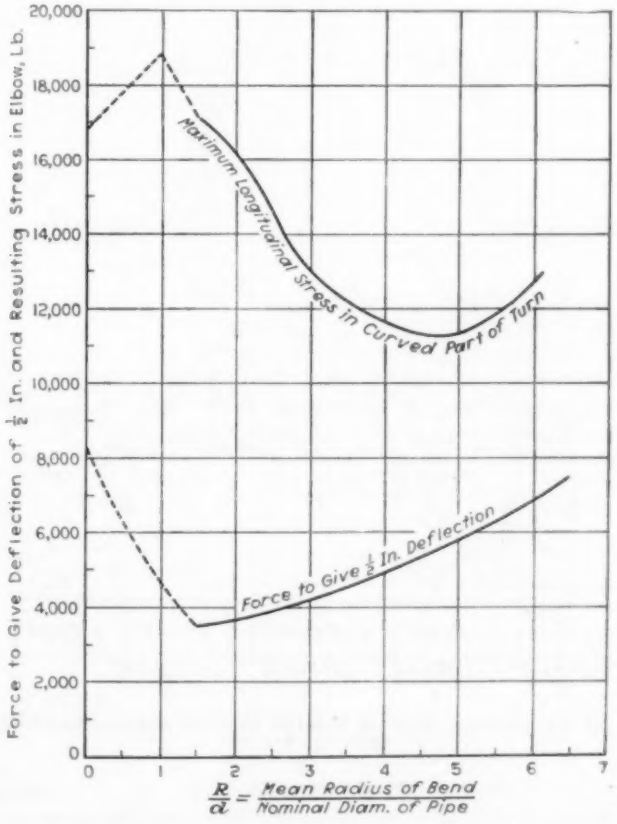

Fig. 13 Relative Flexibility of 90-Deg. Turns Made With Various Types of Fittings and Bends

[10-in. standard-weight pipe; center-to-face length = 60 in. in each case (Fig. 12).]

with no tangent lengths, hence $n = 0$ and the expression for rotation at b drops out and that for rotation at c simplifies to $\psi_c = Fx^2d^2/KEI$. Likewise the expression for deflection reduces to $EI\,\Delta x_c = (Fx^2d^2/K)\ (0.7854xd)$. Hence substituting values for x, d, and K, the relation between force and deflection for a

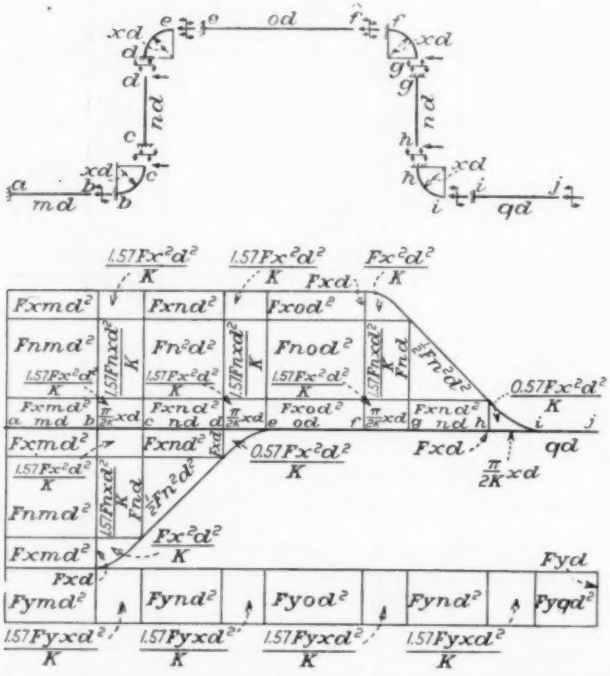

FIG. 15 GENERAL BENDING-MOMENT DIAGRAM FOR SQUARE BEND SHOWN IN FIG. 14

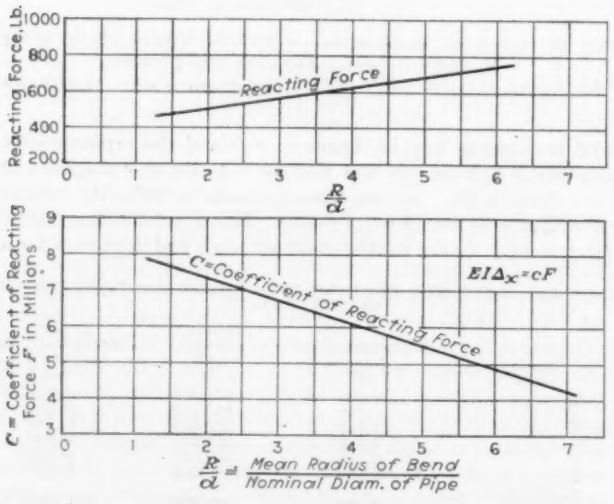

FIG. 16 RELATIVE FLEXIBILITY OF SQUARE BEND (FIG. 14) WITH ARCS OF DIFFERENT RADII

90-deg. bend acted on by a force at the end in the plane of the bend is found. $x = 6$, $d = 10$, $h = tR/r^2 = 0.365 \times 60/29.96 = 0.81$, $K = 0.49$ (Fig. 20).

$$EI\,\Delta_{Xc} = F\,\frac{(36 \times 100)}{0.49}\,(0.7854 \times 6 \times 10) = 346{,}500\,F$$

90-Deg.-Turn Seamless-Tube Fitting. For a seamless-tube fitting ($R/d = 1\frac{1}{2}$) having the same center-to-face dimensions as the bend formed to a radius of 6 pipe diameters, the relation determined between force and deflection is[10]

$$EI\,\Delta_X = 688{,}900\,F$$

90-Deg.-Turn 250-Lb. Flanged Steel Elbow. In the case of the 250-lb. American Standard flanged steel elbow ($R/d = 1$), the greater stiffness of the heavier wall of the fitting must be taken into account. This is done by dividing the length of the abscissa of the diagram representing the elbow by the ratio of the moments of inertia of the cross-section of the elbow and of the pipe comprising the balance of the turn.

The relation between deflection in the direction of the force F and the force acting at the end of the tangent for a turn involving a 250-lb. 10-in. flanged elbow, Fig. 12(*g*), is therefore

$$EI\,\Delta_X = 513{,}000\,F$$

90-Deg.-Turn Miter Elbow. The relation between deflection and force, Fig. 12(*h*), for a miter elbow is

$$EI\,\Delta_X = 288{,}000\,F$$

The relative flexibility of these several types of 90-deg. turns is shown by the equations given in Fig. 12. The greater the value of the coefficient of F, the greater the flexibility. This result is illustrated more effectively by assuming that the free end of each type of turn is displaced an equal amount by the application of a force as indicated. If a displacement of $\frac{1}{2}$ in. is assumed, then, substituting values of E and I for a 10-in. standard-weight pipe, the resulting forces found from the formulas of Fig. 12 give the curves of Fig. 13.

The maximum longitudinal stress S_{1max} which occurs in the middle surface at top of the turn in the curved portion is found by substituting the values of the forces determined in the foregoing into the ordinates of the bending-moment diagrams and applying a factor which takes into account flattening of the cross-section of a curved pipe under flexure. The value of this factor β may be found from Fig. 21 for the various values of h involved in this series of comparative shapes. (See later paragraph for an explanation of the significance of β.) For the particular case in which a seamless-tube fitting is employed, the stress may be found directly from Fig. 22 for standard-weight pipe. The maximum stress occurs at b of Fig. 12(*f*) and is $0.082 \times 3500 \times 60 = 17{,}150$ lb. per sq. in.

The magnitude of the forces required to produce a deflection of $\frac{1}{2}$ in. and the resulting bending moments and stresses produced in the 90-deg. turns of Fig. 12 are tabulated in Table 2.

While the results in Table 2 show the relative flexibility of different types of 90-deg. turns under a conventional condition of one end anchored and the other end free, they are of more or less academic interest in that the important question is not how much more or less flexible an element of this kind is demon-

[10] See Appendix No. 1 for derivation of relations between force and deflection for the several types of 90-deg. turns considered herein.

strated to be with respect to some similar element. The principal consideration is how the bend behaves when incorporated in an actual run of piping. Obviously, since the flexibility of only a portion of a given line will be affected by the substitution of a different type of bend or fitting, the magnitude of the differences found in the above comparison will be reduced when a whole section of piping between anchors is considered as a unit.

Expansion Bends Formed With Different-Radii 90-Deg. Arcs

A series of expansion bends of a given width and height which are composed of 90-deg. arcs of various radii and complementary lengths of straight pipe are illustrated in Fig. 14. This expansion bend is inserted in a straight run of piping rigidly anchored at each end. The dimensions of the various elements are given as ratios to permit a general solution from which proper deductions as to relative flexibility can be readily made. As this shape and the modifications to which it is susceptible are basic elements for providing flexibility in symmetrical piping layouts the general equations involved are given in Appendix No. 2.

The bending-moment diagram for piping arranged as shown in Fig. 14 is given in Fig. 15. From consideration of the requirement that the sum of the rotations of the elements of the line from one end to the other must be zero, an expression for determining the restraining moment at the ends may be developed. This relation is expressed in terms of ratios of length of the elements involved to diameter of pipe. The ordinate of the diagram for restraining moment Fig. 15 is designated as y. Its value is determined from the expression given in Appendix No. 2. The rotations of the elements between each point indicated and the left end of the line are given by the series of equations in Appendix No. 2.

The deflections corresponding to these rotations and to the effect of the forces and moments acting on each element may be found from the general deflection equations of Appendix No. 2. The algebraic sum of the deflections of the elements to the left and right gives the coefficient of the reacting force F. The desired relation between deflection and reacting force is thus obtained. The application of these equations, while tedious, gives directly the relations from which generalizations may be made.

This comparison of a series of square expansion bends of a given width and height installed in a straight run of pipe indicates that for the particular case shown in Fig. 14, the reacting force at the ends is approximately 50 per cent greater if 90-deg. bends having a center-line radius of 6 times the pipe diameter are used than if seamless-tube fittings ($R/d = 1^1/_2$) were employed.

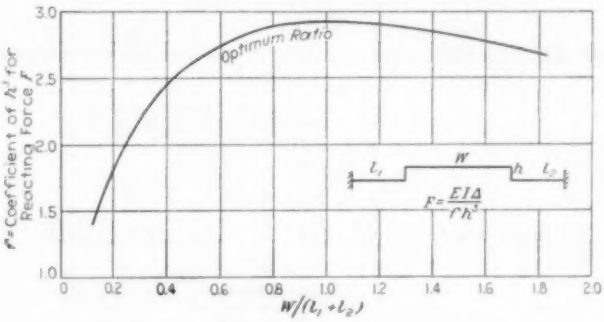

Fig. 18 Optimum Form of Square Bend
[Results obtained from Fig. 39 of Reference 9z.]

The effect of varying the radius of the 90-deg. bends forming the square expansion bend of Fig. 14 is shown graphically in Fig. 16, for an assumed deflection of 0.79 in.

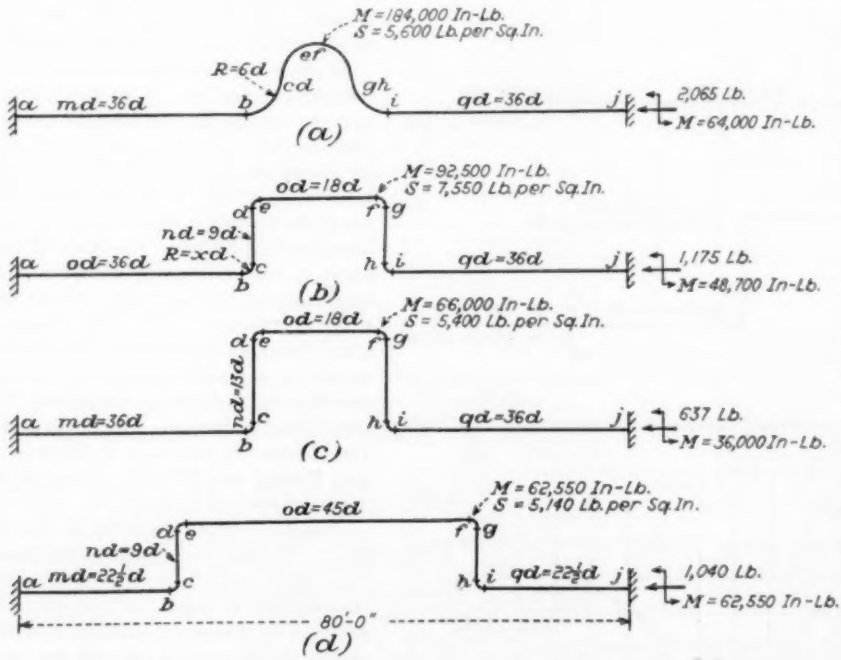

Fig. 17 Comparative Flexibility of Expansion U-Bend and Square Bends

Comparison of Expansion U-Bend and Various Square Bends

A comparison of the relative flexibility of an expansion U-bend and a bend composed of short-radius 90-deg. bends and straight lengths of pipe as shown in Fig. 17 may be made readily from the general equations just described.

Example. Assume a 10-in. line is to carry 15-lb.-gage saturated steam; distance between anchor points is 80 ft.; anchors restrain pipe both as to translation and rotation; and expansion from room to operating temperature is to be taken care of by a suitable expansion U-bend or a square bend formed of seamless-tube fittings and straight lengths of pipe. Required to determine the magnitude of the reacting forces and the maximum bending moment and stress in the line arising from expansion.

Expansion U-Bend. In the case of the expansion U-bend [Fig. 17(*a*)] $x = 6$, $m = 36$, $n = 0$, $o = 0$, $q = 36$, and $K = 0.49$ (see Fig. 20). The coefficient of the reacting force is found to be 2,728,000, hence the relation between the deflection to be cared for and the reacting force is given by

$$EI\,\Delta x = 2{,}728{,}000\,F$$

Square Bend Made With Seamless-Tube Fittings. The square-bend counterpart of the expansion U-bend, Fig. 17(*b*), which employs seamless-tube fittings has the following ratios: $x = 1^1/_2$, $m = 36$, $n = 9$, $o = 18$, $q = 36$, and $K = 0.14$ (see Fig. 20). The coefficient of the reacting force is found to give the relation

$$EI\,\Delta x = 4{,}799{,}200\,F$$

Flexural Rigidity of Pipe. The quantities on the left side of the equations are determined from the elastic properties of the pipe and expansion cared for.

E for steel pipe at 250 deg. fahr. may be taken as 29×10^6

I for 10-in. standard-weight pipe is 160.7 in.^{4}

$\Delta x = 1.51 \times 80/100 = 1.21$ in., where 1.51 represents the linear expansion of 100 ft. of steel pipe from 60 deg. to 250 deg. fahr.

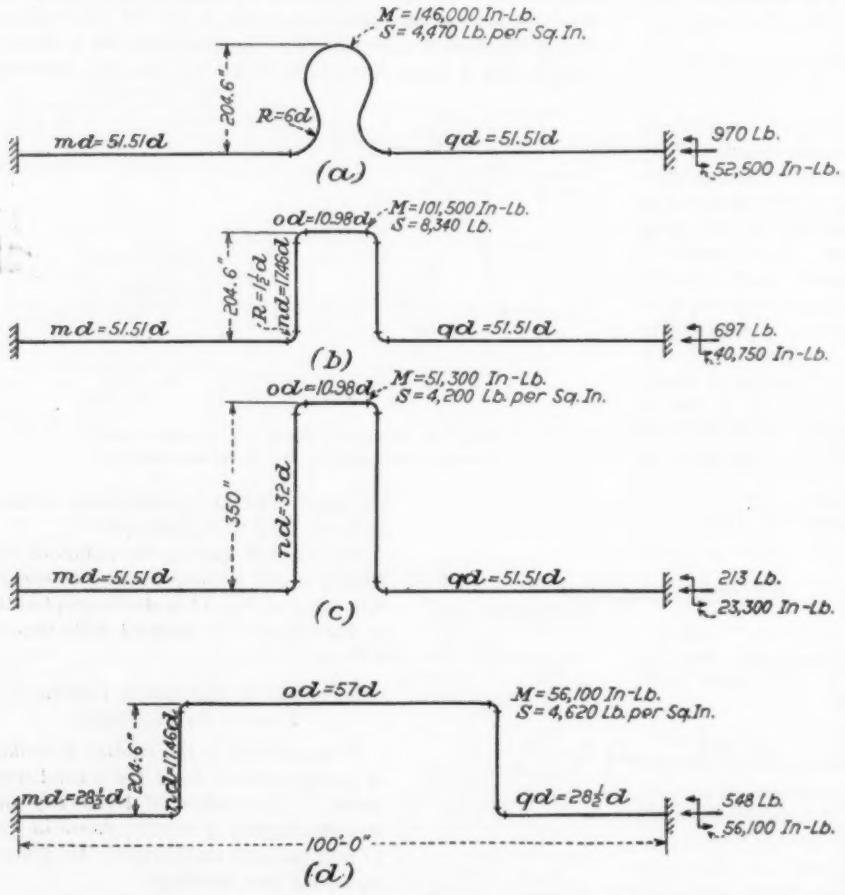

FIG. 19 COMPARATIVE FLEXIBILITY OF DOUBLE-OFFSET EXPANSION U-BEND AND SQUARE BENDS

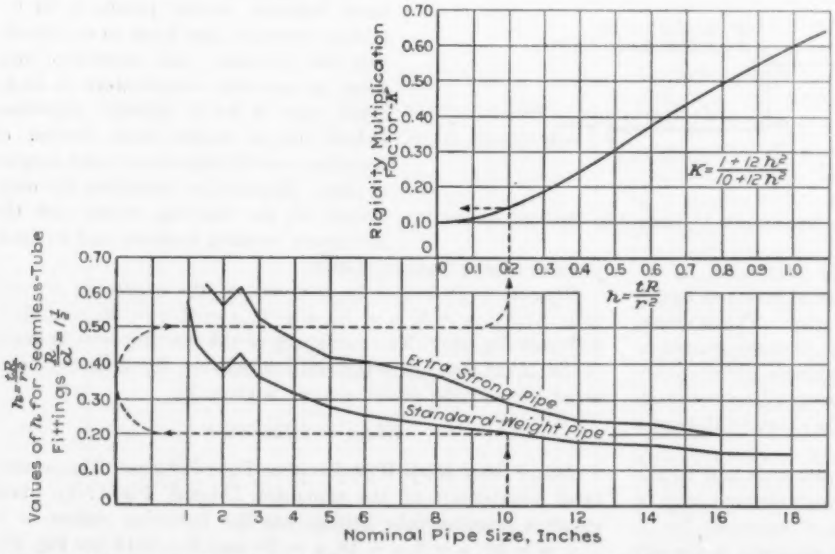

FIG. 20 VALUES OF RIGIDITY MULTIPLICATION FACTOR K FOR FLATTENING OF CIRCULAR CROSS-SECTION OF A CURVED PIPE DURING FLEXURE

Magnitude of Reacting Forces. The reacting force at the end of the line when an ordinary expansion U-bend [Fig. 17(*a*)] is inserted is therefore—

$$29 \times 10^6 \times 160.7 \times 1.21 = 2{,}728{,}000\,F$$
$$F = 2065 \text{ lb.}$$

The corresponding force when the U-bend is replaced by a square bend of the same overall dimensions fabricated of seamless-tube fittings [Fig. 17(*b*)] is found as

$$29 \times 10^6 \times 160.7 \times 1.21 = 4{,}799{,}200\,F$$
$$F = 1175 \text{ lb.}$$

The above values indicating that the latter method [Fig. 17(*b*)] of providing for expansion reduces the reacting forces to approximately 57 per cent of their former value [Fig. 17(*a*)] for the particular conditions used in this example.

Magnitude of Bending Stresses. The bending stresses set up in the curved portions of the line by thermal expansion are found, however, to be greater by about 35 per cent for the square-bend counterpart of the expansion U-bend due to the sharp curvature of the seamless-tube fitting. The effect of the short radius materially increases the magnitude of the longitudinal-stress multiplication factor β which takes into account the effect of flattening of the cross-section of a curved pipe during flexure (see Fig. 21). As indicated in Fig. 17, the maximum stress $S_{l\max}$ occurs at point f and is 5600 lb. per sq. in. in the expansion U-bend and 7550 lb. per sq. in. in the seamless-tube fitting.

Strength Criterion Employed for Curved Pipes. The maximum longitudinal stress $S_{l\max}$ in the middle surface of the pipe cross-section is taken as the strength criterion in the present analysis of bends and fittings in accordance with the conclusions reached by Prof. William Hovgaard in his elaborate study of the stress and strain relations in pipe bends. His conclusion is that, as long as the maximum longitudinal stress as determined by the formula below does not exceed about 20,000 lb. per sq. in. for ordinary steel-piping material, failure of the bend will not occur.

Professor Hovgaard recommends, however, that a total combined stress of 16,000 lb. per sq. in. be used for design purposes, including longitudinal tensile stress due to internal pressure and other stresses which may exist. As a general

principle, limiting the longitudinal bending stress $S_{i\max}$ to 12,500 lb. per sq. in. will provide sufficient margin to cover other stresses involved. Where torsional stress exists, however, it should be combined with the total longitudinal stress, and the maximum equivalent stress determined by the following equation (see Reference 9*c*, p. 559).

$$S_{eq.} = 2\sqrt{S_s^2 + \left(\frac{S_{\max} - S_{\min}}{2}\right)^2}$$

Where $S_{eq.}$ is the total equivalent stress which should not exceed 16,000 lb. per sq. in.; S_s is the shear stress due to torsion in lb. per sq. in.; $S_{\max}$ is the total longitudinal stress in lb. per sq. in. due to bending ($S_{i\max}$) plus the longitudinal stress due to internal pressure; $S_{\min}$ is the direct radial compression due to internal pressure, which at the mean radius of the pipe wall is approximately equal to one-half that pressure in lb. per sq. in. and

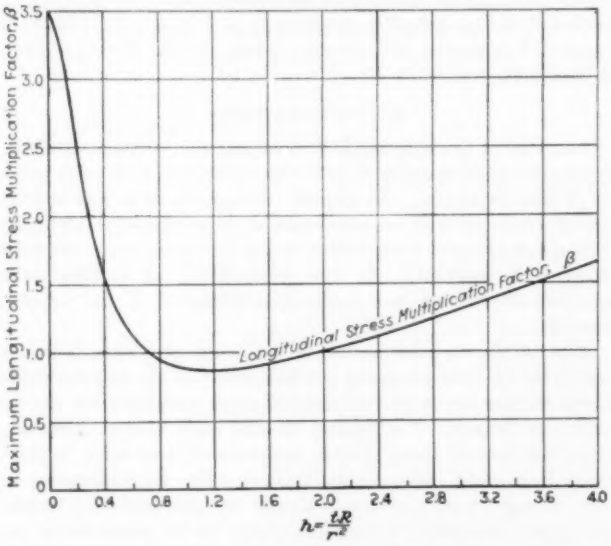

FIG. 21 STRESS MULTIPLICATION FACTOR β FOR MAXIMUM LONGITUDINAL STRESS IN MIDDLE SURFACE OF CURVED PIPE

$$S_{i\max} = \beta Mr/I;\ \beta = \frac{2}{3K}\sqrt{\frac{6h^2+5}{18}},\ \text{where } K = \frac{1+12h^2}{10+12h^2}$$

usually can be neglected. Since compressive stresses are considered as negative, the direct radial stress $S_{\min}$ should be added to $S_{\max}$ if it is taken into account in the computations.

Expression for Maximum Longitudinal Stress in Curved Pipes. The maximum longitudinal stress as developed by Professor Hovgaard is given by $S_{i\max} = \beta Mr/I$ (Reference 9*c*, p. 8), where

$$\beta = \frac{2}{3K}\sqrt{\frac{6h^2+5}{18}}$$

in which $K = (1 + 12h^2)/(10 + 12h^2)$ and $h = tR/r^2$

t = pipe wall thickness, inches
R = radius of center line of bend, inches
r = radius of pipe cross-section to the middle surface, inches.

Values of β are plotted against h in Fig. 21.

This equation is combined with r/I for standard-weight and extra strong pipe so that the stress in a short-radius bend may be obtained directly from the curves of Fig. 22 and the bending moment for each size of pipe. (See equation for maximum moment, Appendix No. 2.)

Comparison of Stresses in Expansion U-Bend and Its Counterpart. Thus in the comparison of the expansion U-bend and its square-bend counterpart made with seamless-tube fittings, it is only necessary to substitute the value of the reacting force F determined for the latter into the ordinates of the bending moment diagram of Fig. 15 to find the maximum bending moment which in this instance occurs at points e or f (see Appendix No. 2 for equations) and is 92,500 in-lb. The stress multiplication factor for a 10-in. standard-weight pipe is found from Fig. 22 as 0.082. The stress at e or f is therefore

$$0.082 \times 92{,}500 = 7550 \text{ lb. per sq. in.}$$

The corresponding stress determined for the expansion U-bend is found from the bending moment at the top of the bend 184,000

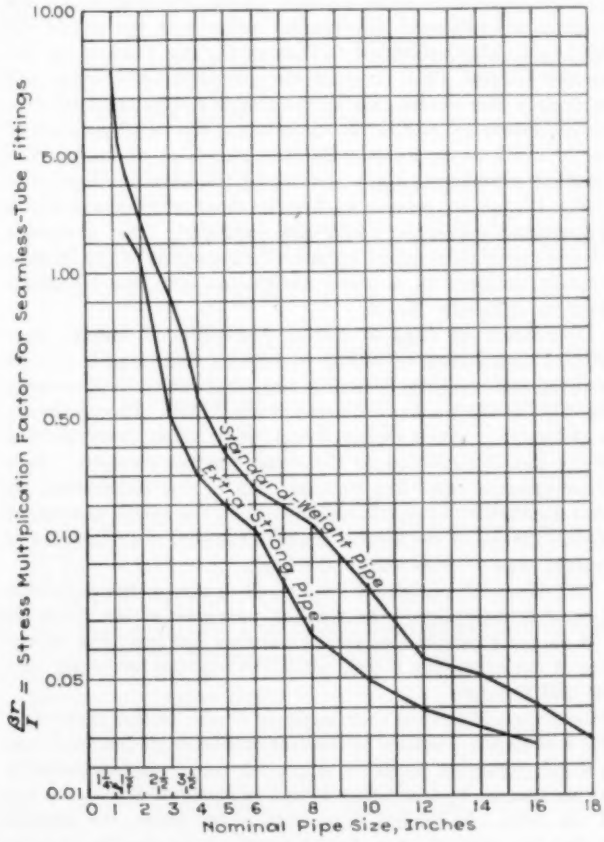

FIG. 22 STRESS MULTIPLICATION FACTOR β FOR MAXIMUM LONGITUDINAL STRESS IN MIDDLE SURFACE FOR SEAMLESS-TUBE FITTINGS

$$S_{i\max} = \left[\frac{2r}{3KI}\sqrt{\frac{6h^2+5}{18}}\right]M$$

in-lb. and the value determined for the longitudinal-stress multiplication factor from Fig. 21 for a bend formed of standard-weight pipe to a radius of 6 pipe diameters ($0.94 \times 184{,}000 \times 5.19/160.7 = 5600$ lb. per sq. in.

An examination of the foregoing comparison shows that the substitution of a square bend composed of seamless-tube fittings and straight lengths of pipe in place of an expansion U-bend has the effect of reducing the magnitude of the reacting forces and bending moments, but at the same time increases the stress in the curved portions of the line.

Bending Moments at Joints. The foregoing comparison deals with bending stresses in the pipe wall and with reactions at anchor points. A third phase of flexibility analysis concerns the maximum amount of bending moment existing at any joint or weld in the line. It is desirable, of course, to choose a design in which the bending moments at all joints are equalized or

minimized with a view to avoiding excessive moments at any of them. Too severe bending moments occurring at joints increase the liability of leaks in service and should be avoided by due consideration in design.

Methods of Reducing Stresses and Bending Moments in Square-Bend Counterpart of Expansion U-Bend. In order that the magnitude of the bending moment at the top of the bend composed of straight lengths of pipe and short-radius bends may not exceed that which is found at the ends of the expansion U-bend, two methods of procedure may be followed. If it is necessary or desirable to maintain the same width as occupied by the expansion U-bend, for some constructional reason, an increase in height of bend by approximately 45 per cent [Fig. 17(*c*)] will result in a lowering of the bending moment at the top of the bend to a value equivalent to that on the end joint of the expansion U-bend. The stress in the curved part of the line will be slightly less in the case of the higher square bend than in the expansion U-bend, while the reacting forces at the ends of the line will be approximately only one-third as large. The foregoing statements apply strictly to the example illustrated in Fig. 17, but are reasonably true for most conditions in which symmetrical expansion bends are employed. The particular relations may be obtained by substituting ratios of the lengths actually involved in a given installation into the equations given in Appendix No. 2.

Distribution of Pipe to Secure Flexibility. A much more efficient distribution of piping as regards total length of pipe involved and resulting flexibility may be obtained by increasing the width of the bend as indicated in Fig. 17(*d*). The maximum flexibility in a given piping layout exists when every portion of the line is subjected to the same bending moment. In a symmetrical straight line such as used in this illustration, an ideal distribution of pipe is obtained when the length of straight pipe at the top of the bend is equal to the sum of the lengths of straight pipe at each end of the bend.

In this case if a height of bend equal to that of the expansion U-bend is maintained, the bending moments at the joints as well as the stress in the curved portions are less than in the case of the expansion U-bend while the reacting forces are only one-half as large.

Conclusion Regarding Distribution of Pipe. In this connection it is well to call attention to the fact that in every practical case in which expansion bends are employed, much greater flexibility can be secured by inserting a length of straight pipe at the top of the bend. In general, for bends in one plane, the amount of straight pipe at the top of the bend should be equal to the sum of the lengths of straight pipe between each end of the bend and the anchor points. This relation is shown graphically for a particular square bend in Fig. 18. It will be noted that the optimum value of f (the coefficient of h^3 which determines the value of the reacting force) results when the ratio of the width to the sum of the lengths between the ends of the bend and the anchor points is unity.

Double Offset Expansion U-Bend

Relative Flexibility. A comparison of the flexibility of a double-offset expansion U-bend with that of a bend having the same overall dimensions made up of seamless-tube fittings is of interest, as this type of bend is often used where a considerable amount of expansion is to be absorbed (see Fig. 19). In this example a 10-in. standard-weight pipe is used as in the foregoing, but the steam pressure is 100 lb. gage (338 deg. fahr.) and the distance between anchors is 100 ft. The resulting forces at the anchors with the double-offset expansion U-bend are 40 per cent greater than with the square-bend counterpart fabricated with short-radius bends [Fig. 19(*b*)], while the maximum longitudinal stress is found to be about 86 per cent greater for the latter.

Methods of Reducing Stresses and Bending Moments in Square-Bend Counterpart of Double-Offset Expansion U-Bend. In this case as with the simple expansion U-bend, two alternatives suggest themselves to reduce the stresses and bending moments so that as good results will obtain as with the double-offset expansion U-bend. If the same width of bend is necessary, the height will have to be 70 per cent greater than that of the double-offset expansion U-bend. If the optimum width may be used as developed in connection with the simple expansion U-bend, the same height can be maintained and the bending moment at the joints will be only slightly greater while the maximum stress will be only 90 per cent as great and the reacting forces only a little more than one-half as large.

Again, it should be noted that the above statements refer to the particular case chosen for analysis but are indicative of the general conclusions which may be drawn. If a true comparison is desired for an actual installation it is necessary to substitute ratios of the lengths of the various parts into the equation given in Appendix No. 2.

III—CONCLUSIONS

An attempt has been made to point out the conclusions drawn from various phases of this paper in connection with each point as it was developed. In general, it may be said that welded piping made up with seamless-tube fittings compares favorably with other types of construction as regards appearance, pressure drop, and flexibility. It has pronounced advantages over mitered elbows and short-radius cast fittings in all the respects named.

Due to the complex nature of expansion problems, it is not advisable to draw sweeping conclusions as to the relative flexibility of pipe bends as distinguished from seamless-tube elbows and cast fittings. The typical specific cases chosen, however, show the general trend of such comparisons, and serve to illustrate how other cases can be treated. The suggestions as to how straight pipe and bends should be distributed to obtain maximum flexibility, the authors deem to be particularly important (see discussion in connection with Figs. 17, 18, and 19).

The rather sketchy nature of the data offered on pressure drop through turns of different radii is appreciated by the authors, who hope that interested engineers will call attention to references which may have been overlooked, or present unpublished data of their own bearing on the subject. The solution of piping-flexibility problems has received considerable attention of late and the authors would appreciate a frank discussion of how to make the methods they have used more readily understood and useful. It is especially desirable to further develop the application of these principles to special cases and work out short-cut methods for computing the flexibility of common types of expansion members.

Appendix No. 1

(1) *90-Deg.-Turn Seamless-Tube Fitting* [Fig. 12(*f*)]. The relation between deflecting force and the deflection is determined as follows: The values of x, n, and K become:

$$x = 1\tfrac{1}{2}, n = 4\tfrac{1}{2}, h = 0.203 \text{ (Fig. 20) and } K = 0.14 \text{ (Fig. 20)}$$

$$\psi_b = 1\tfrac{1}{2} \times 4\tfrac{1}{2} \times 100F/EI + 4\tfrac{1}{2} \times 4\tfrac{1}{2} \times 100F/EI = 2700F/EI$$

$$\psi_e = 2700(F/EI) + \frac{1\tfrac{1}{2} \times 1\tfrac{1}{2} \times 100F}{0.14EI} + \frac{1.57 \times 1\tfrac{1}{2} \times 4\tfrac{1}{2} \times 100F}{0.14EI} = 11{,}745F/EI$$

$$EI\,\Delta x_c = \Sigma\ 2{,}700F \times 1\tfrac{1}{2} \times 10 = 40{,}500F$$
$$1{,}585F \times 0.7854 \times 15 = 18{,}700F$$
$$7{,}460F \times 0.637 \times 15 = 71{,}300F$$
$$EI\,\Delta x_d = \Sigma\ 11{,}745F \times 4\tfrac{1}{2} \times 10 = 528{,}000F$$
$$\tfrac{1}{2}\,(4\tfrac{1}{2})^2\,100F \times \tfrac{2}{3} \times 45 = 30{,}400F$$
$$688{,}900F$$

$$EI\,\Delta_x = 688{,}900F$$

(2) *90-Deg.-Turn 250-Lb. Flanged Steel Elbow* [Fig. 12(*g*)]. The minimum wall thickness of a 250-lb. 10-in. elbow is $^{15}/_{32}$ in. The corresponding moment of inertia is 211 in.^{4} while the moment of inertia of the 10-in. standard-weight pipe is 160.7 in.^{4} The ratio by which the abscissa of the diagram must be divided is therefore 211/160.7 = 1.315. $x = 1$, $n = 5$, $h = tR/r^2 = 0.468 \times 10/27.4 = 0.171$. The value of K corresponding to $h = 0.171$ from Fig. 20 is 0.13.

The equations for rotation and deflections become

$$\psi_b = (1 \times 5 \times 100F/EI) + 25 \times 100F/EI = 3000F/EI$$

$$\psi_c = 3000F/EI + \frac{100F}{1.315 \times 0.13EI} + \frac{1.57 \times 1 \times 5 \times 100F}{1.315 \times 0.13EI} = 8164F/EI$$

and

$$EI\,\Delta x_c = \Sigma\ 3{,}000F \times 10 = 30{,}000F$$
$$584F \times 7.85 = 4{,}580F$$
$$4{,}580F \times 6.37 = 29{,}200F$$
$$EI\,\Delta x_d = \Sigma\ 8{,}164F \times 50 = 407{,}500F$$
$$\tfrac{1}{2} \times 2{,}500F \times 33.3 = 41{,}700F$$
$$512{,}980F$$

$$EI\,\Delta_x = 512{,}980F$$

(3) *90-Deg.-Turn Miter Elbow* [Fig. 12(*h*)]. In the case of the miter elbow, $x = 0$, $n = 6$, and $K = 1$.

$$\psi_c = (F/EI)n^2d^2 = 36 \times 100F/EI = 3{,}600F/EI$$
$$EI\,\Delta x_d = \Sigma\psi_c nd = 3{,}600F \times 60 = 216{,}000F$$
$$\psi_F{}^2/_3 nd = \tfrac{1}{2} \times 36 \times 100 \times 40F = 72{,}000F$$
$$288{,}000F$$

$$EI\,\Delta_x = 288{,}000F$$

Appendix No. 3

LIST OF SYMBOLS

The symbols used in this paper are defined below:

- Δ_X = deflection along the X-axis, inches
- F = generalized force acting as shown, pounds
- l = length of cantilever or section of pipe, inches
- E = modulus of elasticity of pipe material at the working temperature of the piping, pounds per square inch
- I = moment of inertia of pipe cross-section, inches to the fourth power
- K = rigidity multiplication factor $= \dfrac{1 + 12h^2}{10 + 12h^2}$
- β = longitudinal stress multiplication factor $= \dfrac{2}{3K}\sqrt{(6h^2 + 5)/18}$
- h = tR/r^2 = pipe-bend ratio
- t = thickness of pipe wall, inches
- R = mean radius of bend, inches
- r = mean radius of pipe cross-section, inches
- d = nominal diameter of pipe, inches
- ψ_M = rotation due to a moment at the end of a cantilever; = area of rectangular bending-moment diagram, divided by EI
- ψ_F = rotation due to a transverse force at the end of a cantilever; = area of triangular bending-moment diagram, divided by EI
- $\psi_{b\,c,etc.}$ = algebraic sum of the rotations of the elements between the point designated by the subscript and the fixed end of the section of piping; = algebraic sum of the areas of the bending-moment diagrams to the left of the point designated by the subscript, divided by EI
- $m, n, o, q,$ and x = ratios of lengths of pipe to pipe diameter involved in computation of flexibility of symmetrical square bends, U-bends, etc.

Discussion

GEORGE J. STUART.[11] When designing a piping system, the problem of caring for expansion is one of great importance and one concerning which little specific information is at hand. This paper, together with the authors' previous work, is therefore most timely.

Figs. 17 and 19 of the paper and the conclusion that the seamless-tube-fitting method compares favorably with the pipe-bend method of providing flexibility are interesting.

The capacity of a pipe bend to take care of expansion is limited by the maximum stress set up in the pipe. It will be noted from Fig. 19 that for the conditions given the maximum stress in the pipe bend is 4470 lb. per sq. in., whereas, for the same conditions, the stress in the seamless-fitting method is 8340 lb. per sq. in., or an increase of 79 per cent.

It will also be noted that the maximum stress, Fig. 19 (*b*), comes at a weld, while in the pipe bend the maximum stress is taken by the pipe itself.

The authors have suggested a method of reducing the stresses by means of increasing the proportion. The stresses can undoubtedly be reduced in this way, but in actual practice the space available for expansion bends will only rarely permit this expedient; furthermore, when space permits, the method is applicable to pipe-bend as well as to seamless-tube fitting.

It always is desirable to minimize the number of joints in a pipe line. The seamless-tube-fitting expansion U-bend has necessarily eight welded joints, while the equivalent bend has but two joints, which may be either flanged or welded.

It is interesting to compare the quantity of labor and material entering into the two methods. The amount of pipe entering into the seamless-tube-fitting construction is almost the same as in the pipe-bend construction—more exactly, 0.9 as much if the pipe bend has a radius of 5 diameters. If the radius is 6 diameters, 0.95 as much pipe is used, and if the radius is increased to 7 diameters, the quantity of pipe in the two methods is the same. To this must be added the expense of making eight welds and the cost of four seamless-tube fittings. This cost of welding and fittings more than offsets the expense of bending the pipes.

In view of the foregoing, the writer believes that the pipe-bend construction has the following advantages over the equivalent seamless-tube-fitting construction:

1 Lower stress per unit of flexibility
2 Fewer joints
3 If any joints are necessary in the pipe-bend construction, they can be placed at points of low stress
4 More economic of space for equal stress and flexibility
5 Less expensive.

A. M. HOUSER[12] AND S. HIRSCHBERG.[13] Those of us who have dealt with piping flexibility problems can appreciate that the grapho-analytical method based on area moment diagrams introduced by the authors to this application is a decided advancement in solving complicated piping layouts. The authors should be commended for this admirable contribution.

It is interesting to note, however, that throughout the paper the authors emphasize the preferable use of seamless-tube elbows having a mean radius of curvature of $1^1/_2$ times the inside pipe diameter. They treat this subject from two phases, namely, pressure drop and flexibility. The writers realize that treatment of this subject from all angles would entail an article of consider-

[11] Engineer, Power Piping Society, Pittsburgh, Pa. Mem. A.S.M.E.

[12] Product Engineer, Crane Company, Chicago, Ill. Mem. A.S.M.E.

[13] Crane Company, Chicago, Ill.

able length, yet the writers feel that the illustrations and problems as presented by the authors may be misleading to the piping designer not intimate with this subject. The writers wish to bring out some points not discussed by the authors which will indicate that a ready-made elbow need not be confined to a mean radius of $1^1/_2$ times the inside diameter nor should it be made of seamless tubing exclusively; also, that expansion bends made of continuous parts of a circle have many advantages over square bends.

Pressure Drop in Elbows and Bends

Prof. F. E. Giesecke in 1927 conducted a series of tests on short-radius and long-radius standard 90-deg. elbows to determine the comparative friction losses of each. The report of this investigation can be found in the University of Texas Bulletin No. 2712. Quoting Professor Giesecke:

> Comparing a short radius 90-deg. elbow with a long-radius elbow, the friction in a long-radius elbow is about 63 per cent of that in a short-radius elbow, for a velocity of 3 ft. per sec. and a 3-in. pipe. This percentage is reduced slightly as the velocity is increased, and increased as the pipe diameter is increased.

Comparing this statement with the authors' statements and references would indicate that there is considerable difference of agreement of results. According to the authors' curves there is a much more decided rapid decrease in elbow friction as R/d increases from 1 to 4, which is the comparative relation of the short-radius and long-radius elbows' mean radii of curvature.

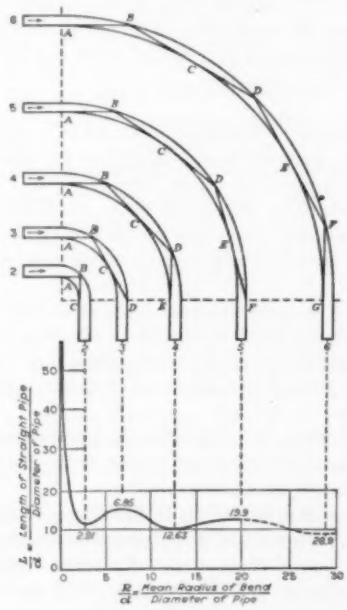

Fig. 23

Fig. 23 is reproduced from *Engineering*, of London, in the November 13, 1925, issue, based on data presented in a paper by Prof. J. Eustice. Professor Eustice showed by colored filaments the motion of water in its flow through curved glass pipes for the purpose of ascertaining the causes of increased resistance to flow due to curvature of pipe. The average curve from results of experiments made by several investigators on circular pipes from 2 in. to 6 in. is shown in Fig. 23. An inspection of the curve indicates that the friction loss in curved pipes with respect to R/d follows a peculiar law of maxima and minima and that the minimum pressure drop for the least R/d is decidedly at 2.91 and not 1.5 to 2 as indicated by the authors. Also, that there is not as decided a rapid decrease in pressure drop when R/d increases from 1 to $1^1/_2$, as the authors contend.

Professor Eustice states that after a series of calculations based on theoretical assumptions, it was found that for right-angled bends, the results which agree most closely with the experiments are obtained when the line AB is drawn as a tangent to the inner circle of the curved pipe and continued as at A, B, C, D, E in Fig. 23. If the joint with the tangent pipe is at E, the fluid passes along the straight pipe with minimum resistance. This is illustrated for right-angled bends in Fig. 23, cases 2, 3, 4, 5, and 6. In each of cases 2, 4, and 6 where the lines BC, DE, and EG, respectively, are tangent at the outlet, there is a minimum. In each case of cases 3 and 5, where the lines BCD and DEF, respectively, cut the curve at the outlet, there is a maximum.

Another consideration of pressure drop in right-angled bends must be made which is discussed in the "Handbook on Hydraulics" by H. W. King. In designing a pipe line, it may be found

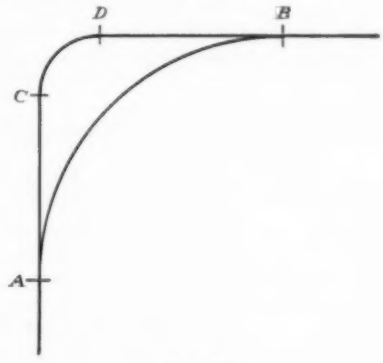

Fig. 24

that the total loss of head in pipe line between two given points will be less by using a curve of greater radius due to shortening the length of pipe. This may be seen from Fig. 24. Assuming that the radius of the bend CD is from 4 to 7 ft., the radius giving minimum excess loss of head, the bend AB having a greater radius than CD; the total loss of head in the pipe AB may be less than the total loss of head in the pipe $ACDB$ because of its shorter length. This would tend to show that in Fig. 12 of the authors' paper pressure drop is sacrificed when comparing Fig. 12 (*f*) with Fig. 12 (*a*).

Relative Flexibility of Elbows and Long-Radius Pipe Bends

Comparing the merits of so-called "square bends" made up of cast-steel fittings and straight pipe as contrasted with "square bends" made up of the seamless-tube elbow and straight pipe, the writers wish to call to the attention of the authors the following:

In Fig. 12 (*g*) of the authors' paper is shown the relation between deflection and force of $EI\,\Delta_x = 513{,}000\,F$ for 250-lb. American standard flanged steel elbow with $R/d = 1$. A comparison of the relative flexibility of cases Fig. 12 (*f*), seamless-tube elbow, with Fig. 12 (*g*) cast-steel elbow, taking tensile strengths in consideration, is as follows:

Seamless-Tube Fitting	*Cast-Steel Fitting*
$R/d = 1^1/_2$	$R/d = 1$
$EI\,\Delta_x = 688{,}900\,F$	$EI\,\Delta_x = 513{,}000\,F$
Max. longitudinal stress = 17,150	Max. longitudinal stress = 18,800
Tensile strength = 54,000	Tensile strength = 70,000

Therefore, using the permissible longitudinal stress of 12,500 lb. per sq. in. as recommended by the authors for seamless steel tubing, the permissible longitudinal stress for cast steel using the same factor of safety would be approximately 15,500. In other

words, using the same factor of safety, it can be computed by simple mathematics that the deflection obtained by the cast-steel elbow bend would be slightly greater than that obtained by use of the seamless-tube elbow, not considering any additional flexibility due to the screw joint over the rigid welded joint. Furthermore, if the authors would have determined the relation between deflection and force for the seamless-tube elbow as in Fig. 12 (*g*) for the cast-steel elbow, the coefficient would have been greater than 688,000 as of $R/d = 1^1/_2$, as in Fig. 12 (*f*), although the longitudinal stress may have been greater.

Comparing Fig. 12 (*a*) with Fig. 12 (*f*), it can be readily seen that for $R/d = 1^1/_2$ the coefficient of the relation between deflection and force shows a decided advantage over $R/d = 6$, yet the longitudinal stress for $R/d = 1^1/_2$ is much greater than when $R/d = 6$. This means that if the permissible stress is 12,500 the deflection would be considerably less for $R/d = 1^1/_2$ than for $R/d = 6$, although the force would be greater in the latter. It must be remembered that the condition selected by the authors is the most beneficial to the $R/d = 1^1/_2$ bend, and here a lesser deflection is obtained than $R/d = 6$, using the same permissible fiber stress.

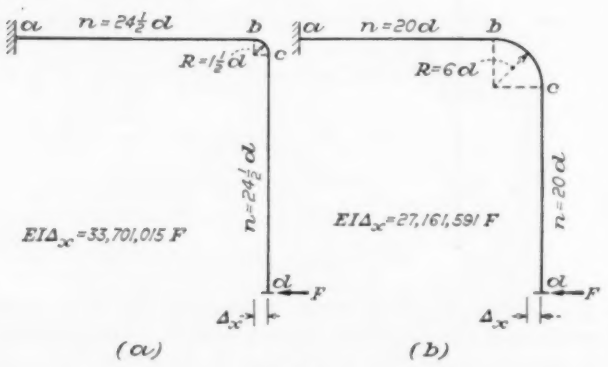

FIG. 25

Suppose a more practical situation, as shown in Fig. 25, where the face-to-face dimension is 26 pipe diameters.

Assuming the same permissible stress of 12,500 and diameter of pipe $d = 10$ in., the two bends as shown in Fig. 25 compare as follows:

Bend $R/d = 1^1/_2$	Bend $R/d = 6$
$\Delta_x = 4^1/_4$ in.	$\Delta_x = 8^1/_2$ in.
$F = 585$ lb.	$F = 1450$ lb.

Upon comparison of the coefficients of the relation between deflection and force in Fig. 24, as contrasted with the authors' Fig. 12 (*a*) and (*f*), the pronounced difference of the coefficients as pointed out by the authors' case becomes insignificant in the case illustrated in Fig. 24.

As indicated, the bend having $R/d = 6$ offers twice the amount of deflection as the bend with $R/d = 1^1/_2$. Is not this the more practical and most economical way of getting the most out of an expansion bend with the same factor of safety? The providing of anchorage of 585 lb. as compared to 1450 lb. to obtain twice the flexibility should not present a difficult problem of structural designing.

From inspection of Fig. 19 of the authors' paper it can be seen that considerably more space and pipe will be required to make up a square bend of seamless-tube elbows and straight pipe as compared with the fabricated double-offset expansion U-bend. The double-offset expansion U-bend requires considerably less pipe and can take up a minimum of space.

One point the authors fail to discuss is that of concentration of stress at the weld. The authors agree that the maximum fiber stress occurs at (*b*) in Fig. 12 of their paper. From an inspection of the illustration shown in Fig. 5 of the authors' paper it can be seen that no tangents are integral with the seamless-tube elbow. The weld is made at the point where the radius meets the straight pipe to which the elbow is welded, and this is where the maximum fiber stress occurs. An elbow having tangents would have a decided advantage over the elbow described by the authors.

The authors also confine their discussion to an elbow made of seamless-steel tubing; is there anything wrong with an elbow forged in two halves and welded together having the same thickness as pipe and made of steel having similar characteristics as tubing? After all, is not a welded line as strong as its welded joints? It may be of interest to state that ready-made tees for welding can be obtained on the market which are made by forging them in halves and welding together.

CONCLUSIONS

In concluding, the writers believe that the seamless-tube elbow and welded elbows having tangents (forged in halves) should be confined to such use as a fitting and not as an integral part of an expansion pipe bend unless in extraordinary cases.

The writers do not agree with the authors that the seamless-tube fittings, as pointed out, compare favorably with long-radius pipe bends as regards flexibility, and have not pronounced advantages, as pointed out by the authors, over the cast fittings as regards appearance, pressure drop, and flexibility.

A fitting made of seamless-tube having tangents has a decided advantage over the seamless-tube described by the authors because of the pronounced decrease of stress concentration due to expansion or other stresses.

J. ROY TANNER.[14] The authors are to be commended for the systematic arrangement of existing data on the losses which occur in changing the direction of the flow of fluids. Such data are more incomplete than one could wish, especially in respect to test conditions and this accounts for the divergence in the specific determination of losses under given conditions by different observers.

Enough observers agree to make it apparent that up to $1^1/_2$ pipe diameters in radius the friction loss in bends is greatly reduced through increasing the radius of the bend and thereafter more slowly, reaching the minimum at about 5 diameters, after which it may increase.

For low velocities the difference in loss between $1^1/_2$ and 5 diameters is small, but for steam at high velocities it becomes appreciable as shown by all observers.

The data from Fig. 8 from the Buffalo Forge Company indicate that for bends with radii of $2^1/_2$ pipe diameters the pressure loss is only 72 per cent of those of $1^1/_2$ diameters. Fig. 9, from Edwards, shows the loss at 5 diameters to be 76 per cent of that for $1^1/_2$ diameters. Fig. 11, from Davis, shows that the loss at 5 diameters is only 43 per cent of that at $1^1/_2$ diameters, and from Weisbach 75 per cent.

These figured losses differ numerically, but all indicate that enough pressure drop can be prevented through the use of pipe bends of about 5 diameters in radius instead of shorter bends or fittings to make their use preferable where space permits.

Another point to be taken into account by the designer is plant investment. From this point of view, in the writer's experience, under present-day conditions and taking into account the cost of additional joints entailed by short-radius bends and the additional pipe necessary to equalize line length, the pipe bend of customary design has the advantage.

[14] Pittsburgh, Pa. Mem. A.S.M.E.

The writer is glad of this opportunity to second the plea of the authors for more reliable data on this subject.

ROBERT CRAMER.[15] This is an excellent presentation of some of the problems which confront the designer of piping systems for modern conditions of high pressure and temperature. One of the merits of the paper is the fact that it refrains from giving explicit instructions or "recipes" for design, which usually cover only some very special case. The authors rather present a thoughtful analysis of some assumed cases, thereby stimulating the attentive reader to apply similar thoughtful methods to his own problems.

A case which came under the writer's observation several years ago illustrates this point. In a straight high-pressure steam line leading from a boiler plant to a group of steam turbines, an expansion bend similar to Fig. 19 (*a*) was installed, without making a close estimate of the flexibility of the bend or the reactions produced. With the first heating up of the system one of the turbines was dislocated from its foundation. The bend was then replaced by an expansion joint of the stuffing-box type.

The authors mention in their conclusions that the data offered on pressure drop are sketchy. This is true of practically all information available on this subject. A thorough review and analysis of all the available data would seem desirable.

In the presentation of data referring to flow of water by the authors the friction in the straight pipe which is replaced by long-radius elbows is taken into consideration. If this were also done in the case of air flow, a picture somewhat different from that presented in Fig. 8 would appear.

For instance, comparing the largest elbow, $R/d = 5$, with the smallest, not only is the elbow with radius $^1/_2d$ equivalent to 121.2 diameters, but the installation of this elbow requires an additional amount of straight pipe of 9 pipe diameters, as compared with the elbow of radius $5d$.

This difference (less than $7^1/_2$ per cent) does not seem large, but the percentage is much greater in the intermediate cases, as is shown in the following table:

R/d	0.50	0.75	1.00	1.25	1.50	2.00	3.00	5.00
$2(5 - R/d)$	9.00	8.50	8.00	7.50	7.00	6.00	4.00	0.00
l/d	121.2	35.09	17.51	12.72	10.36	9.03	8.24	7.85
Total equivalent length in diameters	130.2	43.59	25.51	20.22	17.36	15.03	12.24	7.85

The curve representing these figures, when plotted, will show a much steeper inclination at $R/d = 5$ than the curve of Fig. 10. This seems to indicate that, from the standpoint of friction loss, it is desirable to make the radii of all bends as large as the space limitations permit.

WILLIAM HOVGAARD.[16] The seamless-tube fittings referred to are, it is supposed, of the same type as the so-called "tube-turns." Last year the writer made a series of tests on a 12-in. tube turn bent to 180 deg. with a radius of $1^1/_2$ times the diameter. The wall thickness was $^3/_8$ in. An abstract of the results was given in a paper read before the International Congress of Applied Mechanics in Stockholm in August, 1930. The writer will here merely mention that although the curvature of this pipe was much sharper than assumed in his theory on the bending of curved tubes the deflections as well as stresses corresponded remarkably well with the results of the formulas. As in bends of more easy curvature it was found that the increments in the deflection ΔX remained proportional to the increments in the corresponding force F up to a longitudinal stress of 20,000 lb. per sq. in. It appears that as in case of ordinary pipe bends a total working longitudinal stress of 16,000 lb. per sq. in. is permissible. When torsional stresses exist, the principal stress should be found by the formula given in the paper, and stress so determined should then not exceed 16,000 lb. per sq. in.

This is essentially a practical engineers' paper, and will undoubtedly prove very useful to piping engineers. It brings the problems involved in the design of pipe lines up to the most recent practice and presents to the profession a wealth of valuable information, theoretical and practical.

The proposed area-moment method is very ingenious and practical. It enables the designing engineers to solve otherwise unapproachable three-dimensional problems.

The writer wishes to add that the representation of the stress multiplication factor β, as given in Fig. 21, and which was published in one of his papers on pipe bends, was suggested by Mr. A. Edwards of the Stone & Webster Engineering Corporation.

The correct references to the writer's various papers on this subject are as follows:

Journ. of Math. & Phys., M.I.T., Vol. VI, No. 2, 1926; Vol. VII, No. 3, 1928; Vol. VII, No. 4, 1928; and Vol. VIII, No. 4, 1929.

World Eng. Congress, Tokyo, 1929, "Deflections and Stresses in Pipe Bends."

Intl. Congress of Applied Mechanics, Stockholm, 1930, "Bending of Curved Pipes."

W. R. TOWNSEND.[17] The frictional resistance data furnished are valuable and important from a practical point of view as an assembly of results of previous tests. The discussion has so far demonstrated that there is a considerable difference of opinion regarding results under varying conditions of flow, and has brought out additional data. Further information will doubtless be uncovered on this subject.

It would be well if test results could be given for the second half of the paper, on flexibility; the authors do not make clear whether tests have been conducted, and it is assumed from the paper that the results are on a theoretical basis only.

It is important from the standpoint of the designer to know the practical results and to know how the piping will act when installed. The results of actual tests will be awaited with interest.

W. P. CURLEY.[18] Speaking as a representative of the manufacturers of the seamless tube fittings referred to by the authors, the writer considers their paper a valuable and timely contribution, recognizing as it does the increasing popularity of pipe welding and the somewhat different problems regarding both frictional resistance and flexibility, which must be considered in designing a piping layout having in view welding and stock welding fittings.

Several engineers referred to in the authors' paper are in accord with the theory regarding the rigidity multiplication factor K, which corrects for flattening in the circular cross-section of a curved pipe.

The derivation of K assumes, however, that the stresses are acting on an undeformed section of the pipe, which is true in the case of the seamless tube fitting, but not always true of the pipe bend. Before flexure takes place, the former has a true circular cross-section and a uniform wall thickness corresponding with that of the adjoining straight length of pipe, whereas the pipe bend may have initial ellipticity. It should be emphasized, therefore, that the corrections considered in the paper for flattening cover only the distortion of the circular cross-section during flexure, and do not compensate for any inherent flattening, thinning, and buckling which may have occurred in fabricating the bend from a straight piece of pipe.

A. M. Wahl, in a paper entitled "Stresses and Reactions in Expansion Pipe Bends" (Trans. A.S.M.E., Vol. 50, No. 15, p. 241, Paper FSP-50-49, 1928), has investigated the effect of stress due to permanent flattening or initial ellipticity of the cross-section produced during fabrication of the bend, and has found that while this flattening does not materially influence the stress due to bending moments, it does greatly increase the stress due to internal pressure, and that these stresses, when superimposed on those due to bending moments, may result in stresses sufficiently high to produce permanent set in the piping.

In a more recent paper, "Stresses in Turbine Pipe Bends," (*Mechanical Engineering*, Vol. 51, No. 11, November, 1929, A. M. Wahl, J. W. Bowley, and G. Back), the same author and two co-authors, J. W. Bowley and G. Back, record the results of a test in which actual strain measurements were made around the circumference of a 10-in. extra-strong pipe bend. The test results are compared with the theory developed in the previous paper and show good agreement with the correctness of the theory. Both test and calculations bear out the authors' contention that, because of permanent flattening in fabricating the pipe bends, it might be desirable to specify certain limits regarding the permissible initial ellipticity of the cross-section.

In connection with the flattening theory, it is evident that if a piece of pipe is partly bent and partly straight, as in the case of the square expansion loop, and the point of tangency is subject to a bending moment, the bent pipe will tend to flatten the adjoining straight section, and in turn the straight pipe will have a tendency to restrict the full flattening of the curved pipe. It would be of interest if the authors will clear up these points, since they would seem to influence the location of the point of maximum stress.

In conclusion, considering the several indeterminate factors which may be introduced during the fabrication of a pipe bend, such as ellipticity of cross-section, thinning of outside wall and fiber strains set up due to localized heating during bending, and the bending and torsional stress which may be introduced in the case of flanged bends at the time of installation due to imperfect alignment, all of which tend to have an additive effect on the bending stresses set up when the bend is installed and operating, it seems that, although a maximum stress for design purposes is suggested by the authors to cover both types of loop, a somewhat lower stress-safety factor might be used in laying out the square loop with seamless tube fittings, which has everywhere the full strength and true cross-section of the pipe in the line.

JOHN H. ZINC.[19] The writer is much interested in this paper and discussion because, as a piping contractor, it has been necessary for him to purchase and use both welded fittings and pipe bends. Our industry has accepted and is promoting pipe welding under a control specification supported by the best-known engineering standards. There is no question about it being a new and better type of pipe construction and takes with it the generous use of the tube-turn welded fitting covered by this discussion as well as others. The results obtained by the authors as to flexibility and pressure drop has been confirmed by our experience. It is believed that these tests should be continued to more accurately determine the value of pipe bends for compensation of expansion and contraction with particular reference to incorporated stresses as a result of the bending operation and their relation to the elastic limit of the pipe.

The fact that the tube-turn fitting has no incorporated stresses due to manufacture has prompted us to use them with straight pipe in fabricating our own welded expansion loops of rectangular design with more confidence as to flexibility, anchorage, and convenience of installation to meet our varying structural conditions. Further research in this direction will undoubtedly do much to correct the errors and differences of opinion now in evidence by our present empirical rules in applying values to pipe bends for expansion purposes.

It must not be inferred from this statement that the writer does not recognize that pipe bends have a place in our work, but he must disagree with the statement made by a previous discussor that they properly meet stress conditions and are cheaper. The question of cost will of course depend upon the design of the bend and competitive conditions, but, generally speaking, in our welded piping installations we are eliminating many fabricated pipe bends and using instead the welded fitting and straight pipe for bend construction because of greater flexibility and economy and, further, because we are enabled to control the pipe fabrication within our own shops or on the job itself.

May the writer also refer to the statement of a previous discussor wherein he recommended the use of fittings and straight pipe in making expansion bends as foolproof, cheaper in first cost, and representing an efficiency of only about 5 per cent less than other types. From a practical standpoint, the writer disagrees with him that the fitting expansion bend would be more foolproof because the threaded and flanged joint is not as good a guarantee of tightness, strength, and flexibility as the welded joint, to say nothing of the maintenance cost. As to first cost, in our own shop we can make a welded rectangular bend much cheaper by using a welded design with welded fittings than screw or flanged fittings, and the writer thinks this is generally true.

One representative raises an objection to the welded joint in expansion bends and states that in the design covered in the paper the maximum stresses are concentrated at the weld. It would be interesting to know the basis of this conclusion because it is at variance with the writer's opinion of stress distribution, but assuming he is correct, where else would it be better to concentrate stresses than at the weld, inasmuch as the weld should be equal to or is stronger than the pipe itself? The writer is of course supporting quality welding and passing out of consideration poor welding, as may be expected from workmen who are not able to qualify under similar specification requirements as laid down by our national association. We are prepared to deliver welded pipe installations to meet the most rigid requirements of pressure and temperature. It is the writer's opinion that welding will soon be recognized as the ultimate in pipe installation and that its use will demand a complete revamping of our present methods of determining design for compensation of pipe forces in service.

The writer trusts that his discussion will be accepted in the constructive way intended. He wishes to express his appreciation to the authors for the invaluable service they have rendered the industry, and strongly urges that, as indicated by them, further tests should be made to establish known quantities so that accurate and more readily understood rules for computing flexibility of expansion bends may be made available.

ANDREW A. BATO.[20] Of the points dealt with in the paper that concerning the frictional resistance is showing the longest history of investigations. This is probably because the fact is rather surprising that a greater radius of curvature in a bend does not, beyond a certain limit, mean less resistance, and this fact needs repeated confirmation for every case. Although this fact was discovered more than 25 years ago, the General Electric Company saw fit to conduct experiments to secure further data for the design of large crossover elbows of steam turbines, as published in *General Electric Review*, June, 1927, by Wirt. The results of the tests made with an 8-in. pipe and connected elbows of various shapes and designs, also with square ducts, with air up to 90 lb.

[19] President, The Heat and Power Corporation, Baltimore, Md.

[20] Consulting Engineer, East Orange, N. J. Mem. A.S.M.E.

pressure not only confirm the fact that greater radius does not necessarily mean less resistance, but reveal some new ones; for instance, that the best results could be obtained with an elbow the inner side or throat of which shows a round bend and the outer a sharp, mitered corner.

Before discussing the questions of flexibility and strength a modification in the method of calculating will be presented as it helps greatly in visualizing and demonstrating the various points. The writer showed this method three years ago, and it deserves to be demonstrated more in detail. It is based on the fact that, if the moment at the virtually free end of a pipe line (for instance, of that shown in Fig. 15 of the paper) and the force F acting at the same point are replaced by one single force, parallel to F, but shifted to a distance from the point j so as to give a moment at j equal to the original moment at that point, this shifted force F_M in Fig. 26 of this discussion paper will go through the so-called

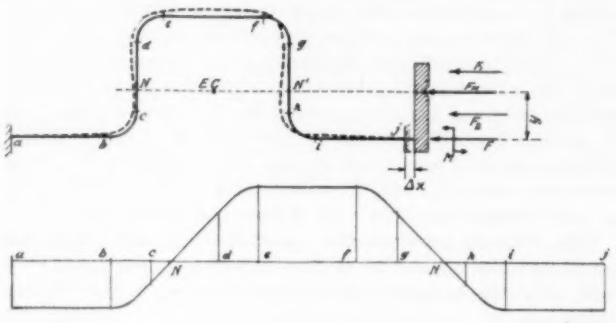

FIG. 26

elastic center EC of the pipe line. EC is nothing but the center of gravity of all elements dl/KEI; that is, of the elements of pipe length divided by the corresponding rigidity factors and modulus of inertia and elasticity. In case of a pipe line made of the same size and type of pipe in its whole length, EC will be very near to the center of gravity of the pipe line itself, the only deviation being caused by K being less than one for the relatively short elbows. The distance y to which the force F has been shifted is the one used in the paper; it is called "ordinate" or "coefficient" of the restraining moment, but it is nothing else but the arm of the force F_M, at the same time the distance of the elastic center for the line connecting the two ends of the pipe line. This can be proved by checking the formula given for y in Appendix No. 2 of the paper, and it can be proved in general for any pipe line held at both ends with the aid of well-known mathematical considerations.

The physical working of this method is visualized on Fig. 26, where the right hand or free end of the pipe line is held by an absolutely rigid arm on which F_M is acting in a distance y from the free end. F_M will have the same effect as F and M together; that is, it will move the point j in a straight line toward a and will at the same time keep the tangent to the piece of pipe ij parallel to itself in j, with no rotation. If F would be shifted into the positions F_1 or F_2, j would move in other directions, and the end at j would rotate. The case is similar to that of a coil spring which will bend out sideways, trying to get out of the way of the force, with the end rotating, unless it will be compressed by a force acting strictly in its axis.

With this modification all the pipe designers will have to do will be to find EC, a relatively simple operation that can be performed graphically, with not much chance for an error, and draw the line containing F_M. The magnitude of F_M itself can then be figured by using the F_M–EC line as the X axis for the system of coordinates. The moments and restraining moments for the end points as well as for any point can be found by multiplying F_M by the distance of the F_M–EC line from those points, which for the purpose of further calculations can be scaled off directly from a drawing, like that in Fig. 26. For the application of the area-moment method to calculate the rotations and deflections, the second diagram of Fig. 26 is drawn, corresponding to the second diagram of Fig. 15 of the paper, with the difference that the ordinates in Fig. 26 give directly the resulting moments. Clockwise above the a-j line and counterclockwise below that line, also the neutral point N where the moment is zero, while in Fig. 15 these ordinates have to be determined by adding and subtracting three lengths or items.

The greatest saving in labor is in the calculation of the rotations and deflections. Of all the figuring in Appendix No. 2, called by the authors "tedious" with right, about 40 per cent can be saved, as the moment areas that have to be added and deducted in Fig. 15 are shown with their net values in Fig. 26.

Furthermore, this presentation helps the designer to bear in mind certain simple rules he has to observe. For instance, the fact brought out by the authors that of the layouts shown in Figs. 17 and 19 the most flexible is the one in which the top of the bend is as long as the sum of the two bottom parts, and that in this case top and bottom are subjected to the same bending moment, can be visualized better if we bear in mind that the elastic center of the bend, in this case identical with the center of gravity of the line, will be just half-way between the top and the bottom of the bend; consequently, the force F_M passing through this center will give equal moments to top and bottom, and will make them work equally, utilizing them for flexibility to the same extent.

This result is also shown in Fig. 18 of the paper, and could be obtained without calculating a number of cases and drawing a curve, simply with the aid of the foregoing considerations.

This "force through elastic center" method points out sharply the importance of the strength of welded joints against bending; this because it shows that wherever the resulting bending moment is a maximum there is always a joint. A paper on the usability of welded joints for pipe lines subject to heat expansion could touch this point by giving figures on the strength of such joints as compared to that of flanged ones. Although the spreading of the use of welding seems to indicate that a welded joint compares favorably with a flanged one, as the costs of the necessary highly skilled labor seem to be offset by the savings on flanged fittings, industrial plants not using the services of firms specializing in piping work but laying their own piping should be warned against making such joints with ordinary steam fitters who are not trained especially in welding pipes, as according to tests quoted by Walker and Crocker in their book on piping both yield point and ultimate strength are about 22 per cent lower for the welded joint than for the pipe itself. On the other hand, joints made by special methods and by trained help proved to be stronger than the pipe.

A very general rule to insure greater flexibility can be arrived at by contemplating the equation giving the force F_M for bends of the discussed type:

$$F_M = \frac{EI\,\Delta x}{\int \frac{y^2 dl}{K}}$$

It is evident that the greater $\int \frac{y^2 dl}{K}$, where dl is the element of length—that is, the more pipe is laid at a possibly great distance from the F_M line—the smaller will F_M be. This is another reason why a square bend is more flexible than a U-bend, and not only

because welded fittings are used. For a fair judging, square bends made with welded joints should be compared with square bends of the same design and layout, but made with flanged joints. The only step in this direction indicated in the paper is a comparison between 90 deg. elbows with welded joints of standard good for 250 lb., which again offers no fair basis. This was probably done because flanged elbows of steel for 125 lb. are not readily obtainable, although they could be used where square expansion bends are preferred to U-bends, but specially skilled labor for welding is not available. For such cases flanged steel fittings may be of good service, as they are more foolproof and if combined with Van Stone connections of sufficient strength they can be readily installed by anybody.

To demonstrate the significance of the layout as compared with that of the seamless tube fittings, the writer figured out the force F acting at the end of the square bend Fig. 19 (*d*) of the paper for the case in which 90-deg. flanged turns are used instead of seamless ones. The turns were assumed to have the dimensions of standard turns, only made of cast steel instead of cast iron. The result obtained for F was 685 lb. as compared with 970 lb. for the double offset U-bend, Fig. 19 (*a*) and 548 lb. for the square bend, Fig. 19 (*d*). With other words for the case in question a 29.5 per cent decrease of F is due to the layout and a further decrease of 14 per cent to the use of the seamless fitting. Naturally the longer the straight sections of the pipe line will be in proportion to the turns the less will be the significance of the seamless fittings from the point of view of flexibility.

It is very hard to find a basis for comparing and demonstrating the significance of the ratio between the radius of the bend R and the pipe diameter d. Where the turn alone was used as such a basis, with a small piece of tangential piping, as in Fig. 12, while R/d changed from $1^1/_2$ to 6, the force necessary to bend it increased 100 per cent, while in the case when the turns were inserted into a square bend, Fig. 14, this increase was only 60 per cent, as the influence of the straight sections came into the foreground. The reader therefore is warned against generalizations on the basis of the paper, and is advised to use the very fine work of Shipman, presented two years ago, for more general information.

All in all, the authors did a nice piece of work in applying the scientific developments of the last few years to a practical problem.

G. K. Sauerwein.[21] This paper will prove of value to many users of piping who are just a little hesitant about the use of welded joints. Such a statement by a prominent piping engineer from a conservative utility should do much to dispel their fears.

That the friction loss in welded lines is less than in lines with screw joints needs no proof. The data given to show that the same is true as regards welded lines when compared with standard flanged construction are very assuring and helpful to the user, because it means saving in pumping power.

The authors have shown further by mathematical investigation that the use of welding elbows with proper design will also give greater flexibility to the lines. This, too, is a fact of great significance to the user. It affects the maintenance and life of the hot-water and steam lines. For our own purpose we arrived at the same conclusion after making some simple comparative tests.

The use of welding and of seamless tube elbows is already spreading at a rapid rate. Except in the most unusual cases the first cost of a job can be reduced by the use of welding. As the price of welding elbows falls by reason of increased use and willing labor becomes more skilful, the initial cost of welded piping will be still further reduced.

Much evidence is being accumulated which shows that maintenance expense is also less for welded lines than for lines with other types of joints. This is true for our own case at Harvard University when we have a great deal of piping in buildings, in tunnels and conduits, and in heating plants. On the older screwed and bolted piping, fittings are failing, and Van Stone lips are cracking off, gaskets giving out, flanges cracking, bolts failing, etc. Wherever practicable, welded work is replacing screwed or bolted work that gives out. It costs less to make a welded joint than to remake a gasketed and bolted joint.

On all of the new work now being done at the university, totaling in value about $20,000,000, welded piping is being specified for lines 2 in. and larger except for valves, in buildings, in tunnels, and in conduits, and also in the new Medicine School power plant. Welded piping in a power plant presents a very nice appearance.

A. E. R. de Jonge.[22] The writer would desire to join the others in thanking the authors for their very interesting paper. There is, however, one question he would like to have cleared up. The authors have confined themselves in their paper to the analysis of the elasticity and flexibility of plane pipe bends and their combinations and have not covered the flexibility of pipe lines in space. The writer would therefore ask Mr. Crocker if any experiments have been made on pipe lines in space and if these have been compared with the calculations by the method given in the "Piping Handbook" by Walker and Crocker.[23]

[Mr. Crocker answered this question in the affirmative and mentioned that the results of these experiments compared very well with the mathematical analysis as given in the "Piping Handbook."]

This is a very interesting statement by Mr. Crocker, as one would have expected considerable deviation of the test results from those of the analysis owing to the latter not being correct. It is always an unpleasant task to have to point out errors committed by others and doubly so if committed by men who by their past contributions have shown that they have the advance of the art very much at heart.

The authors' errors occurred in their mathematical analysis and make their results incorrect. This is to be deplored the more as they are contained in an otherwise very useful handbook, which probably will find its way to every engineer interested in pipe-line problems. Due to the reason that the spreading of this error is thus most difficult to check, the writer has felt forced to draw attention to it. The errors occur in the cases [drawing a sketch on the blackboard] of a 90-deg. pipe bend acted upon by a force perpendicular to the plane of the bend, by a moment acting perpendicular to the plane of the bend and tangentially to its free end and by a moment acting as a twisting moment on the free end, in which class there has been an error committed by interchanging the bending and twisting components whereby sine and cosine in the integrals have been reversed. Besides, in their elementary cases IX and X the authors have omitted one angular component of deviation completely, thereby getting a simple plane set-up for the determination of the components of reaction in the case of a space pipe line where they should get a space set-up.

The writer would add that he has made very careful experiments with bends and has found their results in good agreement with his formulas for these cases, but differing rather widely from the authors' formulas.

In referring to the whole problem of the flexibility of pipe lines, there is no necessity for calculating plane pipe lines according to the rather complicated method of the authors. As Mr. Bato has shown before, the question of plane pipe bends can be dealt

[21] Engineer, Lehman Hall, Harvard University, Cambridge, Mass. Mem. A.S.M.E.

[22] New York, N. Y.

[23] Published by the McGraw-Hill Book Company, New York.

with much easier by making use of the center of elastic weights of the pipe line as a whole. This method is not new at all and is well known to civil engineers who have been using it for the calculation of arched girders for several decades. This method becomes particularly simple if the theory of the ellipse of elasticity is used. By means of the ellipse of elasticity the solution of any plane piping problem can be readily accomplished, and the writer cannot understand why this method, to which he had drawn attention at the meeting of the Society in 1928,[24] is not used more extensively by American engineers. This method presents an almost purely graphical analysis which can be easily carried out on the drafting board.

When we, however, go into space the problem becomes very much more complicated. Here the elasticity ellipse changes into an ellipsoid of elasticity. If the pipe line has in any way a symmetrical set-up, the axes of the resulting ellipsoid can be easily obtained, and the solution of the flexibility problem presents little difficulty. If, however, the set-up is unsymmetrical, as in most practical cases, the ellipsoid lies oblique in the space of the pipe line, and the problem has to be solved to find the principal axes of this oblique ellipsoid. This is a problem of the third degree and not of the second. Thus the solution cannot be tackled by means of compass and ruler solely, if a graphical solution is chosen, nor by quadratic equations, if the analytical

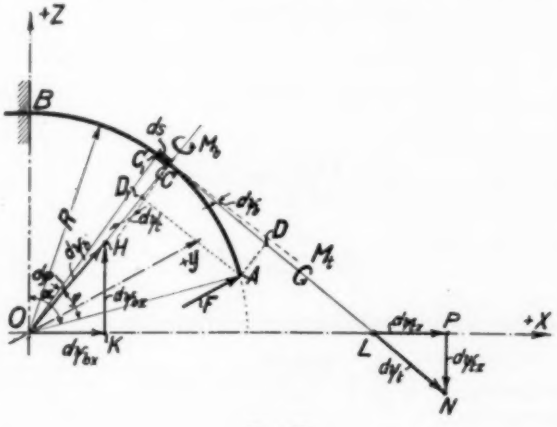

FIG. 27

method of deduction is adopted. In the former case use has to be made of other curves (hyperbolas and ellipses) and in the second case of a cubic equation. This explains why the problem of space pipe lines has been such a difficult one to solve. The writer arrived at the solution of this problem some time ago, and had hoped to be able to present it at this meeting, but was not able to complete the paper.

GENERALIZED FORMULAS AND THEIR DERIVATION

Having been advised by the authors that they propose to publish the derivations of the formulas for their cases VIII, IX, and X ("Piping Handbook") as revised by Dr. Timoshenko in their closure, the writer herewith submits his own formulas, which will be found to embrace several other cases besides the 10 fundamental cases of the authors. As there are many occasions where 30-, 45-, or 60-deg. and even $22^1/_2$-deg. bends are used, it may be convenient to have the necessary formulas handy, and it was for this reason that the writer has derived formulas of a general nature covering these cases.

The derivation of these general formulas is simple and will be given for the case of a bend of an angle α fixed at one end and acted upon at the free end by a force F perpendicular to the plane of the bend.

In Fig. 27 let AB be the bend fixed at B; R the radius of the center line of the bend; CC_1 an element ds; α the angle subtended by the bend; φ the angle AOC; O the center of the bend; $d\varphi$ the angle subtended by the element ds; CDL the tangent of the bend in C; AD a perpendicular from A onto the tangent; AD_1 a perpendicular from A onto the radius OC; F the force acting in A perpendicular to the plane of the bend. Further, let OX, OY, and OZ be the axes of a right-hand-screw space reference system, OY being perpendicular to the plane of the bend.

The force F acting on the lever AD_1 produces a bending moment M_b at C about the radius OC, the rotational direction of which moment is indicated by a circular arrow around the produced radius OC. The reaction F at C producing pure shear in the element ds is of little importance and will be neglected.

Likewise the force F acting on AD produces a twisting moment M_t at C about the tangent CD, the rotational direction of which is indicated by a circular arrow around the tangent CD. Thus the bending moment acting at C is:

$$M_b = FR \sin \varphi \quad \ldots\ldots [1]$$

and the twisting moment acting at C is:

$$M_t = FR(1 - \cos \varphi) \quad \ldots\ldots [2]$$

These moments produce deformations of the element ds.

The angular rotation of the part CA of the bend due to the bending moment, considering ds elastic only, is:

$$d\psi_b = \frac{M_b ds}{EI} \quad \ldots\ldots [3]$$

and that due to the twisting moment:

$$d\psi_t = \frac{M_t ds}{GJ} \quad \ldots\ldots [4]$$

where E = modulus of elasticity
G = modulus of rigidity (shear)
I = plane moment of inertia of pipe cross-section, and
J = polar moment of inertia of pipe cross-section.

Further there is:

$$G = \frac{E}{2(1 + \mu)} \quad \ldots\ldots [5]$$

where μ is Poisson's ratio, which may be taken for steel as $\mu = 0.3$. Since for circular cross-section

$$J = 2I \quad \ldots\ldots [6]$$

then

$$GJ = \frac{EI}{1 + \mu} = \frac{EI}{1.3} \quad \ldots\ldots [7]$$

Substituting this value into Equation [4],

$$d\psi_t = (1 + \mu) \frac{M_t ds}{EI} = 1.3 \frac{M_t ds}{EI} \quad \ldots\ldots [8]$$

Since these angular rotations do not lie in the same plane they cannot be composed algebraically. They can be represented, however, by vectors, using a right-hand screw system throughout, the vectors pointing in such a direction that the rotation, if viewed in the direction of the vector, takes place clockwise or in a "right-hand" sense.

Having established this relation, it is an easy matter to find the correct direction of rotation, the vectors or their components parallel to the reference axes being counted positive if acting in

[24] A.S.M.E. Trans., vol. 51, 1929, APM-51-18, p. 210.

the direction of the positive axes and negative if of opposite sense. Components in the same axis or parallel to it can then be added algebraically.

Thus the rotation due to bending $d\psi_b$ may be represented by the vector $\overrightarrow{OH}$, and the rotation $d\psi_t$ due to twisting by vector $\overrightarrow{LN}$, both being correct as to sense.

The components of these rotations along OX and OZ are:

$$\left.\begin{aligned} OK &= d\psi_{bx} = d\psi_b \sin(\alpha - \varphi) \\ LP &= d\psi_{tx} = d\psi_t \cos(\alpha - \varphi) \end{aligned}\right\} \quad \ldots\ldots\ldots [9]$$

$$\left.\begin{aligned} KH &= d\psi_{bz} = d\psi_b \cos(\alpha - \varphi) \\ PN &= d\psi_{tz} = -d\psi_t \sin(\alpha - \varphi) \end{aligned}\right\} \quad \ldots\ldots\ldots [10]$$

The two Equations [9] added give the total rotation around the X-axis and the two Equations [10] likewise that around the Z-axis. Thus,

$$\begin{aligned} d\psi_x &= d\psi_{bx} + d\psi_{tx} \\ &= d\psi_b \sin(\alpha - \varphi) + d\psi_t \cos(\alpha - \varphi) \end{aligned}$$

or with Equations [3] and [8],

$$= \frac{M_b ds}{EI} \sin(\alpha - \varphi) + (1 + \mu) \frac{M_t ds}{EI} \cos(\alpha - \varphi)$$

and substituting from [1] and [2] gives

$$d\psi_x = \frac{FR^2}{EI} \sin\varphi \sin(\alpha - \varphi)\, d\varphi + (1 + \mu) \frac{FR^2}{EI} (1 - \cos\varphi) \cos(\alpha - \varphi)\, d\varphi,$$

If $ds = Rd\varphi$; and by making

$$\frac{FR^2}{EI} = C \quad \ldots\ldots\ldots\ldots\ldots [11]$$

$$d\psi_x = C[\sin\varphi \sin(\alpha - \varphi) + (1 + \mu)(1 - \cos\varphi)\cos(\alpha - \varphi)]\, d\varphi$$

Integrating this equation over the length AB of the bend, or over the angle α:

$$\psi_x = C \int_0^\alpha [\sin\varphi \sin(\alpha - \varphi) + (1 + \mu)(1 - \cos\varphi)\cos(\alpha - \varphi)]\, d\varphi$$

or

$$\psi_x = C \cdot \left(1 + \frac{\mu}{2}\right) [\sin\alpha - \alpha\cos\alpha]$$

and substituting for C its value in [11], we find for the total rotation around the X-axis:

$$\psi_x = \frac{FR^2}{EI} \left(1 + \frac{\mu}{2}\right) [\sin\alpha - \alpha\cos\alpha] \quad \ldots\ldots [12]$$

In a similar manner we find the rotation around the Z-axis. From Equations [10], [11], [1] to [3], and [8],

$$\begin{aligned} d\psi_z &= d\psi_{bz} + d\psi_{tz} \\ &= C[\sin\varphi \cos(\alpha - \varphi) - (1 + \mu)(1 - \cos\varphi)\sin(\alpha - \varphi)]d\varphi \end{aligned}$$

and by integration over the whole length of the bend:

$$\psi_z = C \int_0^\alpha [\sin\varphi \cos(\alpha - \varphi) - (1 + \mu)(1 - \cos\varphi)\sin(\alpha - \varphi)]d\varphi$$

whence

$$\psi_z = \frac{FR^2}{EI} \left[\left(1 + \frac{\mu}{2}\right) \alpha \sin\alpha (1 + \mu)(1 - \cos\alpha)\right] \ldots [13]$$

For the displacement of A (free end) in the direction of the force we find the deflection:

$$d\Delta = d\psi_b \cdot R \sin\varphi + d\psi_t R(1 - \cos\varphi)$$

or using Equations [1], [2], [3], [8], [10] and putting $ds = Rd\varphi$,

$$d\Delta = RC[\sin^2\varphi + (1 + \mu)(1 - \cos\varphi)^2]d\varphi$$

and by integration over the whole length of the bend from A to B:

$$\Delta = RC \int_0^\alpha [\sin^2\varphi + (1 + \mu)(1 - \cos\varphi)^2]d\varphi$$

whence

$$\Delta = \frac{FR^3}{EI}\left[\left(2 + \frac{3}{2}\mu\right)\alpha + \frac{\mu}{2}\sin\alpha\cos\alpha - 2(1 + \mu)\sin\alpha\right] [14]$$

Equations [12], [13], and [14] are the general expressions for a bend of any angle α. If we put $\alpha = \frac{\pi}{2}$ and $\mu = 0.3$, we obtain the equations for the quarter-bend, thus:

$$\psi_{x_{90}°} = 1.15 \frac{FR^2}{EI} \quad \ldots\ldots\ldots\ldots [12a]$$

and for:

$$\psi_{z_{90}°} = \frac{FR^2}{EI}\left[1.15 \frac{\pi}{2} - 1.3\right]$$

or

$$\psi_{z_{90}°} = 0.5064 \frac{FR^2}{EI} \quad \ldots\ldots\ldots\ldots [13a]$$

Also

$$\Delta_{90°} = \frac{FR^3}{EI}\left[2.45 \frac{\pi}{2} - 2.6\right]$$

or

$$\Delta_{90°} = 1.24846 \frac{FR^3}{EI} \quad \ldots\ldots\ldots\ldots [14a]$$

From these equations we find the radii of rotation:

$$r_x = \frac{\Delta}{\psi_x} = \frac{1.24846}{1.15} R = 1.0856R \quad \ldots\ldots [15a]$$

and

$$r_z = \frac{\Delta}{\psi_z} = \frac{1.24846}{0.5064} R = 2.4654\, R \quad \ldots\ldots [16a]$$

Similarly, for a 45-deg. bend, $\alpha = \frac{\pi}{4}$ and $\sin\alpha = \cos\alpha = \frac{\sqrt{2}}{2}$,

$$\psi_{x_{45}°} = 0.1745 \frac{FR^2}{EI} \quad \ldots\ldots\ldots\ldots [12b]$$

$$\psi_{z_{45}°} = 0.05287 \frac{FR^2}{EI} \quad \ldots\ldots\ldots\ldots [13b]$$

$$\Delta_{45°} = 0.16075 \frac{FR^3}{EI} \quad \ldots\ldots\ldots\ldots [14b]$$

$$r_x = 0.9212\ R \quad \ldots\ldots\ldots\ldots [15b]$$

$$r_z = 3.0404\ R \quad \ldots\ldots\ldots\ldots [16b]$$

The equations developed above form a generalized case corresponding to the authors' case VIII. In a similar manner all other cases can be treated. If one does not confine oneself to quarter-bends, and the writer has not been able to do so in his practice, then 24 general cases result, from which all specific solutions can be obtained by simple substitution of the proper angle of the bend and its trigonometric functions.

FIG. 28 GENERAL CASES FROM WHICH SPECIFIC SOLUTIONS CAN BE OBTAINED BY SUBSTITUTION OF THE PROPER ANGLE OF BEND

Assuming the angular bend to be fixed to a vertical plane, four cases occur:

1 The coordinate system may pass with one of its axes through the fixed end of the bend.

2 The coordinate system may pass with one of its axes through the free end of the bend.

3 The forces and moments may act at the free end of the bend parallel and perpendicular to the fixing plane.

4 The forces and moments may act at the free end of the bend parallel and perpendicular to the free flange.

In all we get thus 24 general cases, which are given in Fig. 28. These cases allow of the numerical calculation of all pipe bends and also of pipe lines if their end reactions are known. It is assumed that the latter have been found. The writer will show how they can easily be found in a later communication.

The factor K in the formulas is the rigidity factor of the pipe section.

AUTHORS' CLOSURE

The discussion has brought forth much of interest regarding pressure drop and flexibility in piping. That certain points which seemed clear to the authors actually need amplification was demonstrated by several additional examples presented in the discussion, either to bring out new phases of the problem, or to develop points which were not explained in sufficient detail. In this connection the authors would again call attention to their statement in the conclusion to the paper that they had chosen typical specific cases for flexibility analysis to show the general trend of such comparisons and how other cases could be worked out, rather than attempting to draw sweeping conclusions. Other points outside the original scope of the paper have been introduced in the discussion and require explanation in this closure.

It was to be expected, of course, that some conclusions drawn by the authors might be misconstrued, or would not be accepted by all. This is apt to be the case when dealing with a new type of construction, especially one involving welding, which is still in a stage of development, involving more or less controversy between enthusiasts for welding and those distrustful of its use. The authors have striven to present the facts as they saw them in an impartial way, calling attention to the advantages or limitations of the product under discussion, and pointing out how to minimize these limitations in laying out pipe lines. In some instances identical points have been raised in two or more discussions and can best be taken up collectively in the closure, while other points require individual attention.

Welded Construction. Much has been said for and against the use of welded construction. Some are against it on the ground that it is a new and relatively unperfected art; others oppose it as upsetting the established use of screwed or flanged fittings and screwed or Van Stoned pipe. Both of these objections are bound to be overcome by time and progress—those who oppose welding now may be its earnest advocates five or ten years hence. An interesting exposition of this point is quoted from an editorial in *Metal Progress* for January, 1931:

It is recorded that the first use of iron pipe (other than cast iron) occurred in 1815, when Murdock promoted a gas-lighting plant for London. The inventor collected old musket barrels, which he screwed together to form continuous tubes reaching from his coal-gas generators to the burners.

Suppose, if you can, that modern equipment for fusion welding had been available to Murdock a hundred years ago, and to the inventors who developed butt-welded and lap-welded iron pipe—not only available, but well enough known so a welded joint was the standard joint in 1887 (when the first steel pipe was made).

In other words, picture a situation where piping or plumbing contractors had acquired long experience with the oxyacetylene cutting and welding blowpipe and had organizations well skilled in the use of these tools. Architects and designers would be familiar with the properties and capabilities of welded joints; pipe and valve manufacturers would be producing lines of goods especially designed for welded joints.

Suppose such a piping contractor in such an age had been approached by a salesman with this new idea: That pipe joints should be made by screwing together instead of welding. How far do you suppose he would get in his argument?

Here are the "advantages" which such a change would involve:

In the first place, the all-purpose tools so familiar (the cutting and welding equipment) would be superseded by hacksaws, pipe cutters, and a series of thread-cutting dies and die holders, a different die for each diameter of pipe to be used.

In the second place, the contractor would be invited to purchase and carry in stock a large number of ells, tees, branches, reducers, plugs, flanges, bolts and gaskets—a complete supply for each diameter of pipe in use, multiplied by two if light-pressure and heavy-pressure work were in prospect.

Third, the owner of the installation would be asked to assume the added expense of buying pipe heavier than really necessary to carry the pressure—pipe with walls thickened from end to end to give enough stock for the threading at the joints.

For a "bottle tight" joint, industry would get a mechanical fitting with many chances of leakage—a joint which, if by excellent workmanship is originally tight, is certain to be the source of eventual trouble, either through the loss of valuable contents of the pipe or by damage to surrounding property by escaping liquid.

Lastly, the prospective purchaser of the screwed joint would be asked to endure multiplication of work, expense, and time when additions or alterations to existing pipe systems were to be made.

To balance these inherent characteristics and disadvantages of the screwed pipe joint, what could be offered in compensation to an industry, a firm or a workman already possessing welding equipment and welding skill?

The authors do not imply that fusion welding as done in the field has reached a state of complete perfection, but the process has made rapid strides in the past few years and those who do not employ it to some extent at least are not keeping abreast of the times. As pointed out in the quotation, the practice of making the whole length of each piece of threaded pipe thick enough to stand threading for a short distance at each end is

FIG. 29 TYPICAL EXAMPLES OF FAILURE FROM CORROSION OF THREADED PIPE ENDS

extremely wasteful of material. On the other hand, if the extra thickness of pipe wall between the threaded ends is required to resist failure from corrosion, why deliberately create weak spots in the structure by threading the joints? The tendency for failure in the threaded portions of standard-weight pipe operating even at low pressures such as obtain in building heating and plumbing systems is not widely enough appreciated. Fig. 29 shows typical examples of failure from corrosion in such piping. The three specimens at the left are "black" steel pipe taken from a "dry" return line in a low-pressure building-heating system after about five years of service. The threaded portions completely rusted through were on the lower side of horizontal runs where condensation washed along more or less continuously. The upper portions, which were not so continuously immersed, were not so badly affected. The two specimens at the right are galvanized steel pipe taken from the city water piping in a residence after ten years use. All specimens were removed from service because of leaks in the threads. The remaining wall thickness in the unthreaded portions of all specimens would have been ample for many more years of service had failure not occurred in the threads. While these specimens which happened to be available at the time represent relatively small nominal sizes of pipe, the same observations hold true for larger sizes which lend themselves more readily to welding. These observations are offered as indicating superior corrosion-resisting properties for welded construction over screwed for pipe of the same material and wall thickness.

Concern has been expressed in the discussion regarding bending moments and stress concentrations at welds. The authors agree that this is a matter worth serious consideration, especially where service conditions involve high temperature or high pressure or both. While it is well known that the strength of good fusion welds frequently exceeds the strength of the normal pipe cross-section, especially where a bead is built up at the weld, this favorable strength relation does not exist, of course, with poorly made welds. The problem therefore resolves itself into controlling the process and the personnel so as to obtain uniformly satisfactory results. Present practice seems to indicate that a consistent weld efficiency of 75 to 80 per cent is within reason to expect. This is borne out by the tentative rules laid down for fusion-welded construction in the A.S.M.E. codes for the construction of boilers and unfired pressure vessels which allow a fusion-weld efficiency of 80 per cent. This efficiency compares to advantage with the relation set up in the Boiler Code between low-carbon seamless steel pipe (allowable stress by formula, 9000 lb. per sq. in.) and lap-welded steel pipe (allowable stress, 7000 lb. per sq. in.), which gives an efficiency for a furnace-welded pipe of $7000 \div 9000 = 0.78$, or 78 per cent. On this basis fusion-welded pipe joints would be considered equal to the lap-welded pipe which is commonly used in moderate-pressure pipe bends for temperatures not exceeding 750 deg. fahr. It is to be expected that as the technique of fusion welding is perfected and more confidence is placed in its reliability, the application of welded construction to piping operating at higher pressures and temperatures will be a matter of course. As an example of what is being done at the present time, high-pressure piping in the power and central heating plants of the Consolidated Gas, Electric Light, and Power Company of Baltimore, Md., is operating satisfactorily with welded joints. Welds for pressures above 350 lb. gage are made up with reinforcing sleeves, and the turns are made with long-radius bends having tangents on the ends to accommodate the sleeves.

Criticism also has been directed at built-up bends on the ground that joints or welds at points of maximum bending moment can be avoided by the use of conventional types of expansion U-bends made in one piece. In a limited sense this is true, but in many actual pipe lines flexibility is obtained by taking advantage of directional changes in the lines rather than through the insertion of expansion U-bends. Where expansion is taken up by the spring in runs of pipe at right angles to one another, it usually is impossible to prevent high bending moments from being applied at some of the joints. Under such circumstances long-radius bends have no advantage over seamless-tube fittings as far as avoiding bending moments at joints goes. The authors employed expansion U-bends in their comparisons as representing simple cases where the analysis could be followed easily, but not with the idea of advocating the replacement of such bends by built-up bends where the former could be used to advantage.

Question has been raised regarding concentration of stress at welds due to the absence of tangents at the ends of seamless-tube elbows as made at present. This may appear objectionable from theoretical considerations, but so far as the authors are aware no actual failure has been attributed to the absence of such tangents. The construction without tangents possesses certain advantages from a manufacturing standpoint in that the fittings can be made as 180-deg. bends and then cut off into forty-fives, nineties, or into any desired angle as required. From a design and installation standpoint, the absence of tangents is desirable in that it provides the maximum radius of curvature for a given center-to-end dimension. While the fittings described by Messrs. Houser and Hirschberg as being forged in halves and welded together

possess tangents at the ends, it would appear that this feature is offset by the presence of two longitudinal welds and a shorter radius of curvature. Consideration should be given the fact that hoop tension in a pipe wall due to internal pressure is for practical purposes exactly twice the longitudinal stress in the wall due to the same pressure. From this it follows that longitudinal welds are subject to twice the bursting stress existing in circumferential welds. If transverse stresses due to flattening of the cross-section of a curved tube during flexure are considered, high stress concentration may occur in the longitudinal welds. This condition should be taken into account in setting safe working stresses for welds in the two positions, bearing in mind that the conditions under which a weld is made also affect its reliability.

The convenience of having ready-made tees, crosses, and the like manufactured by Mr. Houser's method is attractive, and there is bound to be extensive use for both these and seamless-tube elbows. Failure to mention welded fittings forged in halves was not intentional, as they are a recent development which was not announced until after presentation of the paper. It would seem also that there was use for standard sizes of long-radius bends made up with tangents on the ends for welding.

Frictional Resistance. Several engineers discussing the paper have intimated that the authors stated the frictional resistance of seamless-tube elbows having a radius of $1^1/_2$ pipe diameters was less than for long-radius pipe bends. Such is not the case as the authors merely strove to point out that the data indicated not much was gained by using a radius greater than $1^1/_2$ to 2 pipe diameters. Professor Eustice's curve offered by Messrs. Houser and Hirschberg in Fig. 23 tends to support this statement, and at the same time explains in a most interesting manner the observations of certain earlier investigators regarding fluctuations in pressure drop for radii exceeding $2^1/_2$ diameters. Williams, Hubbell, and Fenkell reported having observed the same phenomenon for large pipes in their classical paper from which the following is quoted:[25]

> *Curvature and Other Effects.* The foregoing experiments, taken as a whole, prove beyond question or doubt that the hitherto accepted notions of the laws governing curve resistance are wholly in error. As was suggested in the discussion of the velocity curve, the resistance due to curvature is proved to be very much less in the short than in the long-radius curves for the same total length of pipe and angle of deflection. From the experiments upon the 30-in. pipe, as well as those on the 12-in., it is apparent that the 90-deg. curve introducing the least resistance in a total length of 80 diameters is one of between 2 and $2^1/_2$ diameters radius.

The test-data curves of Williams, Hubbell, and Fenkell show increasing resistance with increasing radius from 2 or $2^1/_2$ diameters up to a secondary maximum point at 6 or 8 diameters, and then continue with an undulating shape similar to that obtained by Professor Eustice. The authors are indebted to Messrs. Houser and Hirschberg for calling attention to the most interesting and valuable exposition of this phenomenon by Professor Eustice which had escaped their notice. This offers a logical explanation for an observed flow characteristic the reason for which previously was not understood as being due to periodical changes in direction of tangential flow vortices. Professor Eustice's curve (Fig. 23) shows a minimum point at $R/d = 2.91$ and a secondary maximum at 6.85, the general shape of the curve bearing out the authors' observation that pressure drops decrease rapidly as R/d ratios increase from less than unity to $1^1/_2$ or 2, and that little is to be gained by using ratios greater than $1^1/_2$ or 2.

The following plausible and clearly stated explanation of the reasons for an increase in bend friction for R/d ratios greater than 2 to 3 was offered by J. L. Campbell[26] in discussing the Williams, Hubbell, and Fenkell paper:

> Undoubtedly, with a given velocity, the intensity of disturbance, and consequently of resistance, in a sharp turn is greater than in a gentle turn; but with equal angular deflections it acts through a shorter distance. As this greater intensity of the shorter turn multiplied by its lesser distance is, apparently, smaller than the lesser intensity of the long turn multiplied by its greater distance, the larger resistance of the latter is clearly due to the continued agitation of the water in the long curve.

The foregoing statement coupled with the explanation of Professor Eustice offers a rather satisfactory analysis of the sinuous-curve shape of Fig. 23. The greater number of times the vortices change direction in the longer-radius curves of Fig. 23 is incidental to the "continued agitation of the water in the long curve." The fact that with certain combinations the vortex emerges tangent to the bend and with others at an oblique angle accounts for the maxima and minima points on the curve. Eventually, as the radius of the bend increases, a point is reached where disturbance due to curvature is so slight that the overall pressure drop is less than the minimum occurring with medium radius bends of 2 to 3 diameters.

In referring to the tests of Professor Giesecke, Messrs. Houser and Hirschberg assign an R/d value of 4 to 3-in. "standard" long radius elbows. It is not clear from either Professor Giesecke's paper or the writers' statement just what a "standard" screwed long-radius elbow is. Apparently the only American standard approaching such a description is that for 150-lb. Long-Turn Sprinkler Fittings B16g-1929. Examination of this standard does not indicate any such favorable relation as $R/d = 4$ for long-radius screwed elbows. The R/d values based on "Radius of Sweep" dimensions taken from this standard compare as follows with the corresponding R/d values for 125-lb. standard screwed elbows as computed by the authors and shown in Table 1 of the paper:

R/d RATIOS FOR 125-LB. STANDARD ELBOWS AND 150-LB. LONG-RADIUS SCREWED ELBOWS

Nominal size, in.....	$2^1/_2$	3	$3^1/_2$	4	5	6
Standard.....	0.7	0.7	0.7	0.7	0.7	0.6
Long radius.....	1.4	1.3	1.3	1.3	1.2	1.2

Assuming that the above values truly represent curvature relations of fittings tested by Professor Giesecke, it would appear that his long-radius elbows have an R/d ratio of 1.3 instead of 4 and that the conclusion of Messrs. Houser and Hirschberg regarding the existence of a considerable difference between these tests and the curves of Fig. 11 is in error. In any event the foregoing comparison serves to emphasize the fact that long-radius elbows are, in the main, inferior to seamless-tube elbows as regards pressure drop.

In Fig. 24 Messrs. Houser and Hirschberg compare two right-angle turns of the same center-to-face dimension, one made with a seamless-tube elbow and the other with a long-radius bend. To carry this comparison through to a definite conclusion, the authors have assumed 12-in. pipe with $R/d = 1^1/_2$ for the seamless-tube elbow and $R/d = 5$ for the long-radius bend. On this basis 7.85 linear feet of pipe are required for the long-radius bend as against 9.36 feet for the seamless-tube elbow with tangents welded on. This corresponds to an excess of 19 per cent in the linear feet of pipe required for the latter. To get at the relative frictional resistance for the two types of bends, assume the equivalent resistance of the seamless-tube elbow as 12 diameters (12 ft. in this case) and that of the long-radius bend as 0.8 the resistance of the former, or 9.6 diameters (or feet). The total equivalent lengths for computing the resistance of the two bends then are:

[25] "Experiments at Detroit, Mich., on the Effect of Curvature Upon the Flow of Water in Pipes," by Gardner S. Williams, Clarence W. Hubbell, and George H. Fenkell, Trans. A.S.C.E., vol. 47 (1902), paper no. 911, p. 183.

[26] Trans. A.S.C.E., vol. 47 (1902), p. 221.

Seamless-tube elbow assembly	9.36	+	12.0	= 21.36 ft.
Long-radius pipe bend.....	7.85	+	9.6	= 17.45 ft.
Difference.....				3.91 ft.

The increased resistance of the seamless-tube elbow assembly over the long-radius bend is 3.91 ÷ 17.45 = 0.222, or 22.2 per cent. Considering bends as only a part of a complete piping system which is made up largely of straight pipe, it seems safe to say that the resistance of the whole system should not be increased more than 10 per cent by the use of the shorter-radius bends. In fact, if there are globe valves, stop and checks, turbine throttles, or similar valves in the line, the percentage increase chargeable to the use of seamless-tube elbows may be less than 10 per cent.

A one-line drawing of a 12-in. line approximating conditions

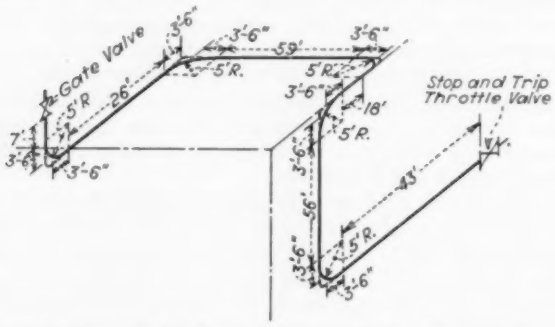

FIG. 30 TYPICAL PIPE LINE IN SPACE (12-IN. TURBINE LEAD)

for an actual turbine lead is shown in Fig. 30. The offsets in this line were required to drop from the steam-header elevation to the turbine-throttle level, and to clear the building structure and mechanical equipment. Assuming a steam flow of 350,000 lb. per hour at a pressure of 380 lb. gage and a temperature of 700 deg. fahr., the pressure drop computed by Fritsche's formula is approximately 3 lb. per 100 ft. In the case of long-radius bends the pressure drop due to change in direction is assumed to be 0.8 that of the seamless-tube elbows, although whether this relation holds true at such high velocities is uncertain. The equivalent lengths of the line with the corresponding pressure drops, including valves, are shown below for (*a*) turns made with long-radius pipe bends, and (*b*) turns made with seamless-tube elbows.

	R/d	Equivalent length, ft.	Pressure drop, lb. per sq. in.
(*a*)	5	403	12.09
(*b*)	1½	422	12.66

From which it appears that in this instance the excess friction loss in the line made up with seamless-tube elbows is less than 5 per cent greater than that in the line made up with long-radius bends.

The authors have not attempted to draw cost comparisons in the paper, but it is pertinent to point out that the 19 per cent excess in linear feet of pipe required in their analysis of Fig. 24 (which includes the seamless-tube elbow itself) plus the cost of making four welds would be balanced against the relative cost of fabricating a seamless-tube elbow vs. a long-radius bend, plus the cost of two pairs of flanges with their bolts and gaskets. On the other hand, if the long-radius bend is to be connected in the line by welds, there will be a reduction of one or two in the total number of welds required, which saving should be balanced against the convenience of using a ready-made seamless-tube elbow. Exception is taken to the generalized cost inferences drawn by Mr. Stuart on the grounds that they do not refer to any definite construction details and are not supported with cost data of any sort.

In commenting on Mr. Tanner's discussion, the authors would say that his analysis of the relative friction loss in bends having R/d ratios of 1½ and 5 affords an interesting comparison for design purposes. Attention is called to an error on his part in computing the relative losses from the Buffalo Forge Company's curve. Referring to the original curve in that company's handbook "Fan Engineering," which is drawn to a larger scale than the curve reproduced in Fig. 8 of this paper, it appears that the correct ratio is 81 per cent rather than the 72 per cent stated by Mr. Tanner. Based on a rough average from the curves of Figs. 8, 10, 11, and 23, the authors would suggest for design purposes that the resistance of long-radius pipe bends (R/d = 5 to 6) be considered as approximately 80 per cent of the resistance of seamless-tube elbows (R/d = 1½). This suggestion is offered as furnishing a working value for the time being until more complete data embracing more fluids, pipe sizes, and velocities are available. In this connection the authors would question the authority for Mr. Tanner's statement that "For low velocities the difference in loss between 1½ and 5 diameters is small, but for steam at high velocities it becomes appreciable as shown by all observers." As previously stated by the authors, they are not aware of any comprehensive tests on the pressure drop of steam flowing through bends of different radii.

In discussing the flow of air through elbows of different radii Mr. Cramer has assumed that the resistances given in Figs. 9 and 10 include an allowance for the measured length of travel along the center line of the bends which was not included in the curves for water flow in Fig. 11. Subsequent review of this point by the authors indicates that Mr. Cramer's assumption is in error and that the measured length of travel should be added to the bend resistance in each case. This practice is followed in most texts and papers on ventilation, although treatment of the subject often is not as clear as might be desired. The authors referred Mr. Cramer's interpretation of Figs. 9 and 10 to W. D. Edwards, who was the original source of these data, and received the following explanation:

> The linear feet of pipe, including the center line length of the bend, is separated from the resistance offered by the shape of the bend, or in other words, in my piping length I would measure and include this center line, to which I would add the bend resistance factor. This is in opposition to the interpretation of Mr. Cramer.

However, in the case of Fig. 8, which is reproduced from "Fan Engineering," subsequent inquiry indicates that in the opinion of the engineers of the Buffalo Forge Company and of the Carrier Engineering Corporation, the measured length of travel along the center line of the bends is included in the curve for pressure loss in bends presented by the late Frank L. Busey.

The authors regret that this distinction was not made clear in presenting their paper, and thank Mr. Cramer for calling attention to the oversight so that it can be corrected. Taking into account the measured length of travel gives the following tabular relation which is offered in lieu of that presented in Mr. Cramer's discussion:

R/d.....	0.50	0.75	1.00	1.25	1.50	2.00	3.00	5.00
Measured length in diameters = $2(5 - 0.215R/d.)$	9.79	9.68	9.57	9.46	9.36	9.14	8.71	7.85
Elbow resistance in diameters.....	121.20	35.09	17.51	12.72	10.36	9.03	8.24	7.85
Total equivalent length in diameters.....	130.99	44.77	27.08	22.18	19.72	18.17	16.95	15.70

FLEXIBILITY

General. In considering the discussion dealing with flexibility the authors feel that some agreement is needed regarding what constitutes an "expansion bend." The conventional expansion and double-offset expansion U-bends as shown in Figs. 17(*a*)

and 19(*a*) find appropriate application where there is a long run of pipe in one direction. Where there is opportunity to place sections of the line at right angles to one another it usually is possible to utilize the inherent flexibility of the line to good advantage and dispense with "expansion bends." An arrangement of this kind shown in Fig. 30 is typical of such a layout fitted in to clear structural and mechanical interferences in a power plant. Such layouts are far more common in steam power plants than those employing "expansion bends" for flexibility. Obviously the turns can be made with long-radius quarter-bends, seamless-tube fittings, forged fittings, or cast fittings as the designer prefers, and assembled with flanged or screwed joints or by welding. The authors discussed conventional types for ease in comparison, leaving it to the individual designer to use the methods indicated and make his own choice of layout.

Grapho-Analytical Method. The grapho-analytical method used in presenting information regarding the relative flexibility of symmetrical bends was employed to demonstrate its application in the simpler problems, and to suggest the manner in which it can be applied to problems in space. There are several alternate methods which can be applied successfully to symmetrical shapes in one plane such as those considered in this paper, but the alternate methods have definite limitations which render them unsatisfactory for application to pipe lines in space. The grapho-analytical method and the basic relations of the various elements of a pipe line which have been developed in connection with it, enable the designer to determine as accurately as he desires the relations between deflection and force throughout a complex piping layout.

Since in the application of the grapho-analytical method the ends of the run of piping under investigation are assumed as fixed, the sum of the bending-moment areas from one end of the structure to the other is zero. This fact enables the designer to check the numerical accuracy of his diagrams as he proceeds.

Maxwell's theorem of reciprocity of displacements also affords a convenient check on the accuracy of the final computations required for the solution of a pipe line in space. The coefficient of the F_y force in the expression for displacement along the X-axis is numerically equal to the coefficient of the F_x force for displacement along the Y-axis. The same equality exists between the coefficients of the F_z force along the Z-axis. Likewise the coefficients of the F_z force along the Y-axis and the F_y force along the Z-axis are equal.

The authors are pleased with the favorable reception accorded the grapho-analytical method. In considering the simplifications employed in other methods, it appears that the possibility of reducing the grapho-analytical method to three simple elementary principles has not been stressed sufficiently. If one is content to consider bends and fittings as square corners, all modifying factors may be neglected and the number of elements of the line reduced by at least 40 per cent in most cases. For preliminary layouts these simplifications are a great saving in labor and can be used to advantage, but the final layout should be checked to determine the actual stresses, bending moments, and thrusts on anchors as accurately as possible. The assumption that all turns can be considered as square corners may be in error as much as 40 per cent, depending upon the radius of the bend employed and the particular distribution of the piping.

Force-Through-Elastic-Center Method. The "force-through-elastic-center" method described by Mr. Bato affords a good picturization of the bending moments acting on a symmetrical expansion bend, and the explanation of the method, together with general conclusions drawn, constitutes a worth-while contribution to the paper. C. T. Mitchell described this method in detail in an A.S.M.E. paper entitled "A Graphic Method for Determining Expansion Stresses in Pipe Lines."[27]

The method as described by Mr. Mitchell was designed to give an approximation of the flexibility of both symmetrical lines and lines in space. The method in its present development seems to possess certain limitations which may be stated as follows:

a It cannot be used with any degree of accuracy for piping in more than one plane

b It neglects flattening of the cross-section of curved pipe during flexure

c Due to neglect of the effect of flattening of the cross-section, it does not correctly locate or evaluate the maximum bending stress in a pipe line

d It is not adaptable to dealing with a composite line made up with pipe of different diameters or wall thickness, or with fittings having a greater wall thickness than the pipe.

Attention is called to the general application of the grapho-analytical method as given in the "Piping Handbook" where congruent bending-moment areas above and below the base line are canceled directly and only net values used as suggested by Mr. Bato. In the comparison of a series of square bends made up with turns of different radii, which was the purpose of this paper, the expedient of expressing lengths in terms of pipe diameter was resorted to and certain general equations developed which facilitated such a comparison.

The majority of the practical problems in flexibility of piping which the authors have encountered are of the space variety as illustrated in Fig. 30. The solution of such a problem involves the construction of six bending-moment diagrams to determine the relations between deflection and force. It is customary to construct a resulting bending-moment diagram from these diagrams in order to correctly locate the point of maximum bending moment.

Regarding Mr. Bato's substitution of a 150-lb. cast-steel elbow (dimensions of 125-lb. cast iron) in place of the 250-lb. elbow used in the authors' comparison, the authors would explain that the pipe and seamless-tube fittings are suitable for 250-lb. W.S.P., so it seemed only fair to compare assemblies which could be used interchangeably.

Allowable Stress in Piping. Messrs. Houser and Hirschberg contend that the superior strength of cast-steel fittings should be taken into account in assigning allowable stresses, while Mr. Curley suggests that the true circular cross-section and uniform wall thickness of the seamless-tube fitting should permit of a higher working stress than in the case of a pipe bend which may possess considerable initial ellipticity and thinning of the pipe wall due to the process of forming a bend. Professor Hovgaard has offered supporting data as to maximum allowable stresses in pipe bends. As indicated in their paper, the authors have drawn liberally on the theoretical and test results presented in recent papers by Professor Hovgaard, and wish to take this opportunity of thanking him for his important contributions to the knowledge of the behavior of pipe bends and seamless-tube fittings.

The following specifications as to minimum physical properties of cast steel conforming to A.S.T.M. specification A95 and of open-hearth medium-carbon seamless pipe A53 are submitted with reference to the contention of Messrs. Houser and Hirschberg. The properties of seamless tubing (0.150 to 0.200 in. wall thickness) as given by the National Tube Company also are included as corresponding to the tensile strength data quoted by them.

---

[27] Trans. A.S.M.E., May-Aug., 1930, FSP-52-25, p. 167.

	Steel castings, A95	Seamless pipe, A53	Seamless tubing, National Tube Co.
Tensile strength, lb. per sq. in.....	70,000	62,000	54,000[a]
Yield point, lb. per sq. in.....	36,000	35,000	36,000
Elongation in 2 in., percentage.....	22	25	42

[a] Value used by Messrs. Houser and Hirschberg for comparison with tensile strength of cast steel.

An examination of these specifications shows that the yield points are practically the same for both classes of material, the principle variation in physical properties occurring in the value of tensile strength and elongation. In modern analysis of the strength of ductile materials, except in the case of fatigue, which seems to be more directly related to tensile strength, the yield point of the material is the criterion of the strength commonly employed, and factors of safety are based on the yield point rather than on the tensile strength. From this viewpoint which may be obtained from any recent work on strength of materials, this point of Messrs. Houser and Hirschberg does not appear to be well taken.

The example illustrated in Fig. 25 gives essentially the same information as developed in connection with the authors' Figs. 14, 16, 17, and 19: namely, that (1) for equal dimensions, the stresses are higher when using seamless-tube fittings in place of long-radius bends while the reacting forces and the bending moments at the joints are lower, and (2) the magnitude of the differences between the several types of 90-deg. turns depends largely upon their location and the general proportions of the piping layout.

If a flanged joint were located at point *b* of Fig. 25, as the discussers seem to favor, the bending moment would be $1450 \times 260 = 377{,}000$ in-lb. as compared with 152,000 in-lb. in the case of the seamless-tube-fitting assembly. While in the past, general practice has been to design piping to secure certain allowable stresses, the present tendency is to inquire as to just what constitutes "failure" due to lack of flexibility. The practical answer seems to be leaks in joints and excessive thrusts on equipment. An instance of the latter type of "failure" is cited by Mr. Cramer in his discussion where he mentions the dislocation of a turbine from its foundation. In view of the closer scrutiny being given the actual manifestations of lack of flexibility and the obvious objections to having excessive thrusts at anchor points, it does not appear that the proposal of Messrs. Houser and Hirschberg for "getting the most out of an expansion bend" by using greater thrusts and larger bending moments can be applied indiscriminately.

With respect to Mr. Curley's statements concerning initial ellipticity of pipe bends, what information is available seems to indicate that the initial flattening in carefully made bends should not exceed 1 to 2 per cent of the pipe diameter, and usually may be neglected. Cases have been reported, however, where initial ellipticity ran as high as 5 to 10 per cent, but it is believed that this represents the exception rather than the rule.

The maximum longitudinal stress in the middle surface of the pipe cross-section was used as the criterion of strength of curved pipe in bending throughout the paper, since this stress as explained in detail seems to bear a direct relation to the observed failure of a bend. The transverse bending stresses were shown by Professor Hovgaard to exceed the yield point of the material in some instances where no evidence of instability of the bend occurred. Mr. Curley reasons from the work of A. M. Wahl that the effect of internal pressure on the initial ellipticity of the cross-section of a bend should tend to augment the transverse stresses occasioned by flattening of the cross-section of a curved pipe during flexure. Actually, however, Mr. Wahl's papers show that the two transverse stresses in question tend to neutralize each other quite effectively around the pipe cross-section.

There is a possible correction in the value of K which was suggested by Harold E. Jenks in a discussion of the paper on "The Design of Steam Piping to Care for Expansion,"[18] by W. H. Shipman. Mr. Jenks shows that theoretically the expression for K should be modified when applied to sharp-radius turns by subtracting a factor j, whose value for a 10-in. standard-weight seamless-tube fitting is 0.307, from the expression for K as follows:

$$K = \frac{10 + 12h^2 - 0.307}{1 + 12h^2 - 0.307}$$

If this correction were used, the calculated flexibility of a 10-in. standard-weight seamless-tube fitting would be increased by approximately 20 per cent. As the tests made by Professor Hovgaard indicated that the usual expression for K represented the behavior of a seamless-tube fitting accurately enough for practical purposes, this modification was not taken into account in the flexibility comparisons of the paper.

Supporting Data and Recent Tests. Messrs. Zinc, Townsend, and de Jonge have inquired as to recent tests or supporting data tending to confirm the authors' methods for computing the flexibility of piping.

During the past summer extensive tests were conducted by the Research Department of The Detroit Edison Company with a view to verifying the 10 elementary cases for straight pipe and quarter-bends given in Chapter VII of the "Piping Handbook," by Walker and Crocker. It was deemed advisable to check the elementary cases as offering a more general proof of the method developed in the "Piping Handbook" rather than to attempt to deal with the complications involved in making and interpreting tests on complete pipe lines in space. This work demonstrated satisfactory agreement between test and theory, except that in Case X the measured deflection was considerably greater than that computed by formula. This pointed to the need for further check of the theory, and the problem was referred to Prof. S. Timoshenko, who was the first to call Karman's derivation of K to the attention of American engineers (see footnote 9(*b*)). The resulting derivation, which Professor Timoshenko presented under date of November 10, 1930, affords a basis for all the cases involving action of forces and moments on a quarter-bend. The derivation, which is reproduced in an appendix to this closure, furnishes an excellent example of the application of the Castigliano-theorem method to the analysis of such problems. The results of the recent Detroit Edison tests were presented by Messrs. E. T. Cope and E. A. Wert as an A.S.M.E. paper at a meeting of the Fuels and Steam Power Division held in Hartford, Conn., in June, 1931.

In replying to Mr. De Jonge's criticism of cases IX and X, the authors would point out that these cases apply to pipe lines in space and do not concern piping in one plane as treated in the present paper. While the authors question the propriety of discussing a matter distinctly outside the scope of the paper and should have hesitated to take the initiative in bringing it up at this time, they feel indebted to Mr. de Jonge for the opportunity to correct a previous error. It should be mentioned at this point that cases VIII, IX, and X have been corrected in the second edition (1931) of the "Piping Handbook," and that the derivation on which they are based is included as an appendix to this closure. The revised cases, also included in the appendix, have been referred to and checked by Mr. de Jonge.

In reply to Mr. Zinc's question as to the general reliability of methods for computing the flexibility of piping, the authors would assure him that present knowledge properly applied is sufficiently

[18] Trans. A.S.M.E., Sept.-Dec., 1929, FSP-51-52, p. 443.

accurate to preclude any difficulty due to lack of flexibility. They join with him in stressing the need for short-cut methods of applying present knowledge to practical every-day problems.

Conclusion. In conclusion the authors wish to thank all those discussing the paper who by reason of their interest and special knowledge of piping problems have contributed so much to its completeness and usefulness. Due to space limitations, only those points which appear to require further analysis have been considered in the closure. While separate acknowledgment of all the suggestions and views tending to confirm the findings of the paper has not been possible, the authors appreciate this support of their conclusions.

APPENDIX TO AUTHORS' CLOSURE

The following derivation embracing all the cases involving forces and moments acting on a quarter-bend was presented by Professor Timoshenko under date of November 10, 1930. This derivation is so comprehensive and concise that it may well serve as a model for such analyses.

A quarter bend is illustrated in Fig. 31 with all the possible forces and moments indicated thereon. Forces, moments, and angular and linear displacements are considered as positive when in the directions shown by arrows. The general set-up for the moments acting on a particle at point a of Fig. 31 about the three axes is as follows:

$$M_\xi = M_X \sin\varphi + M_Y \cos\varphi - ZR\,(1 - \sin\varphi)$$
$$M_\eta = -M_X \cos\varphi + M_Y \sin\varphi - ZR\cos\varphi$$
$$M_\zeta = M_Z + Y\,R\cos\varphi - XR\,(1 - \sin\varphi)$$

The potential energy stored in the bend by these moments is given by

$$U = \int_0^{\pi/2} \frac{M_\xi^2 R d\varphi}{2C} + \int_0^{\pi/2} \frac{M_\eta^2 R D\varphi}{2B} + \int_0^{\pi/2} \frac{M_\zeta^2 R d\varphi}{2KB}$$

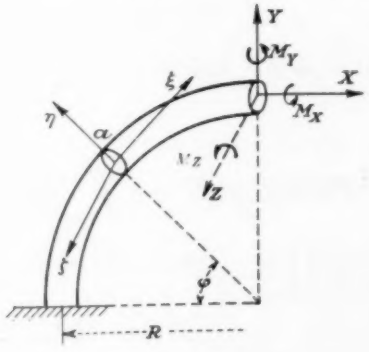

FIG. 31 QUARTER-BEND

in which $C = JG$ = torsional rigidity, $B = EI$ = rigidity in bending, and K is a rigidity multiplication factor which compensates for reduction in flexural rigidity of a curved pipe in the plane of the bend.

From the theorem of Castigliano, the partial derivative of potential energy with respect to any external force gives the displacement corresponding to that force

$$\frac{\partial U}{\partial F} = \int_0^{\pi/2} \frac{M_\xi \left(\frac{\partial M_\xi}{\partial F}\right) Rd\varphi}{C} + \int_0^{\pi/2} \frac{M_\eta \left(\frac{\partial M_\eta}{\partial F}\right) Rd\varphi}{B} + \int_0^{\pi/2} \frac{M_\zeta \left(\frac{\partial M_\zeta}{\partial F}\right) Rd\varphi}{KB}$$

The rotation of the free end of the bend around the X-axis is given by

$$\psi_X = \frac{\partial U}{\partial M_X}$$

$$\frac{\partial M_\xi}{\partial M_X} = \sin\varphi; \quad \frac{\partial M_\eta}{\partial M_X} = -\cos\varphi; \quad \frac{\partial M_\zeta}{\partial M_X} = 0$$

$$\frac{\partial U}{\partial M_X} = \int_0^{\pi/2} \frac{M_\xi \sin\varphi Rd\varphi}{C} - \int_0^{\pi/2} \frac{M_\eta \cos\varphi Rd\varphi}{B}$$

Substituting values of M_ξ and M_η from the general relations above

$$\frac{\partial U}{\partial M_X} = \int_0^{\pi/2} \frac{[M_X \sin\varphi + M_Y \cos\varphi - ZR\,(1 - \sin\varphi)]\sin\varphi Rd\varphi}{C} - \int_0^{\pi/2} \frac{[-M_X \cos\varphi + M_Y \sin\varphi - ZR\cos\varphi]\cos\varphi Rd\varphi}{B}$$

Performing the indicated multiplications and integrations the expression for rotation about the X-axis in terms of all the forces and moments is obtained

$$\psi_X = \frac{\partial U}{\partial M_X} = \frac{R}{4}\left[\frac{\pi M_X + 2M_Y - (4 - \pi)ZR}{C} + \frac{\pi M_X - 2M_Y + \pi ZR}{B}\right]$$

If the rotation due to the action of M_X alone is desired, the other forces and moments drop out and the expression reduces to

$$\psi_X = \frac{R}{4}\left[\frac{\pi M_X}{C} + \frac{\pi M_X}{B}\right]$$

If torsional rigidity is expressed in terms of rigidity in bending, the expression for rotation about the X-axis due to the moment M_X becomes

$$\psi_X = \frac{1.806\,M_X R}{EI} \qquad [\text{Case X}(a)]$$

The rotation of the free end of the bend around the Y-axis is given by

$$\psi_Y = \frac{\partial U}{\partial M_Y}$$

$$\frac{\partial M_\xi}{\partial M_Y} = \cos\varphi; \quad \frac{\partial M_\eta}{\partial M_Y} = \sin\varphi; \quad \frac{\partial M_\zeta}{\partial M_Y} = 0$$

$$\frac{\partial U}{\partial M_Y} = \int_0^{\pi/2} \frac{M_\xi \cos\varphi Rd\varphi}{C} + \int_0^{\pi/2} \frac{M_\eta \sin\varphi Rd\varphi}{B}$$

Substituting values of M_ξ and M_η from the general relations,

$$\frac{\partial U}{\partial M_Y} = \int_0^{\pi/2} \frac{[M_X \sin\varphi + M_Y \cos\varphi - ZR(1 - \sin\varphi)]\cos\varphi Rd\varphi}{C} + \int_0^{\pi/2} \frac{[-M_X \cos\varphi + M_Y \sin\varphi - ZR\cos\varphi]\sin\varphi Rd\varphi}{B}$$

which, when terms are multiplied together and indicated integrations are performed, gives the equation for rotation about the Y-axis in terms of all the forces and moments which may act on the quarter-bend:

$$\psi_X = \frac{\partial U}{\partial M_Y} = \frac{R}{4}\left[\frac{2M_X + \pi M_Y - 2ZR}{C} - \frac{2M_X - \pi M_Y + 2ZR}{B}\right]$$

If the rotation due to action of M_X alone is required, this expression becomes

$$\psi_Y = R/4\left[\frac{2M_X}{C} - \frac{2M_X}{B}\right]$$

which may be combined as

$$\psi_Y = \frac{0.150\,M_X R}{EI} \qquad \text{[Case X}(b)\text{]}$$

The rotation of the free end of the quarter-bend around the Z-axis is found from

$$\psi_Z = \frac{\partial U}{\partial M_Z}$$

$$\frac{\partial M_\xi}{\partial M_Z} = 0\,; \quad \frac{\partial M_\eta}{\partial M_Z} = 0\,; \quad \frac{\partial M_\zeta}{\partial M_Z} = 1$$

$$\frac{\partial U}{\partial M_Z} = \int_0^{\pi/2} \frac{M_\zeta R d\varphi}{KB}$$

Substituting value of M_ζ from the general relations

$$\frac{\partial U}{\partial M_Z} = \int_0^{\pi/2} \frac{[M_Z + YR\cos\varphi - XR\,(1 - \sin\varphi)]\,Rd\varphi}{KB}$$

which when integrated gives the expression for rotation about the Z-axis in terms of all possible forces and moments as

$$\psi_Z = \frac{\partial U}{\partial M_Z} = \frac{R}{2KB}\,[\pi M_Z + 2YR - (\pi - 2)XR]$$

In this expression the M_z term does not appear, so it follows that

$$\psi_Z = 0 \text{ due to } M_Z \qquad \text{[Case X]}$$

The above general expressions have been carried through in terms of the moment M_z as that is the case principally in dispute. It is only necessary to drop out the proper terms in the expressions for rotation about each axis developed above to find the effect of any force or moment acting individually and hence check the cases given in the second edition (1931) of the "Piping Handbook."

The deflection of the free end of the bend along the X-axis is found from

$$\Delta_X = \frac{\partial U}{\partial X}$$

$$\frac{\partial M_\xi}{\partial X} = 0; \quad \frac{\partial M_\eta}{\partial X} = 0; \quad \frac{\partial M_\zeta}{\partial X} = -R(1 - \sin\varphi) = R(\sin\varphi - 1)$$

$$\frac{\partial U}{\partial X} = \int_0^{\pi/2} \frac{M_\zeta\,(\sin\varphi - 1)\,R^2 d\varphi}{KB}$$

$$\frac{\partial U}{\partial X} = \int_0^{\pi/2} \frac{[M_Z + YR\cos\varphi - XR(1 - \sin\varphi)]\,[\sin\varphi - 1]\,R^2 d\varphi}{KB}$$

$$\Delta_X = \frac{\partial U}{\partial X} = \frac{R^2}{4KB}\,[(3\pi - 8)XR - 2YR - (2\pi - 4)M_Z]$$

$$\Delta_X = 0 \text{ due to } M_X \text{ alone} \qquad \text{[Case X]}$$

The deflection of the free end of the bend along the Y-axis is given by

$$\Delta_Y = \frac{\partial U}{\partial Y}$$

$$\frac{\partial M_\xi}{\partial Y} = 0; \quad \frac{\partial M_\eta}{\partial Y} = 0; \quad \frac{\partial M_\zeta}{\partial Y} = R\cos\varphi$$

$$\frac{\partial U}{\partial Y} = \int_0^{\pi/2} \frac{M_\zeta R^2 \cos\varphi d\varphi}{KB}$$

$$\frac{\partial U}{\partial Y} = \int_0^{\pi/2} \frac{[M_Z + YR\cos\varphi - XR + XR\sin\varphi]R^2\cos\varphi d\varphi}{KB}$$

$$\Delta_Y = \frac{\partial U}{\partial Y} = \frac{R^2}{4KB}\,[-2XR + \pi YR + 4M_Z]$$

$$\Delta_Y = 0 \text{ due to } M_X \text{ alone} \qquad \text{[Case X]}$$

The deflection of the free end of the bend along the Z-axis is found from

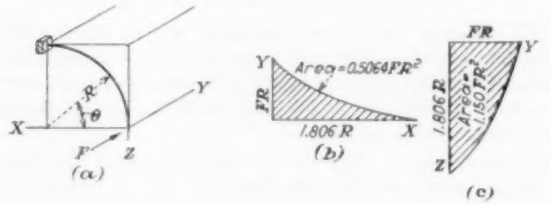

FIG. 32 ILLUSTRATING CASE VIII

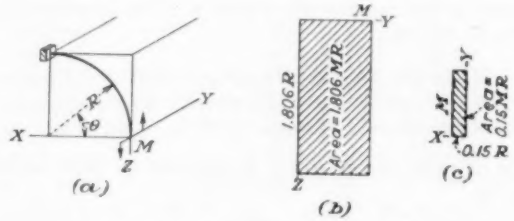

FIG. 33 ILLUSTRATING CASE IX

$$\Delta_Z = \frac{\partial U}{\partial Z}$$

$$\frac{\partial M_\xi}{\partial Z} = -R(1 - \sin\varphi) = R(\sin\varphi - 1); \quad \frac{\partial M_\eta}{\partial Z} = -R\cos\varphi; \quad \frac{\partial M_\zeta}{\partial Z} = 0$$

$$\frac{\partial U}{\partial Z} = \int_0^{\pi/2} \frac{M_\xi\,(\sin\varphi - 1)R^2 d\varphi}{C} + \int_0^{\pi/2} \frac{M_\eta(-R\cos\varphi)Rd\varphi}{B}$$

$$\Delta_Z = \frac{\partial U}{\partial Z} = R^2/4\left[\frac{(\pi - 4)M_X - 2M_Y + (3\pi - 8)ZR}{C} + \frac{\pi M_X - 2M_Y + \pi ZR}{B}\right]$$

$$\Delta_Z = R^2/4\left[\frac{(\pi - 4)M_X}{C} + \frac{\pi M_X}{B}\right] \text{ due to } M_X \text{ only}$$

$$\Delta_Z = \frac{0.5064\,M_X R^2}{EI} \qquad \text{[Case X]}$$

From the general equations for rotation and deflection given in the foregoing, the elementary cases which are in terms of individual forces and moments can be obtained. The cases IV, V, VI, and VII which are involved in this paper are not affected by this rederivation, but cases VIII, IX, and X which are concerned with the solution of piping in space are modified to a greater or lesser degree. The revised cases follow.

CASE VIII. Quarter-Bend Fixed at One End and Acted Upon by a Force F Perpendicular to Plane of Bend (Fig. 32).

(a) $\psi_{XY} = \dfrac{0.5064\,FR^2}{EI}$; $\Delta_{FXY} = \psi_{XY}\,0.754\,R$ = deflection

in direction of force (proportional to rotation in plane perpendicular to free end of bend).

(*b*) $\psi_{YZ} = \dfrac{1.150\ FR^2}{EI}$; $\Delta F_{YZ} = \psi_{YZ}\ 0.754R$ = deflection in direction of force (proportional to rotation in plane tangent to free end of bend).

$\Delta F_Y = \Delta F_{XY} + \Delta F_{YZ} = \dfrac{1.2485\ FR^3}{EI}$ = total deflection in direction of force.

CASE IX. Quarter-Bend Fixed at One End and Acted on by a Moment M Perpendicular to Plane of Bend (Fig. 33).

(*a*) $\psi M_{XY} = \dfrac{0.150\ MR}{EI}$; $\Delta M_{XY} = \psi M_{XY}\ 0.695\ R$ = deflection to *left* along moment arm (proportional to rotation in plane perpendicular to free end of bend).

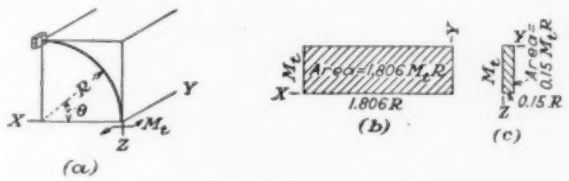

FIG. 34 ILLUSTRATING CASE X

(*b*) $\psi M_{YZ} = \dfrac{1.806\ MR}{EI}$; $\Delta M_{YZ} = \psi M_{YZ}\ 0.695R$ = deflection to *right* along moment arm (proportional to rotation in plane tangent to free end of bend).

$\Delta M_Y = \Delta M_{YZ} - \Delta M_{XY} = \dfrac{1.150\ MR^2}{EI}$ = resultant deflection to right.

(*c*) $\Delta M_Y = \psi M_{YZ}\ 0.637\ R = \dfrac{1.150\ MR^2}{EI}$ = resultant deflection in terms of larger rotation.

CASE X. Quarter Bend Fixed at One End and Acted on by a Torque Moment M_t, in Plane Perpendicular to Free End of Bend (Fig. 34).

(*a*) $\psi_{XY} = \dfrac{1.806\ M_tR}{EI}$; $\Delta M_{tXY} = \psi_{XY}\ 0.306\ R$ = deflection to *right* perpendicular to plane of bend (proportional to rotation in plane perpendicular to free end of bend).

(*b*) $\psi_{YZ} = \dfrac{0.150\ M_tR}{EI}$; $\Delta M_{tYZ} = \psi_{YZ}\ 0.306R$ = deflection to *left* perpendicular to plane of bend (proportional to rotation in plane tangent to free end of bend).

$\Delta M_{tY} = \Delta M_{tXY} - \Delta M_{tYZ} = \dfrac{0.5064\ M_tR^2}{EI}$ = resultant deflection to right.

(*c*) $\Delta M_{tY} = \psi_{XY}\ 0.280\ R = \dfrac{0.5064\ M_tR^2}{EI}$ = resultant deflection in terms of larger rotation.

In applying these elementary cases to the solution of pipe lines in space it is expedient to use the expressions for deflection in terms of the larger rotation and neglect the effect of the smaller rotation. An examination of cases IX and X shows that the smaller rotations are only one-twelfth as large as the principal rotation and in practical problems can be neglected safely.

The changes made necessary by the correction of errors in the original elementary cases given in the "Piping Handbook," while in themselves of considerable magnitude, affect practical problems by only a small percentage. In the particular example of a pipe line in space given in the "Piping Handbook," the maximum stress found for the line is increased by only 1½ per cent by reason of changes in the elementary cases.

With reference to the generalized formulas appended to Mr. de Jonge's discussion, the authors would say that his continued interest in the subject has developed valuable data supplementing the 10 elementary cases presented in the "Piping Handbook." The usual practice in solving expansion problems is to consider pipe lines as consisting of elements built up from quarter-bends and tangents loaded by certain definite applications of forces and moments. The necessity of considering included angles other than 90 deg. in some cases was recognized as early as 1910 by Prof. A. Bantlin[29] in analyzing the characteristics of "lyre shaped" (double offset expansion U-bends), which point also was covered by Crocker and Sanford in their 1922 paper.[30] The general derivation of Professor Timoshenko given in the appendix to this closure works the whole problem out in terms of an indefinite angle to which particular values may be assigned as desired. The final equations are given in terms of a 90-deg. bend as being of the most general use.

Mr. de Jonge has broken up the problem of determining the flexibility of straight pipe and arcs of circles into 24 separate cases. These cases permit the determination of deflections perpendicular to and along a tangent to the arc at the free end as well as along the principal coordinate axes of the system for any given included angle of arc. The case of a straight pipe inclined at an angle other than 90 deg. to the acting force is being developed by Messrs. E. A. Wert and Samuel Smith of The Detroit Edison Company, who hope to present their results in the near future.

Certain of the cases developed by Mr. de Jonge should prove of assistance in calculating the flexibility of arcs of circles other than 90 deg. in cases where need for greater accuracy is apparent than can be obtained by approximating such arcs to straight pipe and quarter-bends. Except when verifying test procedure, it is doubtful if the increased complexity introduced by attempting to use some 24 cases involving generalized angles would be warranted. The ten elementary cases covering 90-deg. bends and tangents given in the Second Edition of the "Piping Handbook," together with the general equations given in the Appendix to this closure, should meet the needs of the practical piping designer.

Corrosion Tests on Condenser Tubes

Progress Report No. 4 of The A.S.M.E. Special Research Committee on Condenser Tubes[1]

AT the annual meeting in 1929, the report of the committee included evidence that the circulating water in certain surface condensers carried a quantity of air, both in the entrained and dissolved conditions. It was suggested at this meeting that investigations be made on condensers of possibly a dozen selected companies to determine if air is a common cause of trouble. A small budget is necessary to carry out such a course of action. During the year this report was presented to the Prime Movers Committee of the National Electric Light Association with the suggestion that it contribute the necessary funds to carry on this particular feature of the investigation. At the Prime Movers Meeting in Montreal, Oct. 6 and 7, 1930, a resolution was passed endorsing the solicitation of funds either through the N.E.L.A. headquarters or from member companies most vitally interested.

Meanwhile other investigations have been carried on for the committee. A series of tests was made to determine the extent of the effect of air on tube material. The method used was to make comparative corrosion tests with solutions saturated with air and under vacuum.

In consideration of the fact that all chemical reactions such as found in condenser tube corrosion are ionic, an electric current was used in the laboratory tests to accelerate the corrosive action. Cells were made, using Admiralty brass anodes and copper cathodes. These comparative tests were made on a series of solutions ranging in concentration from zero parts per million to 25,000 parts per million of potassium chloride. The arrangement of the apparatus used, both with air and under vacuum, is shown in Figs. 1 and 2, respectively. The data obtained are given in Tables 1 and 2 and also are plotted in curves in Figs. 3 and 4. In Fig. 3 the Admiralty brass anode loss in milligrams per volt drop across the cell is plotted against the concentration of potassium chloride in parts per million. Comparing the two curves—that is, one with air-saturated electrolyte and the other with electrolyte under 27-in. hg. vacuum—it is clear that air decidedly accelerates the rate of corrosion. It is true that its effect is not constant at all concentrations, but its effect is of sufficient magnitude at all concentrations to make its presence undesirable. Referring to Fig. 3, there are peculiarities in the data of the air-saturated solutions at the lower concentrations which are receiving further investigation. Another feature which developed in this investigation is shown in Fig. 4, where the loss of zinc as a percentage of the total anode loss was plotted against concentration. These curves show the tendency of Admiralty brass to dezincify and also the concentration most favorable to dezincification. It appears that a point of maximum is reached at intermediate concentrations. There is a decided break in these curves at from 1000 to 2000 parts per million. It is interesting to note that there was a change in the appearance of the anodes in this range of concentration. At lower concentrations the anode had a darkened

[1] The personnel of this committee is as follows:

ALBERT E. WHITE, *Chairman*, Director, Department of Engineering Research, University of Michigan, Ann Arbor, Mich.

BERT HOUGHTON, *Vice-Chairman*, Operating Superintendent, Brooklyn Edison Company, Inc., Brooklyn, N. Y.

PAUL A. BANCEL, Manager, Condenser Department, Ingersoll-Rand Company, New York, N. Y.

R. H. BARBER, International Paper Company, New York, N. Y.

WILLIAM H. BASSETT, Technical Superintendent, American Brass Company, Waterbury, Conn.

GEORGE G. BELL, Manager, Power Development, West Penn Power Company, Pittsburgh, Pa.

DONALD K. CRAMPTON, Metallurgist, Chase Metal Works, Waterbury, Conn.

HARVEY M. CUSHING, Chief Engineer, Buffalo General Electric Company, Buffalo, N. Y.

HAROLD F. EDDY, Mechanical Engineer, Foster Wheeler Corporation, Chicago, Ill.

VINCENT M. FROST, Assistant to General Superintendent of Generation, Public Service Electric & Gas Company, Newark, N. J.

WALTER L. GREEN, JR., Superintending Engineer, Luckenbach Steamship Company, Inc., Brooklyn, N. Y.

CHARLES F. HARWOOD, Manager, Condenser Department, Worthington Pump & Machinery Corporation, New York, N. Y.

C. F. HIRSHFELD, Chief, Research Department, Detroit Edison Company, Detroit, Mich.

HOWARD W. LEITCH, General Superintendent of Power Plants, United Electric Light & Power Company, New York, N. Y.

J. P. LIDIAK, Condenser Department, Westinghouse Electric & Manufacturing Company, Philadelphia, Pa.

ROGER W. PAINE, Lieutenant Commander, Officer in Charge, Specifications Section, Design Division, Bureau of Engineering, Navy Department, Washington, D. C.

WILLIAM B. PRICE, Chief Chemist and Metallurgist, Scovill Manufacturing Company, Waterbury, Conn.

NORMAN G. REINICKER, General Superintendent, Penn Power & Light Company, Allentown, Pa.

HORACE A. STAPLES, Vice-President, British-American Metals Company, Inc., Plainfield, N. J.

WILLIAM REUBEN WEBSTER, Chairman of the Board, Bridgeport Brass Company, Bridgeport, Conn.

Presented before a meeting of the Committee at the Annual Meeting, Dec. 1 to 5, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

oxidized appearance, while at 1000 parts per million and over, the anodes were very coppery in appearance.

The theory that corrosion due to stray electrical currents is the fundamental cause of all condenser tube failures has been suggested from time to time and has been brought forward in recent technical literature. It is argued that, if a condenser is short-circuited properly, the tubes will not corrode, these claims being supported by exhaustive investigation, both in the laboratory and in the plant. As a check of this theory, a large condenser was wired, making eight taps in each water box on the condenser shell and eight taps on each tube sheet. The leads were brought out, and while the condenser was in operation,

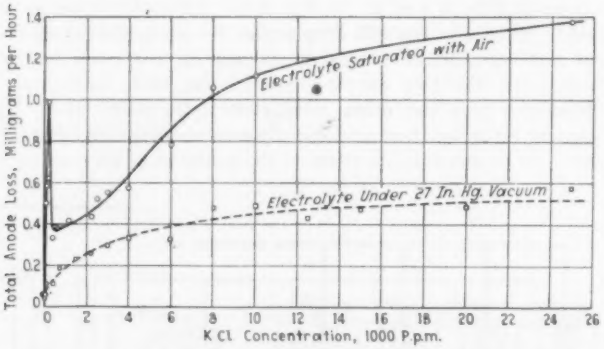

FIG. 3 CORROSION TEST ON ADMIRALTY METAL WITH POTASSIUM-CHLORIDE ELECTROLYTE

(Total anode loss in milligrams per hour, corrected to 1 volt potential difference.)

readings were taken between each pair of leads, from one water box to the other and also across each water box. A very sensitive galvanometer was used for the test, but not the slightest indication was found of voltage drop anywhere in the condenser.

The tubes in this condenser have been in service six years, and in that time 76 tubes have failed out of 13,600 tubes. Inspection of the tubes indicates that the tubes still have several years of life. The corrosion rate on the condenser tubes is therefore slow, and the committee expects to make a similar test on

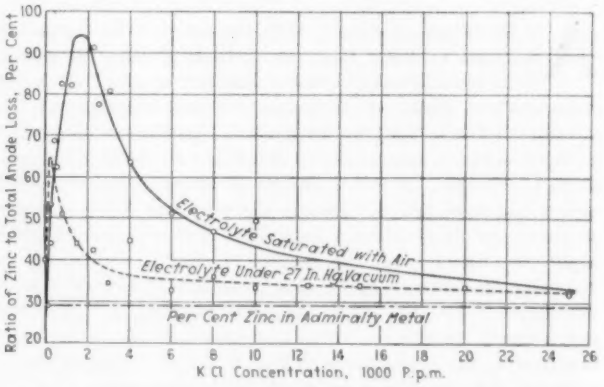

FIG. 4 CORROSION TEST ON ADMIRALTY METAL WITH POTASSIUM-CHLORIDE ELECTROLYTE

(Ratio of zinc to total anode loss.)

condensers having a higher rate of tube failure as a further check on the electrolysis theory.

Investigation of failures of the upper tubes in the second pass of a large condenser was carried on during the year. Tube failures in this condenser were grouped near the top, as shown in the diagram of the tube sheet, Fig. 5. The failed tubes were removed and in many cases were found to be badly dezincified. Further examination of these tubes showed that by far the greater amount of dezincification had taken place on the top of the tube, the bottom of the tube being almost free from dezincification. Figs. 6 and 7 are typical of this condition. The fact that the failures take place near the top of the condenser may be explained by the fact that the upper rows of tubes are not filled with water at all times, and the tubes are exposed to higher concentrations of air in water. That the dezincification took place largely at the top of the tube may be explained by the fact that the air in the circulating water would no doubt follow along the top of the tube, and in line with the committee's investigations concerning the action of air, would speed up dezincification at this point. It was interesting to note that, while in this section dezincification had progressed almost through the tube wall in some cases, in the lower sections of the condenser the tubes showed no attack whatever.

Evidence that the work of this committee is receiving widespread interest is shown by the fact that a number of cases of condenser-tube failure have been sent to the committee for examination. Several of them that are of particular interest are cited.

Several instances of failure of 60/40 brass tubes have been brought to the attention of the committee during the year.

Each case was a fresh-water installation, and in each case the tubes were badly dezincified after a comparatively short life. One case was that of an inter-and-after cooler. Dezincification had progressed from the outside, or steam side, of the tube. Considered as an electrolyte, the medium of air, condensed steam, and carbon dioxide was extremely weak, but 60/40 metal is so subject to dezincification that even under such apparently favorable conditions the tubes failed. A photomicrograph of this metal is shown in Fig. 8.

Another case that has come to the attention of the committee is the case of a main condenser in the Middle West. This also is a fresh-water installation, using 60/40 brass tubes. The outside, or steam side, of the tube was spotted with a thin film of white deposit about 1 in. in diameter. These spots occurred every few inches along the tube and were generally scattered through the condenser. Upon examination it was found that this was plug-type dezincification which had progressed from the inside entirely through the tube and that the white deposit came from the circulating water and not from the steam. The circulating water was of low concentration and was not contaminated by sewage nor was it acid, having a hydrogen-ion concentration of 7.5. A photomicrograph of this metal is shown in Fig. 9. This case is cited to call further attention to the seriousness of using alloys with high zinc content.

Another recent case of failure occurred in a harbor installation on the Atlantic seaboard. Two large condensers were installed, and presumably were tubed with Admiralty brass. In less than a year of operation 103 tubes have failed in one condenser and 98 tubes in the other. Upon examination it was found that the failed tubes, with one exception, were not Admiralty metal, but what is known in the trade as leaded two-and-one brass. The analysis of one of these tubes is as follows:

	Per cent
Copper	66.88
Tin	Trace
Lead	0.41
Iron	0.06
Zinc (by difference)	32.65

The tubes were pitted in rows of 2 or 3 ft. in extent. These pitted areas did not occur in any particular section of the condenser or in any particular position of the tube. A photograph of a pitted section is shown in Fig. 10. A photomicrograph of the metal, showing a quantity of slag inclusions in which the lead drops may be seen, is shown in Fig. 11. It has been well determined and generally conceded that the alloy leaded two-and-one brass is not suitable for sea-water installations.

Corroded condenser tubes were recently submitted from a plant which was using the chlorine method of tube cleaning. These tubes were protected by Flowrites about 3 in. from the inlet end. Within the Flowrite area the tube was unattacked and in good condition. Then for a distance of several feet the tube was badly pitted, in several places entirely through the tube wall. Chlorine is a very strong corrosive agent, and its action on brass is well known. In order to bring out the rapidity by which brass is corroded in the presence of chlorine and hypochlorous acid, a new condenser tube was exposed to a water-and-chlorine solution for a period of 48 hours. A photograph of this tube is shown in Fig. 12. The vigorous action of the chlorine on the brass is evidenced by the deep corrosion present on the tube. A photograph of the original tube taken out of service is also shown in Fig. 13. While the desirability of preventing algæ growth in the condenser tubes is appreciated, it should be pointed out that the use of so strong a corrosive and oxidizing agent as chlorine should be guarded with great care as it is possible to ruin entirely a condenser-tube installation in a very short time should the chlorine attack the tubes.

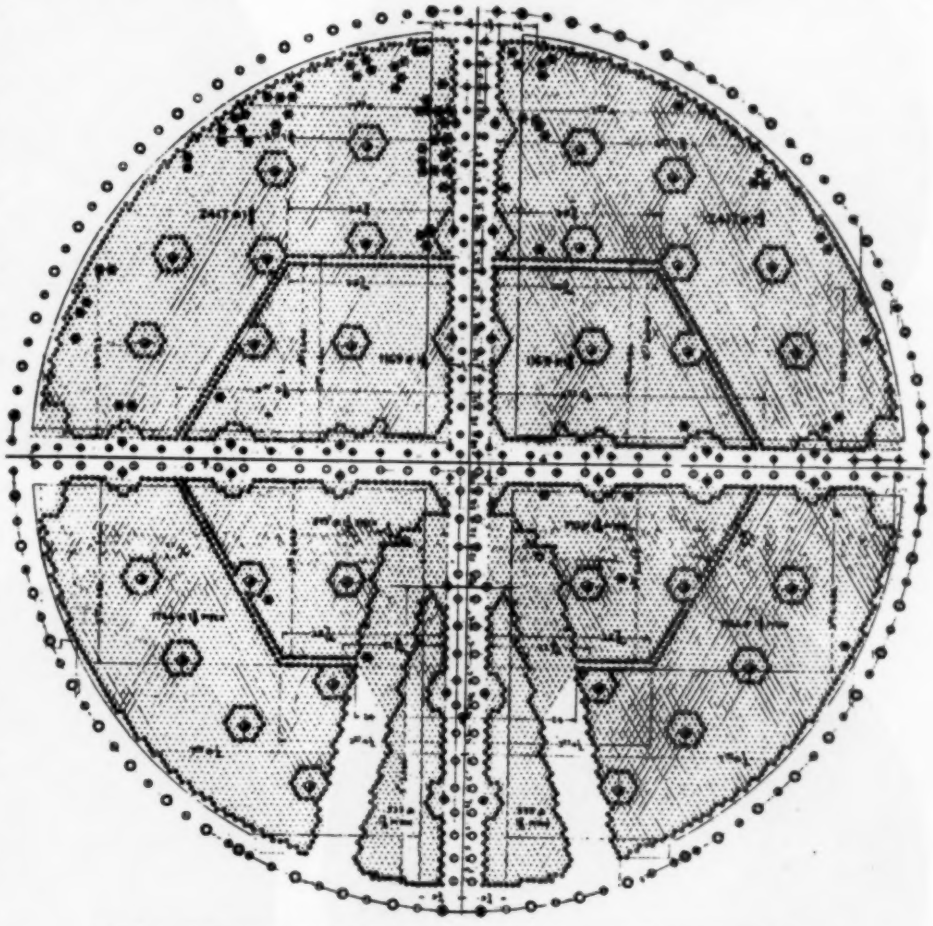

FIG. 5 CONDENSER-TUBE SHEET, SHOWING POSITION OF DEZINCIFIED TUBES

A case of corrosion which, without question, was caused by stray electric currents was submitted from the Middle West. This was a Radojet inter-and-after cooler in a fresh-water installation. The cooler was tubed with Admiralty brass, the tubes being set vertically in groups. The upper half of the tubes in two of these groups was badly corroded on the inside, or water side, of the tube. The lower half of each tube was

Photographs of the comparative tube-wall thickness, indicative of the extent of corrosion, and the formation of the insoluble products of corrosion as scale in the tube are shown in Figs. 14 and 15.

During the coming year the laboratory and field tests will be continued and their scope broadened as opportunity permits.

FSP-53-19a

Heat Absorption in Water-Cooled Furnaces

By WM. L. DeBAUFRE,[1] NEW YORK, N. Y.

Based on the furnace heat balance, an empirical "effectiveness factor" is derived for water-cooled surfaces therein, relating the heat radiated by the burning fuel and products of combustion to the furnace-outlet temperature. The value of this factor is calculated from certain experimental data for turbulent horizontally fired pulverized-coal furnaces with bare water-cooled tube walls. For these experimental data, the fraction radiated of the heat liberated in the furnace has also been calculated and is compared with Broido's curve and with the value calculated by the Orrok-Hudson formula. The method of applying the effectiveness factor to design problems is illustrated by showing the effect of preheated-air temperature upon the furnace-outlet temperature.

WHEN "water screens" were installed in pulverized-fuel furnaces to prevent slagging of ash in the furnace bottoms, tests were made to determine the rate of heat absorption in order to design properly the downcomers and risers. These tests generally consisted in isolating certain tubes and passing water through them at a sufficient velocity to give a moderate temperature rise. In other cases, the "water screens" were connected to steam drums separate from the main steam drums of the boiler so that the steam generated therein could be measured. The rate of heat absorption so determined per square foot of water-cooled surface exposed to radiation, was compared with the operating capacity of the boiler in per cent of rating rather than attempting to connect the rate of heat absorption with the furnace temperature. This method of handling the problem was satisfactory as long as small portions only of the furnace walls were covered by water-cooled surfaces.

When larger portions of the refractory walls were replaced by water-cooled surfaces, a relation between rate of heat absorption and furnace temperature was based on these data and on an experiment by John Bell made some years previously, in which one of a first row of boiler tubes was replaced by a similar tube through which water was circulated and the temperature rise noted.[2]

With the development of steam generators in which the furnace walls are almost entirely replaced by water-cooled surfaces, it became desirable to have a relation which would more definitely proportion the total heat absorbed by the unit between the heating surface exposed to radiation in the furnace and the heating surface in the boiler tube banks. About that time appeared the timely papers upon the subject by Broido[3] and Wohlenberg,[4] with Orrok's discussions thereon. Broido and Orrok gave empirical relations for calculating the ratio of the heat absorbed by radiation to the heat liberated in the furnace, which relations were assumed to apply to all types of furnaces and conditions of operation; but the actual ratio might differ by 20 per cent from the calculated value. The paper by Wohlenberg showed how complicated the subject becomes when it is attempted to take account of all factors involved in the problem.

The idea was therefore conceived of applying a comparatively simple relation involving a factor which measures the effectiveness of the water-cooled surface and varies with the furnace design and the character of the fuel burned. This relation will be derived and applied to certain experimental data from pulverized-coal-fired furnaces. The method of applying the results to design problems will then be explained.

The above-mentioned relation is based on the furnace heat balance that the heat R radiated from the burning fuel and products of combustion plus the sensible heat P in the products leaving the furnace must equal the net heat B produced by burning the fuel plus the sensible heat A in the preheated air supplied for combustion; that is,

$$R + P = B + A$$

These heat quantities may be total hourly rates for the furnace in question, or may be based on one square foot of water-cooled surface in the furnace or on one pound of fuel fired.

Due to unburnt combustible in the ashes and flue dust, the heat B actually liberated in the furnace is less than the calorimeter heating value of the fuel, which is accordingly reduced by 14,600 times the fraction of a pound of unburnt carbon per pound of fuel fired. A further reduction is made equal to the heat required to evaporate the moisture in the fuel and that formed from the hydrogen burned. The latent heat of this water vapor is taken as approximately 1050 B.t.u. per lb. at room temperature. That is,

$$B = H - 14{,}600 \times C - 1050 \times M$$

where H = gross calorimeter heating value of the fuel fired B.t.u. per lb.
C = lb. unburnt carbon per lb. of fuel fired, and
M = lb. moisture in fuel and formed from hydrogen per lb. of fuel fired.

The latent heat of the water vapor could be added to the sensible heat P in the products of combustion leaving the furnace instead of being subtracted from the gross heating value of the fuel fired. The latter method is preferred, however, because it is considered more logical to base the heat radiated upon the net heat liberated in the furnace than upon the gross heating value of the fuel. Also, it is customary abroad to base the efficiency of

---

[1] Head of Technical Research Department, International Combustion Engineering Corp. Mem. A.S.M.E. Mr. DeBaufre was graduated from the Baltimore Polytechnic Institute in 1903, and acquired the degrees of E.E., M.E., and M.S. from Lehigh University. He taught at Baltimore Polytechnic for several years, and during the latter part of this period was head of the Department of Engineering there. For a number of years thereafter he was mechanical engineer with the U. S. Naval Engineering Experiment Station, leaving this work to become professor of mechanical engineering and later chairman of the Mechanical Engineering Department at the University of Nebraska. He left this position in 1926 to assume his present duties.

steam-generating equipment upon the net heating value of the fuel rather than penalize the steam power plant in comparison with the internal-conbustion power plant by using the gross heating value of the fuel, as is done in this country.

The sensible heat A in the preheated air is calculated from the amount of air supplied for combustion, the portion of it which is preheated, and the temperature to which it is preheated. The quantity of air supplied per pound of fuel fired may be calculated from the analysis of the products of combustion leaving the furnace, the composition of the fuel fired, and the loss of combustible in the ashes and flue dust. The sum of A and B is the net heat available for radiation in the furnace and for heating the products of combustion to the furnace-outlet temperature. The sensible heat S in the products of combustion may be calculated for the composition and temperature of the products leaving the furnace. The heat R radiated is then found by difference.

Now, the more effective the water-cooled surfaces in absorbing heat within the furnace, the larger must be R and the lower must be the temperature of the products leaving the furnace. Hence, the ratio of R to some function of the furnace-outlet temperature is an "effectiveness factor" for the water-cooled surfaces within

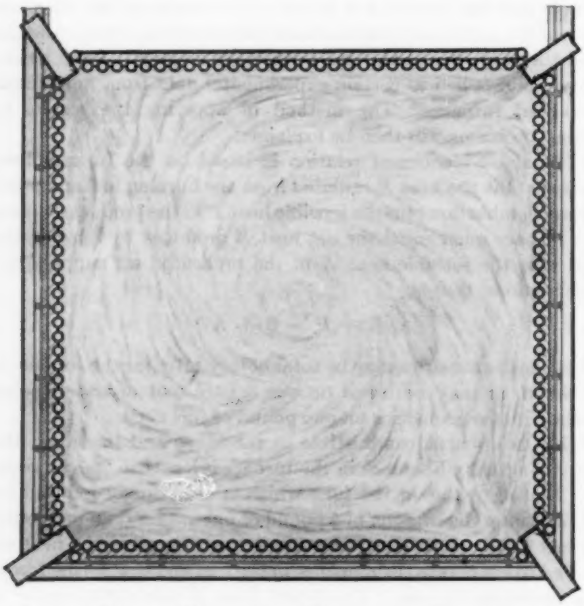

FIG. 1 HORIZONTAL TANGENTIAL FIRING

the furnace. As the effectiveness of these surfaces must vary with their arrangement and condition, the effectiveness factor will show by its variations, the effect of such changes rather than be a universal constant which will apply under all conditions.

The temperature function which has been chosen as a basis for calculating the effectiveness factor of the water-cooled surfaces is the fourth power of the absolute temperature of the products of combustion leaving the furnace minus the fourth power of the absolute temperature of the water evaporating within the water-cooled surfaces. The effectiveness factor E may be employed to calculate the heat R radiated per pound of fuel fired by means of the relation:

$$R = \frac{E}{F}\left[\left(\frac{T_G}{1000}\right)^4 - \left(\frac{T_S}{1000}\right)^4\right]$$

where T_G = absolute temperature of the products of combustion leaving the furnace, deg. fahr.

T_S = absolute temperature of the water evaporating into steam within the water-cooled surfaces, deg. fahr.

F = fuel fired per hour per square foot of water-cooled surface exposed to radiation, lb.

R = heat radiated per lb. of fuel fired in B.t.u.; and

E = effectiveness factor of the water-cooled surfaces.

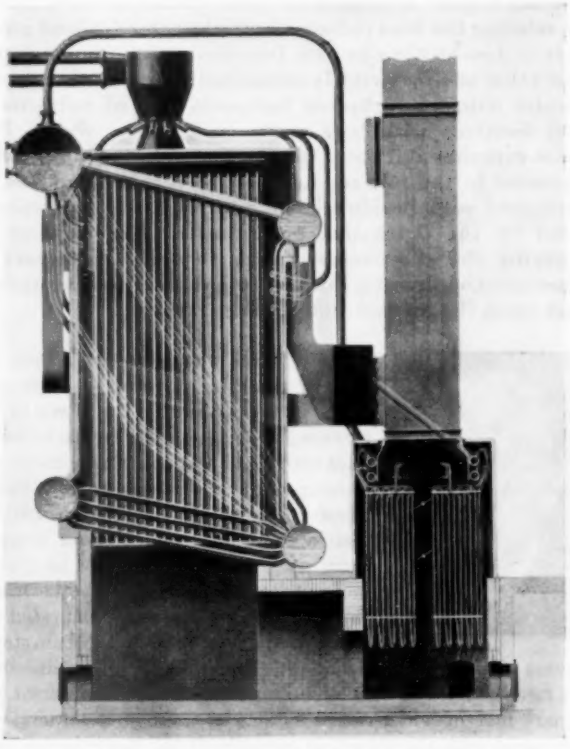

FIG. 2 WATER-COOLED FURNACE AT MANCHESTER, ENGLAND

There are a number of reasons why the heat radiated by the burning fuel and products of combustion to the water-cooled surfaces should not be proportional to the difference of the fourth powers of the furnace-outlet absolute temperature and the absolute steam temperature; thus:

The temperature of the burning fuel and products of combustion within the furnace is not uniform, but varies from a maximum at the place of most intense combustion, to a minimum generally at the furnace outlet.

The water-cooled surfaces absorbing radiant heat are at a higher temperature than the water evaporating into steam within these surfaces.

Some heat may pass by convection and conduction rather than by radiation.

Radiation from non-luminous gases does not follow the fourth-power law, and radiation from burning fuel may not follow this law.

The flames may not entirely fill the furnace volume.

Clouds of cool, unburnt fuel may intervene between the hot flames and part of the water-cooled surface.

Combustion may not be complete within the furnace, but continue into and through the boiler-tube banks.

All of these discrepancies affect the effectiveness factor when the above relation is applied to determine its value for any set of experimental conditions. All of them, however, depend mainly if not entirely upon the characteristics of the fuel, the arrange-

ment and condition of the furnace, and the capacity at which it is operated. Hence, the effectiveness factor determined by the above relation should apply to similar fuels, similar furnace arrangements, and equal capacities.

The effectiveness factor will also vary with the way in which the water-cooled surface exposed to radiation is measured. While the projected area is the simplest way of measuring such surfaces, actual exposed areas have been employed, partly because it has been customary to measure these surfaces in this way, but also because the actual areas were considered to give a better comparative measure of the heat absorbed, for example, by the first rows of boiler tubes and by furnace-wall tubes. Two-thirds of the surface of the first row of boiler tubes and one-third of the surface of the second row have been taken as exposed to radiation. Two-thirds of the surface of the "screen tubes," which are usually widely spaced, has been taken as exposed to radiation. When a wall is made up of plain tubes closely spaced, the exposed area has been taken as one-half of the tube surface. If widely spaced in front of a refractory wall, two-thirds of the surface has been taken. For fin tubes, the actual area of tube and fins on the furnace side has been taken as exposed to radiation.

Table 1 gives experimental data from four pulverized-coal-fired furnaces in which all sides of the furnaces are nearly completely water cooled by bare tubes, and in which tangential firing is used as illustrated in Fig. 1.

The first furnace is that of the Wood steam generator located at Manchester, England. This furnace, as shown in Fig. 2, has the dimensions: width, 12 ft. 6 in.; depth, 12 ft. 0 in.; height, 18 ft. 9 in. It was fired near the top by burners located in the four corners of the furnace. The effectiveness factor is plotted in Fig. 3. In run 1, the furnace was comparatively clean, with a resultant factor of 1600. In run 2, a lower factor was obtained at a reduced rating. Runs 3 and 4 were not completed. In runs 5 and 6, the factor was around 1400. When runs 7, 8, and 9 were made, considerable amounts of slag had collected in the furnace, thereby accounting for the low factors around 800 and 700. The second series of runs with this furnace showed the same drop in the effectiveness factor from run to run as slag accumulated in the furnace.

In the second steam generator, installed at Brighton, England, the furnace walls were kept in a very clean condition by use of steam-jet blowers. Factors of 2000 and more were obtained, as shown by the points plotted in Fig. 3. These factors indicate the effectiveness of unusually clean furnace surfaces. The arrangement of the furnace at Brighton is similar to the one at Manchester shown in Fig. 2.

The data from the third furnace at Hellgate show the effectiveness of water-cooled surfaces in a large furnace operated with good coal at moderate combustion rates. This furnace is 26 ft. 5 in. by 25 ft. 1 in., making a cross-sectional area of 662 sq. ft. The effectiveness factors are plotted in Fig. 4 and indicate a falling off in effectiveness of the surface as the rate of heat liberation is reduced.

The fourth furnace, Fig. 5, has about the same volume as the third furnace, but is higher with a somewhat less cross-sectional area, being 20 ft. 4 in. by 28 ft. 4 in. with a corresponding cross-sectional area of 576 sq. ft. The effectiveness factor is less than for the third furnace, due probably to a thicker layer of slag adhering to the furnace walls.

In view of these and other data, a factor of 1500 has been selected for clean or but slightly dirty furnaces with rates of combustion around 28,000 to 30,000 B.t.u. per hr. per cu. ft. of furnace volume. As the rate of heat liberation is reduced, the factor is taken to drop off in a straight-line relation, as indicated in Figs. 3 and 4, to a value of 500 at zero heat liberation. For a moderately dirty furnace, a factor of 1000 is used at the maximum combustion rate. For a considerable amount of slag adhering to the furnace walls, the factor is taken as 500 for all rates of heat liberation.

Table 2 shows how the heat radiated by the burning fuel and products of combustion varies with the furnace-outlet temperature for several values of the effectiveness factor. These results are based on a steam pressure of 450 lb. gage, with a corresponding saturated steam temperature of 460 deg. fahr. Slightly higher results would be calculated for lower steam pressures and

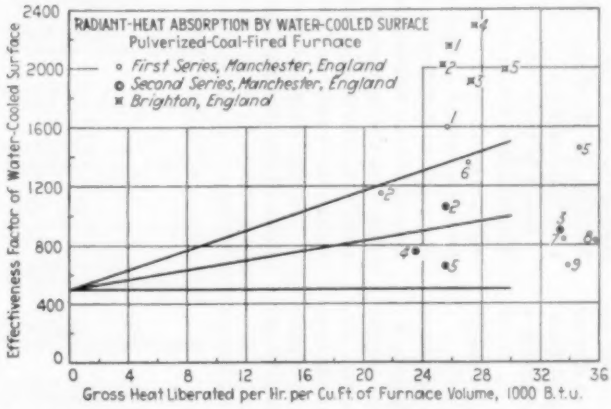

FIG. 3 EFFECTIVENESS FACTORS FOR WATER-COOLED FURNACES AT MANCHESTER AND BRIGHTON, ENGLAND

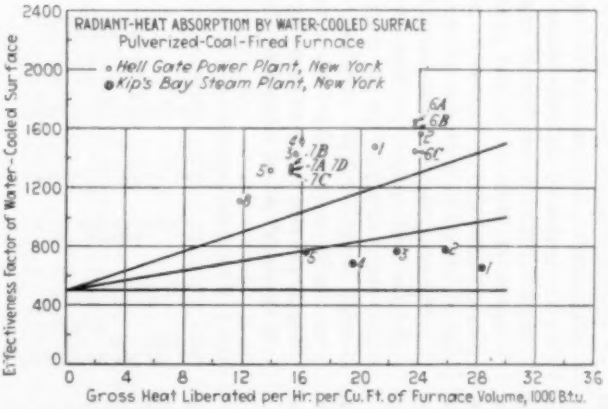

FIG. 4 EFFECTIVENESS FACTORS FOR WATER-COOLED FURNACES AT HELL GATE POWER PLANT AND KIP'S BAY STEAM PLANT

the reverse for higher steam pressures. For example, with a furnace-outlet temperature of 2000 deg. fahr., the calculated heat radiated would be 0.7 per cent higher for 125 lb. steam pressure and 1.4 per cent lower for 1400 lb. steam pressure than tabulated.

In addition to the effectiveness factor, Table 1 also contains the ratios of the heat radiated to the gross heating value of the fuel and to the net heat liberated and in the preheated air. These ratios are plotted in Figs. 6 and 7, respectively, in which Broido's curve has been drawn for comparison.

Table 3 contains the ratios calculated by Hudson's formula as modified by Orrok, and the deviations from the experimental values.

One particularly interesting set of data is found in runs 7-A to 7-D for the third furnace. In these runs, the rate of combustion was maintained constant while the air supply was varied to give from 11.5 to 15 per cent CO_2 in the products of combustion leaving the furnace. The furnace-outlet temperature varied

nearly 100 deg. The fraction of the heat liberated which was absorbed by the furnace walls varied from 45 to 53 per cent. The effectiveness factor averaged 1320, having this value at both the lowest and highest quantities of air supplied for combustion and differing by 20 only above and below the average. As a variation in the effectiveness factor from 1500 to 1000 would change the furnace-outlet temperature by about 200 deg. fahr., a variation of 20 would affect the furnace-outlet temperature by less than 10 deg.

These data therefore indicate that the effectiveness factor is not affected by the CO_2 percentage. It would also seem reasonable to assume that the factor is not affected by the preheated-air temperature.

To illustrate the use of the effectiveness factor, we shall calculate the furnace-outlet temperature as affected by the preheated-air temperature for a typical Pittsburgh bituminous coal burned in a furnace having a volume of 8396 cu. ft. and having 3040 sq. ft. of water-cooled surface exposed to radiation, or 0.3620 sq. ft. per cu. ft. of furnace volume.

The composition of this coal as fired is: Moisture, 3.4 per cent; sulphur, 1.0 per cent; hydrogen, 4.7 per cent; carbon, 74.4 per cent; nitrogen, 1.4 per cent; oxygen, 6.7 per cent; ash, 8.4 per cent. Assuming 80 per cent of the ash to be flue dust containing 20 per cent combustible and practically no carbon in the ashpit refuse comprising the remaining 20 per cent of the ash of the coal, the unburnt carbon will be $0.017\frac{1}{2}$ lb. per lb. of coal fired. The carbon burned will be 0.744 — 0.017 = 0.727 lb. per lb. of coal fired.

Hence, in the furnace exit gases will be 0.727/12 = 0.0606 mole of CO_2 and CO per lb. of coal fired. There will also be 0.010/32 = 0.0003 mole of SO_2 which will be treated as CO_2. With no CO and 15 per cent CO_2, there will be 0.0609/0.15 = 0.4060 mole of dry products, of which 0.4060 — 0.0609 = 0.3451 mole is O_2 and N_2. From the hydrogen in the coal there will be formed 0.047/2 = 0.0235 mole of H_2O. The moisture present in the coal is equal to 0.034/18 = 0.0019 mole of H_2O.

The dry air supplied for combustion equals the moles of dry products plus one-half the moles of H_2O

TABLE 1 EXPERIMENTAL DATA FROM PULVERIZED-COAL FURNACES

formed from the hydrogen in the fuel minus the number of moles equivalent to the nitrogen and oxygen in the fuel. The last mentioned are equal to 0.014/28 = 0.0005 mole of N_2 and 0.067/32 = 0.0021 mole of O_2, respectively. Hence, 0.4060 + 0.0118 — 0.0005 — 0.0021 = 0.4152 mole of dry air. For a relative humidity of 70 per cent at 70 deg. fahr., each mole of dry air has with it 0.0176 mole of water vapor, or 0.4152 × 0.0176 = 0.0073 mole of water vapor per pound of coal fired.

The air supplied for combustion per pound of coal fired thus consists of 0.4152 mole of dry air and 0.0073 mole of water vapor. The products of combustion leaving the furnace consist of 0.0609 mole of CO_2 (and SO_2), 0.3451 mole of O_2 and N_2, and 0.0235 + 0.0019 + 0.0073 = 0.0327 mole of H_2O.

By means of Table 4, the sensible heat in the preheated air and in the products of combustion may be determined for any temperature desired.

Now, the gross heating value of this Pittsburgh coal is 13,700 B.t.u. per lb. The loss due to unburnt carbon is 0.017 × 14,600 = 248 B.t.u. The heat required to evaporate the moisture in the coal and that formed from the hydrogen is 1050 (0.047 × 9 + 0.034) = 480 B.t.u. Hence, the net heat liberated is 13,700 — 248 — 480 = 12,972 B.t.u. per lb. of coal fired. Assuming 90 per cent of the air supplied for combustion to be preheated to 300 deg. fahr., we find the sensible heat above 70 deg. fahr. to be 610 B.t.u., making 12,973 + 610 = 13,583 B.t.u. for radiating and raising the temperature of the products of combustion.

For a gross heat liberation of 29,500 B.t.u. per hr. per cu. ft. of furnace volume, we have 29,500/13,700 = 2.153 lb. of coal fired per hr. per cu. ft., or 2.153 × 0.3620 = 5.948 lb. per hr. per sq. ft. of the water-cooled surface that is exposed to radiation.

By assuming various temperatures of the products of combustion leaving the furnace, a balance may be found in which the heat radiated per square foot with a factor of, say, 1500, divided by 5.948 lb. of coal fired per sq. ft., plus the sensible heat in the products of 1 lb. of coal, just equals 13,583 B.t.u. For the conditions assumed, this temperature is 1874 deg. fahr.

By similar calculations for other preheated-air temperatures, the following furnace-outlet temperatures are found to correspond to several effectiveness factors:

Effectiveness factor	1500	1000	500
Furnace-outlet temperature, deg. fahr.:			
70-deg. fahr. air	1837	2014	2325
For 300 deg. fahr. preheated air	1874	2057	2379
For 600 deg. fahr. preheated air	1922	2111	2446

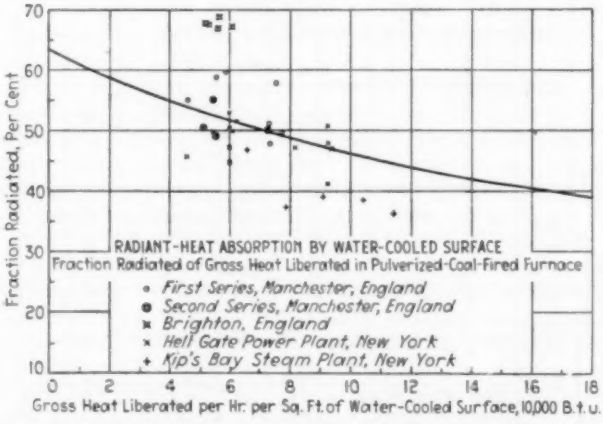

FIG. 6 RATIO OF HEAT RADIATED TO GROSS HEATING VALUE OF FUEL FIRED

The above furnace-outlet temperatures show an increase of somewhat less than 200 deg. fahr. for a change in the factor from 1500 to 1000, and a further increase of about 300 deg. fahr. for a change in the factor from 1000 to 500.

The heat absorbed by the water-cooled surfaces exposed to radiation in a furnace is somewhat less than the heat radiated from the burning fuel and products of combustion as calculated by this method, by reason of loss of heat from the furnace casing to surrounding objects. Also, the "unaccounted for" loss assumed as a margin of safety in a heat balance for a pulverized-coal-fired furnace, may be subtracted from the heat radiated as the most convenient place of including this item in an analysis of a steam-generating unit.

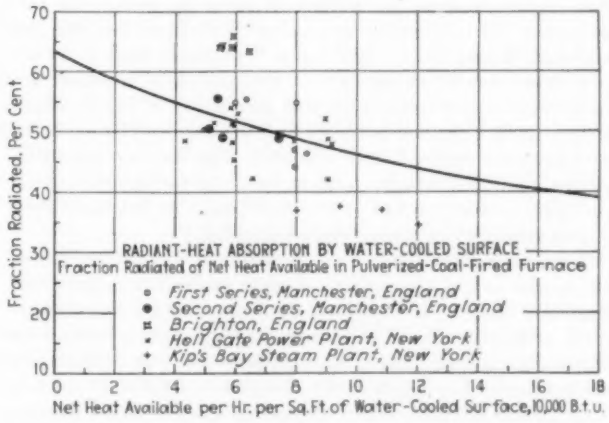

FIG. 7 RATIO OF HEAT RADIATED TO NET HEAT LIBERATED AND IN PREHEATED AIR

The "effectiveness factor" can be applied to stoker-fired furnaces as well as to pulverized-fuel furnaces, and also to oil- and gas-fired furnaces. By experimental and operating experience with furnaces of different types burning various fuels, judgment is developed in selecting the proper factor for determining the heat absorbed by radiation and the furnace-outlet temperature, either by calculation or from curves for typical fuels.

Discussion

A. G. CHRISTIE.[5] This is a subject in which the writer has been interested for many years and which was discussed by him in an earlier paper of a general nature presented before this Society at its Milwaukee meeting in 1925. Since that time such heat transfer has received much attention. However, a study of the now voluminous literature on the subject indicates the need of still further data on the subject of radiation and of the laws governing the dissipation of radiant heat from burning fuels and from flames in a boiler furnace. A further need is the simplification and rationalization of the analytical methods that have been applied in the past, and this paper of Mr. DeBaufre offering such a method is timely and welcome. The method of treatment for radiant heat problems suggested by the author carries additional weight from the fact that he has, through his professional position, had ample opportunity to test the validity and applicability of the solutions suggested.

A paramount factor in this discussion is the determination the proper area of the surfaces of tubes exposed to radiant heat. Professor Ramzin, in a paper before the World Power Conference, analyzed radiant heat absorption in a bank of boiler tubes above a furnace and found that this total area was equivalent to the product of the length of the tubes and the width of the tube bank measured from between the outside tubes. This is less than assumed by the author. Professor Ramzin found that the equivalent area of a Murray fin-tube wall was 1.1 times the total projected area measured over the fins. This also is less than assumed by the author. The writer stresses these differences in order to indicate the need of standardization of the measurement of such heat-absorbing surface and recommends that this question of standardization receive the attention of A.S.M.E. probably through its Power Test Code Committee.

The author suggests an "effectiveness factor" E which will serve as a measure of heat absorption. This can be defined as the B.t.u. absorbed per square foot of surface per hour per unit of difference of the fourth powers of the results of dividing both absolute furnace temperature and absolute tube temperature by 1000. His analysis indicates that this factor is unaffected by variations in CO_2 or by preheated air temperatures. It is well known that both of these materially affect furnace temperature and the total heat absorbed per square foot of heat-absorbing surface. The author assumes that the Stefan and Boltzmann law, based on the difference of the fourth powers of absolute furnace and tube temperatures, holds for furnace conditions. Some have cast doubt on the applicability of this relation. An experimental research to prove or disprove the Stefan and Boltzmann law seems desirable at this time.

A perusal of Figs. 3 and 4 shows many values above the upper line which presumably represent clean surfaces and for which condition an effectiveness factor of 1500 was assumed with a gross heat liberation of 28,000 to 30,000 B.t.u. per hr. per cu. ft. of furnace volume. Why was a higher value not chosen for clean surfaces?

Slag of varying thickness has an appreciable effect on heat transfer. Why was an effectiveness factor of 500 chosen for all rates of heat transfer with considerable slag adhering to the furnace walls?

Evidently the selection of an effectiveness factor for any given case is a matter of judgment based on the condition of the heat-absorbing surface and the presence of slag on such surfaces. This would indicate that this effectiveness factor is still empirical and is not an exact measure of heat transfer.

Hudson's formula as modified by Orrok has been widely quoted. A study of Table 3 indicates divergences from DeBaufre's figure ranging as high as 20 per cent of the observed values. Which is probably in error, the empirical Hudson formula or the empirical effectiveness factor of DeBaufre?

The author deserves the thanks of engineers for developing this interesting solution. Its acceptance will depend to a large extent upon confirmation based on further tests and observations.

[5] Professor of Mechanical Engineering, Johns Hopkins University, Baltimore, Md. Mem. A.S.M.E.

ARNOLD WEISSELBERG.[6] From the valuable experimental data which Mr. DeBaufre has made available through this paper, tests 7-A to 7-D at the Hell Gate Station are singled out to demonstrate that the effectiveness factor is not affected by the CO_2 percentage. This statement should be taken with reservation. If the data of these tests permit the drawing of a conclusion, no doubt tests 6-A to 6-C should enjoy the same privilege. However, these tests show that the effectiveness factor changes considerably with the CO_2 content. If the effectiveness factors of these tests are plotted against the CO_2 values, there is obtained practically a linear relation. Furthermore, with test 3 of the same station carried out at the same firing rate as 7-A to 7-D, the effectiveness factor is a great deal off the average by plus 100. However, this test differs from 7-A to 7-D in that the preheat temperature is 20 deg. fahr. lower, which would also cast doubt on the assumption which the author takes as probable that the effectiveness factor is not affected by preheat. On the other

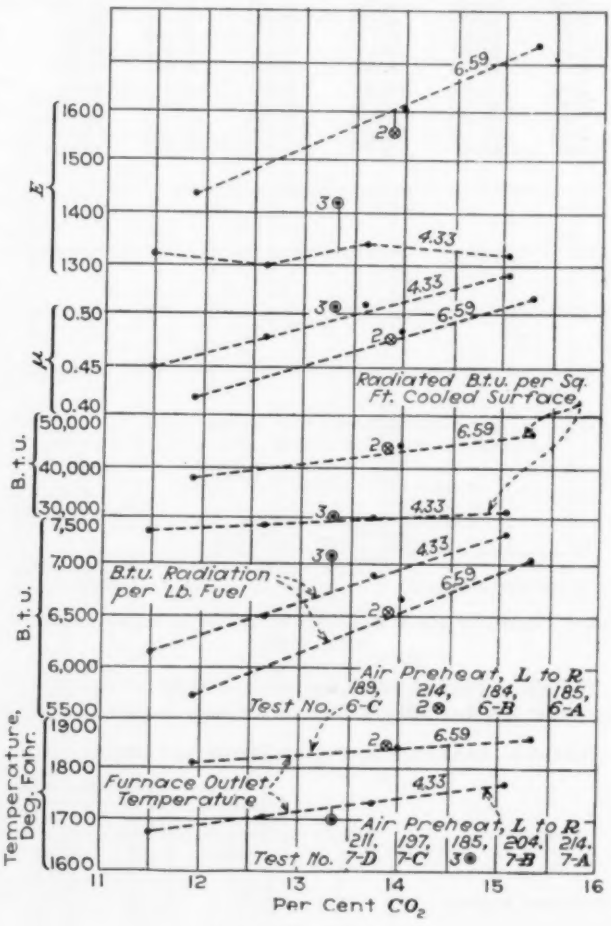

FIG. 8

[6] Mechanical Engineer, Jersey City, N. J.

hand, test 3 at the same station, with a firing rate practically equal to 6-A to 6-C, but with a preheat of about 30 deg. fahr. lower, has an effectiveness factor of 50 points lower than the point corresponding to its CO_2 on the line connecting the effectiveness factors of tests 6-A to 6-C. This proves that the effectiveness factor is manifestly influenced by the preheat. It may be contended that the experimental data of the tests mentioned are not sufficiently reliable to permit of any conclusion regarding the effectiveness factor. But this is not so. If there are plotted the values of furnace-outlet temperature, heat radiated per pound coal, and heat radiated per square foot of cooling surface of all these tests, a decided conformity in the relation of the values will be observed. So far as tests 7-A to 7-D and tests 6-A to 6-C are concerned, the values are practically on straight lines. The values of test 3 in their relation to the lines for tests 7-A to 7-D indicate the effect of the lower air preheat as an increase of heat absorbed by radiation due to the lowering of the furnace thermal level upon which the radiant heat is superimposed. Also, in general, the values check fairly well with Artsay's formula of radiant heat absorption. Therefore, we must conclude that the experimental data are at least fairly accurate.

The author is of the opinion that, with experimental and operating experience, judgment may be developed in the proper selection of the effectiveness factor and thus enable the determination of radiant heat absorption. This may be true, but it also is true that judgment may develop eventually to the point where one may dispense with the use of such a factor entirely.

OLLISON CRAIG.[7] The writer does not believe that it will ever be possible, or even desirable, in every-day practice, to calculate heat absorption by water-cooled walls in boiler furnaces from the empirical formulas based on basic laws of radiation. Mr. Hottel's paper gives a number of the variables that are encountered in problems of this kind and gives a formula for the calculation of heat transmission for each of these variable conditions.

The amount of work that would be involved in calculating total heat absorption in a given furnace, taking into account all of these variable conditions and applying each of these formulas, would be tremendous. Besides, there are other factors involved affecting the amount of heat that would be absorbed which are not taken into account in Mr. Hottel's paper.

It is quite probable that the accuracy obtainable, and even desirable can be obtained by means of empirical formulas and which will reduce the work of calculation enormously. The writer makes use of Orrok's modified Hudson formula and finds that the results check with sufficient accuracy in almost all cases in practice. To carry these calculations still further, the writer has reduced this formula to a series of curves, each curve representing 1 per cent of carbon dioxide and the coordinates the temperature rise of gases and heat release in the furnace per square foot of water-cooled surface.

Mr. DeBaufre has given experimental data for a number of installations and group these into a series of tests. These might be considered as divided into six series, three of the series being at Manchester—one at Brighton, one at Hell Gate, and one at Kip's Bay. In Table 3 of Mr. DeBaufre's paper he has tabulated the fraction of heat radiated for each test as calculated by the Orrok's Hudson formula and has shown the deviation based on both gross heat liberated and on the heat available.

The writer has calculated the percentage variation from the deviation based on the heat available and obtained the average percentage for each of the six series of tests mentioned. In the first series of tests at Manchester, being tests 1, 2, 5, and 6, the average percentage deviation is minus 8.3. The water-cooled surfaces were described in the paper as being comparatively clean. In the second series of tests at Manchester, being tests 7, 8, and 9, the percentage is plus 5.5, the paper stating that considerable amounts of slag had accumulated. The third series of tests, being tests 2, 3, 4, and 5, show a percentage deviation of plus 6.9, and the paper indicates an accumulation of slag as in tests 7, 8, and 9. In the tests at Brighton the percentage deviation was minus 18.5, and the paper states that the walls were kept very clean. In the test at Hell Gate the deviation was minus 8.3, with no comment as to the condition of the walls. For the tests at Kip's Bay the percentage deviation is plus 9.5, and the paper states that the water-cooled surfaces had accumulated a thicker layer of slag than at Hell Gate.

It is quite obvious of course that clean water-tube surfaces in furnace walls will absorb more heat than surfaces which have accumulated ash and slag, as is nicely indicated by the foregoing averages. This is a factor which the engineer cannot evaluate in advance and for which he must of necessity assume an average value.

Taking the average percentage deviation from Table 3, a figure of minus 3.3 per cent is obtained, this being for both clean surfaces and surfaces having more or less slag. The writer believes that it is fair to assume that the Orrok's Hudson formula will give results with sufficient accuracy as to cover the average case of water-cooled furnaces under average operating conditions with an average amount of slag and ash adhesion. If there is any error, it is probable that the actual absorption is somewhat greater than would be indicated by the formula, and for most purposes of calculation the error involved would be on the right side.

It would seem, then, that the use of Orrok's Hudson formula, or curves derived from this formula, would take into account the effectiveness factor as indicated in Figs. 3 and 4, with sufficient accuracy as regards the variation in rating, but would not give consideration to the slag condition of the tubes, the temperature of which is not under the control of the designer.

In this connection it is well known that in starting a new pulverized-coal furnace with clean water surfaces it is more difficult to obtain efficient combustion conditions and smokeless operation than can be obtained after the furnace has been in operation for a considerable period of time and after a certain amount of ash has accumulated on the water-cooled surfaces. Since the normal condition of operation is one in which a certain amount of ash deposit on the wall tubes exists, it might be desirable to arbitrarily produce a comparable condition during the initial stages of operation. The writer has found that this can be produced by spraying a thin film of refractory cement on to the tubes by use of a cement gun. The tubes of course should be clean. The film will gradually crack and fall away, but will be replaced with the ash accumulation when the falling away occurs. This method has been found to make the initial period of operation much easier.

Mr. Hottel has given one extremely interesting set of curves in Fig. 5. From curve 5 in Fig. 5 it is to be noted that if one row of bare tubes is placed around the furnace walls and spaced twice their diameter it might be expected that 90 per cent as much heat will be absorbed by these tubes as if the spacing was equal to the diameter or the tubes touching each other, this of course being on the condition that they are set out from the refractory wall and not imbedded in refractory material.

The writer had occasion to examine a section of a tube cut out from such a wall in which the spacing of the tubes was 1.3 times the diameter of the tube. In the particular installation water conditions were such that there was a considerable deposit of scale inside the tube. The amount of scale adhering to the

[7] Consulting Engineer, Riley Stoker Corporation, Worcester, Mass. Mem. A.S.M.E.

half of the tube facing the furnace was determined as well as the amount of scale in the half of the tube adjacent to the furnace wall. It was found that the outer half of the tube contained 1.6 times as much scale as the rear half of the tube.

It is reasonable to assume that there is some relation between heat absorption in a given surface and rate of scale deposit. The distribution of deposit in the tube referred to shows the effectiveness of heat absorption on the side of the tube adjacent to the furnace wall, which is confirmed by curve 5 in Fig. 5 of Mr. Hottel's paper.

The engineer makes use of heat-radiation and heat-absorption calculations in the case of water-cooled walls, either for the purpose of determining the amount of such surface necessary in order to maintain ash above its fusion temperature or to determine how much steam can be made in the walls and how much will need to be made in the convection portion of the boiler. In either case the absorption of a certain amount of heat is desirable for a particular installation. It is also desirable to obtain this absorption with the least expense.

The writer believes that this can be done by the use of bare tubes spaced apart and set out from the furnace wall. The use of Orrok's formula or curves derived from this formula will give results which are accurate within the limits of variables of operation.

N. C. Artsay.[8] The present trend in steam-generator designs is toward pure radiant-heat boilers with convection zones given to superheaters, reheaters, economizers, and air heaters. In these conditions the correct evaluation of heat absorption by the furnace envelope becomes of acute necessity. Several eminent authors have developed methods of applying the Stefan and Boltzmann formula to the furnace conditions. Wohlenberg and his collaborators, Haslam and Hottel in this country, Rozzak in France, Munzinger in Germany, have tried to embrace a number of factors and have developed cumbersome procedures requiring expert handling. Some doubts as to the validity of the main premises of such methods were already cast by Schack and Damour. The correct determination of furnace-gas temperatures is well-nigh impossible, and only the direct measurement of heat absorption by the total radiant surface is of any value; thus the mentioned methods are hard to verify due to the dearth of proper experimental work and data.

Broido and Orrok started from more general considerations in giving their empirical formulations of the radiant-heat absorption. Their results are sufficiently correct for most of the practical cases and are easy to obtain. Mr. DeBaufre's paper shows a method which is a combination of theory and empiricism and which is introducing a very fortunate term, the efficiency of furnace envelopes. The paper is so valuable that a searching criticism of its main premises is warranted. Let us take, first, its quantitative side.

DeBaufre's quantitative results stand or fall on the correctness of furnace-gas temperature determinations. Unfortunately, this item is the most unreliable of all the boiler test data. Many authors have pointed out the errors usually incurred in most elaborate pyrometric readings. High gas velocity thermocouples (Munzinger's suction pyrometers) have been analyzed in a specific case: gas at 1730 deg. fahr. true temperature, flowing in a bank of tubes, was subject to temperature measurement by different devices, among which a plain thermometer indicated 1290 deg. fahr., while suction pyrometers gave readings spread in between these limits. Temperature measurements in water-cooled furnaces are so sensitive to the uncontrollable conditions existing there that it is quite hazardous to use the readings for any but the roughest qualitative considerations.

The premises from which the formula is derived are open to criticism also.

A. Schack plainly writes that radiation is emitted from sources at higher temperature than that of the exit gas, and he takes the actual flame temperature and its surface. E. Damour investigating industrial ovens prefers the theoretical combustion temperature in the first term of the Stefan and Boltzmann formula, which is already much better. In his latest work on radiation (*Mechanical Engineering*, October, 1930, p. 915), Wohlenberg points out that radiation equilibrium of an oxidizing molecule with its ambient surroundings is reached earlier than the dynamical thermal equilibrium, and this comes to support the view that the initial radiation emission due to combustion is independent of the actual furnace temperature. It is easy to compute the radiation due to chemical processes is by far the greatest part of the total radiation and, hence, the use of exit-gas temperature is illogical.

It should be borne in mind that radiation laws holding for hot permanent surfaces have no connection whatever with radiation emitted by matter undergoing chemical processes. Unfortunately this is too often omitted or forgotten. The familiar sight of bright flames is responsible for the common misconception that the heat of oxidation is conveyed first to the mixture of products of combustion with residual air and then part of the heat is radiated away. Even a cursory glance at the process of oxidation if reduced to a molecular scale would show that this is impossible. The more probable scheme is that a group of molecules at the instantaneous chemical combination emits pulses of radiation until the resultant molecules of the product have time to separate and fly away with the remaining energy. Depending upon the properties and size of the furnace enclosure, a part of this initial radiation will be absorbed, and the remaining radiation will be returned via the CO, CO_2, H_2O constituents of gas and transformed by thermal diffusion into kinetic energy of the hot gas. The ensuing thermal radiation according to some power of absolute temperature will be superimposed on the initial or combustion radiation. The amount of radiant energy in this thermal radiation is small compared with the amount released by the oxidation, and hence we are facing the still more complex question of radiation absorption on the water-cooled walls. It is thus apparent that in any furnace where fuel is burning at a sensible rate there is an excess of radiant heat over the capacity of the envelope to absorb radiant heat, and in such conditions we do not need to study the emission. It is the extent and quality of the water-cooled surface which are of utmost importance, and the society should be indebted to Mr. De Baufre for pointing out the effect of slagging, the first time in such investigations of radiant-heat exchange. It should be remembered that the bulk of radiant energy is of low frequency way down in the infra-red, and for these wave lengths the absorbing capacities of metals are surprisingly low.

Thus the solution of the radiant-heat exchange problem lies, not in temperatures or solid angles, but in the change of absorbing capacity in the layers of slag rust and pure metal on the water-cooled surfaces.

W. G. Wohlenberg.[9] On the first page the author refers to the paper entitled "Radiation in the Pulverized-Fuel Furnace," which was prepared by Mr. Donald Moran and myself and published in Vol. 47 of the Transactions. On page 148 of the latter paper there appears an expression which, for short, is designated by the symbol μ_3. To quote from this paper:

[8] Assistant to Geo. A. Orrok, Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

[9] Professor of Mechanical Engineering, Sheffield Scientific School, Yale University, New Haven, Conn. Mem. A.S.M.E.

"This ratio measures the total heat absorption at the cold surface as compared to that striking this surface by a black fuel bed immediately in front of it. The quantity μ_3 is thus the relative absorption of the furnace as compared to that of a total black furnace with the same amount of cold surface."

Values of this coefficient as computed in the Wohlenberg and Moran paper vary from about 40 to something over 80, depending on the conditions, but in no case does the coefficient value exceed one, and this is as it should be when radiation is the sole mode of heat transfer. The interesting point now is that Mr. DeBaufre's effectiveness factor, except for the units in which it is expressed, is exactly this coefficient. For black-body radiation the relative absorption coefficient μ_3 has a value of unity and the De Baufre effectiveness factor E has a value of 1720. This, then, is the number which relates the two factors.

DeBaufre reports values of E as high as 2300, and in a number of cases the values are above the black-body figure of 1720. It is conceivable that under certain conditions radiation intensities in excess of black-body intensities could exist, but they certainly do not exist in the pulverized-fuel furnace. Then such head-absorption figures either are wrong, the associated temperature measurements are wrong, or heat is absorbed in an appreciable amount by a process other than radiation. No doubt there may be some errors in measurements of conditions, as we all know how difficult it is to measure furnace temperatures. But the divergence from black-body conditions seems too large and this appears so in too many different cases. The only other tenable conclusion is that there must in such cases have been a considerable heat transfer by convection, which, added to the normal radiation transfer, accounts for the very high total heat transfer.

In this connection it is significant to note that such results were obtained in furnaces with tangential firing under which conditions there is at least the possibility for a much stronger convection current of the furnace gases as they sweep directly over the water-cooled furnace walls than for some other types of firing. That point is, I think, worth noting.

The author in setting up charts (Figs. 3 and 4) from which values of the effectiveness factor should be determined relies of course wholly on the method of empiricism. He does not at the outset attempt to expand the factor into an expression containing within it terms which represent each of the conditions a variation of which may influence the value of the factor. This of course is the method which was employed in the radiation papers to which the author refers and which, he says, show how complicated the subject becomes when such an attempt is made. Not to expand such an expression may, however, prove dangerous. Such a factor as E is really but a single symbol for a large number of variable conditions that enter into the heat-transfer process in the furnace. How dangerous a bulk consideration of the phenomena may prove becomes evident from a closer investigation of the data shown in Figs. 3 and 4.

In these curves are shown relating the value of the effectiveness factor to the heat release. In each chart the upper curve, which is for clean surfaces, shows an increasing effectiveness of this surface as the heat-release rate is increased. The lowest curve, which is for dirty surfaces, shows a constant value for the effectiveness factor.

Without going into the mathematics of the situation now, let it suffice to say that it may be shown in a simple manner that it is the clean surface condition, or upper curve in the chart, which should show a constant effectiveness factor value. If the surface is clean and has black-body surface characteristics, then this curve should be represented by a horizontal line $E = 1720$.

The curves representing the dirty surfaces should not show an increasing value of E with increase in heat release, but rather a decrease of this value with increase in heat release. It may now be noted that the experimental point shown may be fitted just as closely by sets of curves with the latter set of specifications as they will the specifications which the author's curves fit. Empiricism might thus lead one to construct either set, of which the author has chosen the wrong set. Other curve sets might likewise be fitted into the points as closely as do the author's, but only one trend condition is admissible from the point of view of the fundamental principles involved, and so this is an example of the slips that may enter into any system based primarily on empirical methods.

The writer does not wish to imply here that as a result of this the author's method is all wrong. The curves shown in Figs. 3 and 4 certainly have wrong trends and should, he thinks, be corrected. When corrected in accordance with the above specifications as to trends, they will fit this specification:

(1) For clean heat-absorbing surfaces, the effectiveness factor of the cold surface in a given furnace is a constant
(2) For dirty or covered surfaces, the effectiveness factor of the surface decreases with increasing heat-release rates.

It will be noted that in each of the foregoing statements the qualifying cause, "for a given furnace," is introduced. There should be other qualifying causes, such as for a given fuel, for a given excess air, for a given air temperature, etc.

Thus the simpler the resulting formulas under such conditions the more must be left to the judgment of the man who attempts to use it. In fact, for a process as complex as is this one, simple formulas probably must leave so much to the judgment of the individual that he is hopelessly lost unless he is an expert in the field.

In closing, the writer wishes to present just one more thought and this is it: A comprehensive analysis of any situation in which account is taken of all of the factors involved results in a theory and in formulas which leave less and less to the judgment of the individual according as the theory approaches perfection. This of course is obvious. If a theory developed on such a basis becomes so formidable in appearance that the results of the theory (such as formulas, etc.) are difficult of application, this in itself is a very good indication that in such a problem a minimum gap should be left to the judgment of the individual. The degree of complexity of the theory is usually a direct measure of the difficulty which would be required in arriving at results based on judgment. The boiler-furnace problem is just of this sort, and those who would use simple relations for its evaluation must not forget the magnitude of errors into which they might fall.

Author's Closure

As stated by Professor Christie, the "effectiveness factor" proposed in this paper is an empirical value to be selected by the furnace designer with judgment based on the condition of the heat-absorbing surface, etc. The value of 1500 was selected for a heat release of 28,000 to 30,000 B.t.u. per hr. per cu. ft. of furnace volume because this value is well within the data obtained for clean or slightly dirty bare surfaces with horizontal turbulently fired pulverized-fuel furnaces, and is therefore a safe value for design purposes under these conditions. The value of 500 was selected to represent a very dirty furnace because this value is below the lowest values obtained with considerable slag adhering to the water-cooled surfaces, and therefore represents conditions worse than actually have been encountered.

Table 3 is a comparison of experimental data with results calculated by Hudson's formula and is not a comparison of the "effectiveness factor" with this formula, as stated by Professor Christie.

Professor Wohlenburg unfortunately confuses the effectiveness factor based on the furnace outlet temperature with his ratio μ_8 based on the furnace temperature immediately in front of the heat-absorbing surface. Experiments not described in the present paper have shown that the heat absorption based upon the temperature immediately in front of the heat-absorbing surface corresponds to about one-half the black-body coefficient. But the furnace temperature varied from about 2500 deg. fahr. at the zone of most intense combustion to about 1800 deg. fahr. at the furnace outlet. Basing the heat absorption on the furnace outlet temperature necessitates the use of an "effectiveness factor" approximately equal to the black-body coefficient, although the actual factor is one-half this coefficient when based on the actual temperature of the flame in front of the surface absorbing heat.

This point is covered in the paper among the reasons given for the fourth-power radiation law not strictly applying in the way used.

When the furnace is operating nearly full of flame, the heat-absorbing surfaces are evidently in a better situation for effective heat absorption than when the flame only partly fills the furnace volume at reduced ratings if the surface of the flame is a factor in the amount of energy radiated. This was taken as an explanation of the falling off in the value of the effectiveness factor based on the area of the absorbing surface as indicated by the experimentally determined points for reduced ratings with comparatively clean surfaces. When the surfaces in the most intense zone of combustion contain more slag than those in cooler parts of the furnace, the flame at reduced ratings apparently does not contract to the same extent as with clean surfaces, so that the effectiveness of the water-cooled surface does not fall off to the same extent. With certain gas-fired furnaces, the effectiveness factor has been found to increase at reduced ratings, but this is attributed to combustion within the furnace being incomplete at the higher ratings so that not as much heat was available for radiation as the heating value of the fuel would indicate. In calculating the performance of steam-generating units at reduced ratings with pulverized fuel, a constant effectiveness factor of 1500 gives temperatures which drop off more rapidly with reduction in rating than experience would indicate to be so. It is therefore believed that the trends of the curves in Figs. 3 and 4 are not as wrong as Professor Wohlenburg concludes.

With regard to the curves plotted by Mr. Weisselberg, it is unfortunate that his point for run 6-A was plotted for an effectiveness factor of 1740 instead of 1640 as given in the paper. If correctly plotted, little difference would be seen between 1640 for 15.35 per cent CO_2 and 1610 for 14.02 per cent of CO_2. There is an appreciable drop, however, between 1610 for run 6-B with 14.02 per cent CO_2 and 1440 for run 6-C with 11.94 per cent CO_2. This may have been due to accumulation of slag in the furnace, which would also account for the smaller difference between runs 6-A and 6-B. It will be noticed that the other values plotted do not line up exactly although plotted to a less open scale than used for the effectiveness factor. However, the lines for runs 6-A, 6-B, and 6-C are nearly parallel to the lines for runs 7-A, 7-B, 7-C, and 7-D, thus indicating that if the temperatures and heats radiated were calculated for a constant value of the effectiveness factor, nearly the same curves would be obtained. One advantage of the use of the effectiveness factor is that a considerable variation in its value affects the quantities determined by means of it to a much smaller extent; hence, a reasonably close choice will give fairly accurate results.

Mr. Craig is correct in concluding that the experimental data in this paper confirms the use of the Hudson formula as representing on an average the heat absorbed by water-cooled bare surfaces in boiler furnaces. For many purposes, an approximate average value meets the requirements, particularly for stoker-fired furnaces. But for more nearly accurate calculations, particularly with pulverized fuel, some differentiation is necessary for various furnace conditions and arrangements. The use of various effectiveness factors provides such a differentiation.

In the present state of the art, more or less empirical methods are necessary to divide the heat absorbed by radiation in the furnace from that remaining in the products of combustion leaving the furnace. Methods having a better theoretical basis may come into use in the future through the efforts of such students of the subject as Mr. Artsay.

While the method of calculation described in this paper may seem rather laborious, it is possible to plot curves for typical fuels which render the determination of the furnace-outlet temperature based on the "effectiveness factor" a very simple matter.

Radiant Heat Transmission Between Surfaces Separated by Non-Absorbing Media

By H. C. HOTTEL,[1] CAMBRIDGE, MASS.

Fundamental laws of radiation from solids have been discussed and applied to individual problems of heat transfer in numerous papers. In this one the author indicates just what principles are involved, to how many problems they have been applied, and gives a number of applications of the principles to problems in industrial-furnace design.

Fundamental principles and definitions discussed include: The definition of normal intensity, Lambert's cosine principle, relation between intensity and emissive power, the square-of-the-distance law, Kirchoff's law, and the Stefan-Boltzmann law. Various surface arrangements are divided into two groups: (1) in which one of the two surfaces is small relative to the distance separating them, and (2) in which both surfaces are of considerable extent relative to their distance apart. Various cases of these and the effect of incomplete absorption are treated mathematically. The task of applying many of the equations given in the paper is simplified by presentation of numerous graphs.

THE fundamental laws of radiation from solids have been treated in many textbooks, and have been applied to individual problems of heat transfer in numerous articles in technical and scientific journals (2–7).[2] No satisfactory presentation has been made, however, of the subject in a form indicating just what principles are involved and to how many problems they have been applied; and a number of applications of the principles to problems of some importance in industrial furnace design have never been made. A summary of the results on the more important problems was presented briefly in a recent paper (11), but no indication was given of the method of obtaining the results. Inasmuch as an intelligent use of the results and the application of the principles to new problems depends on familiarity with the method of obtaining the results, it is felt that they merit a more detailed treatment than it was possible to give them in the paper referred to.

The treatment of problems in radiant heat transmission between surfaces involves the application of certain fundamental principles or definitions which may be grouped into (*a*) principles of photometry and illumination, and (*b*) principles of thermal radiation. The first group includes:

1 *The definition of normal intensity*, as being the energy emitted per unit area of emitting surface per unit solid angle per unit of time, in a direction normal to the surface. Mathematically, this says:

$$dq = i\, dA\, d\omega$$

in which q is energy per unit time, i is normal intensity, A is area, and $d\omega$ is a differential element of the solid angle above dA and normal to dA.

2 *Lambert's cosine principle*, which states that if the cone of radiation dq lying within the solid angle $d\omega$ is not normal to the surface dA but makes an angle θ with the normal to the surface, then the above equation must be modified to

$$dq = i\, dA \cos\theta\, d\omega \qquad [1]$$

The term $dA \cos\theta$ is the projected area of dA on a plane normal to the beam of radiation. The cosine principle, which amounts to the assumption that the intensity i of Equation [1] is independent of the angle θ and is equal to the normal intensity, is not exact except for "black" surfaces, or perfect radiators, but is in small error for most surfaces met in heat-transfer problems (7). The magnitude of the error will be discussed later.

3 *The relation between intensity and emissive power* of a surface, depending on the definition of the latter as being the amount of energy emitted per unit of time per unit of area in all directions throughout the solid hemispherical angle above the surface. It is designated by E, and is sometimes called hemispherical intensity instead of emissive power. Obviously the integration of Equation [1] to include the total hemisphere above dA should lead to the relation between intensity i and emissive power E.

$$E\, dA = i\, dA \int \cos\theta\, d\omega$$

Any textbook on photometry gives the integration, which leads to the relation $E = \pi i$.

4 *The square-of-the-distance law*, which follows directly from Equation [1] and is sometimes more useful. If the beam of radiation from dA, lying within the solid angle $d\omega$, is intercepted by a surface element dA' at a distance r from dA, and the line of length r connecting dA and dA' makes an angle θ' with the normal to dA', then $d\omega$, by definition of a solid angle, may be placed equal to $dA' \cos\theta'/r^2$.

Equation [1] then becomes

$$dq = i\, \frac{(dA \cos\theta).(dA' \cos\theta')}{r^2} \qquad [1a]$$

which states that the radiation from one small surface element to another is proportional to the product of their areas projected on the planes normal to the line connecting them, and is inversely proportional to the square of the distance separating them. This is generally referred to as the square-of-the-distance law.

The principles of thermal radiation necessary to the solution of the problems at hand include:

5 *Kirchoff's law*, which states that the emissive power of a surface divided by its absorptivity is the same for all surfaces at

---

[1] In Charge of Course in Fuel and Gas Engineering, Massachusetts Institute of Technology. Professor Hottel received the degree of A.B. in Chemistry from Indiana University in 1922, and that of M.Sc. in Chemical Engineering in 1924 from the institution with which he is at present connected.

[2] Numbers in parentheses refer to bibliography at end of paper.

Contributed by the Fuels Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

a given temperature, and is equal to the emissive power of a "black" body or perfect radiator. The absorptivity of a surface is defined as the fraction of the radiation incident on it which it absorbs. If we define emissivity as the radiation from a surface divided by the radiation from a black body at the same temperature, we see from Kirchoff's law that emissivity and absorptivity are numerically equal. The law is proved in many textbooks on physics; it is frequently misapplied in radiation problems not involving equilibrium radiation; and the extent to which the result is an approximation is not stated, and in some cases not realized.

6 *The Stefan-Boltzmann law*, which states that the emissive power of a black body is proportional to the fourth power of its absolute temperature. This law was determined by Stefan in 1879 from Tyndall's experiments, and was proved on thermodynamic grounds by Boltzmann in 1884.

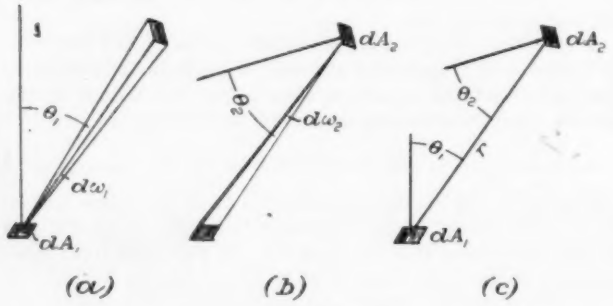

FIG. 1

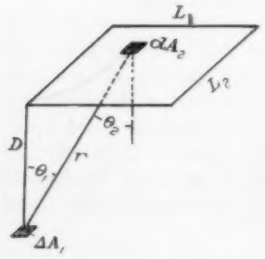

FIG. 2

From Equation [1] the radiation from a surface A_1 to another surface A_2 is

$$q = i_1 \int dA_1 \cos \theta_1 \, d\omega_1$$

with the integration taken over the whole area A_1 and throughout the total angle ω_1 subtended by A_2 [see Fig. (1*a*)]. The reverse radiation from A_2 to A_1 is

$$q = i_2 \int dA_2 \cos \theta_2 \, d\omega_2$$

with the integration taken over the whole area A_2 and throughout the total angle ω_2 subtended by A_1 at A_2 [see Fig. (1*b*)]. But we know from the equivalence of Equations [1] and [1*a*] that either of the above integrals might have been evaluated in the form

$$\int \frac{dA_1 \, dA_2 \cos \theta_1 \cos \theta_2}{r^2} \quad \text{..... [see Fig. (1c)]}$$

and that they are therefore equal. Remembering that $E = \pi i$ and that for black surfaces $E = \sigma T^4$, we may express the net heat interchange between two black surfaces A_1 and A_2 in any of the three forms

$$q = \frac{\sigma}{\pi} (T_1^4 - T_2^4) \int dA_1 \cos \theta_1 \, d\omega_1 \quad \text{.....[2a]}$$

or

$$q = \frac{\sigma}{\pi} (T_1^4 - T_2^4) \int dA_2 \cos \theta_2 \, d\omega_2 \quad \text{.....[2b]}$$

or

$$q = \frac{\sigma}{\pi} (T_1^4 - T_2^4) \iint \frac{dA_1 \, dA_2 \cos \theta_1 \cos \theta_2}{r^2} \quad \text{.....[2c]}$$

The choice among them is determined by the relative ease of evaluation of the different integrals for the problem at hand.

In applying the principles discussed so far to the solution of problems of heat interchange in systems consisting of various surface arrangements, we find it convenient to treat separately the two factors, shape of the system and emissivity of the surfaces composing it, by considering temporarily that the surfaces with which we are concerned are perfect radiators and absorbers, i.e., black bodies, and that therefore only the factor of shape enters.

Effect of Shape of System

We may classify the various surface arrangements into two groups, in the first of which one of the two surfaces is very small relative to the distance separating the two, and in the other of which both surfaces are of considerable extent relative to their distance apart. In the first group, Equation [2] will require integration over but one area. The various cases follow:

Case 1. Interchange between a small surface element ΔA_1 and a parallel plane A_2 of infinite extent. The problem of integrating Equation [2*a*] to include the total hemispherical angle above A_1 is treated in many textbooks, and leads to

$$q = \sigma(T_1^4 - T_2^4) \, \Delta A_1 \quad \text{.....[3]}$$

Case 2. Element ΔA_1 and a circular disk of radius a in a plane parallel to the plane of ΔA_1 and distant from it the distance K. Let x be the distance from ΔA_1 to the normal through the center of the disk. The illumination problem analogous to this has been treated by Foote (3) and leads to

$$q = \sigma(T_1^4 - T_2^4) \, \Delta A_1 \left\{ \frac{1}{2} - \frac{x^2 + K^2 - a^2}{2\sqrt{x^4 + 2(K^2 - a^2)\,x^2 + (K^2 + a^2)^2}} \right\} \quad \text{.....[4]}$$

Case 3. Element ΔA_1 and a rectangle in a plane parallel to the plane of ΔA_1, with a corner of the rectangle contained in the normal to ΔA_1. Equation [2*c*] is of the form most readily applied. Fig. 2 defines the terms appearing in Equation [2*c*].

$$dA_2 = dx \, dy$$

$$r = \sqrt{x^2 + y^2 + D^2}$$

$$\cos \theta_1 = \cos \theta_2 = \frac{D}{\sqrt{x^2 + y^2 + D^2}}.$$

Substituting these terms into [2*c*], we have

$$dq = \frac{\sigma(T_1^4 - T_2^4)}{\pi} \frac{\Delta A_1 \, dx \, dy \, D^2}{(x^2 + y^2 + D^2)^2}$$

If the rectangle has sides L_1 and L_2, the radiant heat interchange is given by

$$q = \sigma(T_1^4 - T_2^4) \, \Delta A_1 \cdot \frac{D^2}{\pi} \int_0^{L_1} \int_0^{L_2} \frac{dx \, dy}{(x^2 + y^2 + D^2)^2}.$$

On integrating this and redefining L_1 and L_2 as the ratio of each side to the distance separating the planes, we have

$$q = \sigma(T_1^4 - T_2^4) \, \Delta A_1 \frac{1}{2\pi} \left[\frac{L_2}{\sqrt{L_2^2 + 1}} \sin^{-1} \frac{L_1}{\sqrt{L_1^2 + L_2^2 + 1}} + \frac{L_1}{\sqrt{L_1^2 + 1}} \sin^{-1} \frac{L_2}{\sqrt{L_1^2 + L_2^2 + 1}} \right] \quad \text{.....[5]}$$

Case 4. Element ΔA_1 and any rectangle in a plane parallel to

ΔA_1. This can be treated as above by dividing the rectangle into four rectangles having a common corner above ΔA_1. If the large rectangle lies completely outside the normal to ΔA_1, the same principle is applicable if we remember to add areas algebraically.

Case 5. Element ΔA_1 and any surface generated by a line of infinite length moving always parallel to the plane of ΔA_1. This case has considerable industrial applicability, and includes radiation to a nest of tubes whose length is great compared to the distance from them to the radiator, radiation from banks of strip and rod heaters in electric furnaces, etc.

In Fig. 3 the surface element ΔA_1 is at the origin, in the XY-plane. Line ABC represents the trace, in the XZ-plane, of the infinite line generating the surface A_2. The figure defines the terms of Equation [2*a*] as follows:

$$d\omega_1 = \frac{\rho^2\, dy\, d\theta}{(\rho^2 + y^2)^{3/2}}$$

$$\cos\theta_1 = \frac{\rho\cos\theta}{\sqrt{\rho^2 + y^2}}$$

$$d\omega_1 \cos\theta = \frac{\rho^3 \cos\theta\, d\theta\, dy}{(\rho^2 + y^2)^2}$$

Substituting into Equation [2*a*], and inserting the limits of $\pm\ \infty$ for y, we have

$$q = \sigma\,(T_1^4 - T_2^4)\ \Delta A_1 \frac{1}{\pi} \int_{-\infty}^{+\infty} \int_{\theta''}^{\theta'} \frac{\rho^3 \cos\theta\, d\theta\, dy}{(\rho^2 + y^2)^2} \quad [6]$$

which on integration becomes

$$q = \sigma(T_1^4 - T_2^4)\,\Delta A_1 \frac{(\sin\theta' - \sin\theta'')}{2} \quad [6a]$$

It is to be noted from Equation [6*a*] that the evaluation of q for this case does not necessitate the use of a three-dimensional still calculations. Fig. 4 shows a cross-section through a bank of infinitely long tubes. It is desired to find the heat interchange between the surface element ΔA_1 of the lower plane and the tubes above. The shaded areas represent intercepted beams. If a circle of unit radius is drawn, inspection of the figure indicates

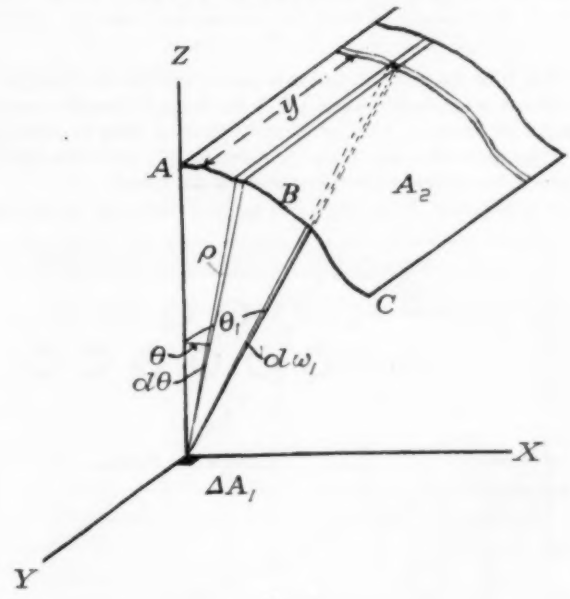

FIG. 3

that for any tube the expression $(\sin\theta' - \sin\theta'')$ is equal to the projection, on the base line, of that arc of the unit circle which lies between the bounding lines of the tube. The sum of the projections, indicated, divided by the diameter of the

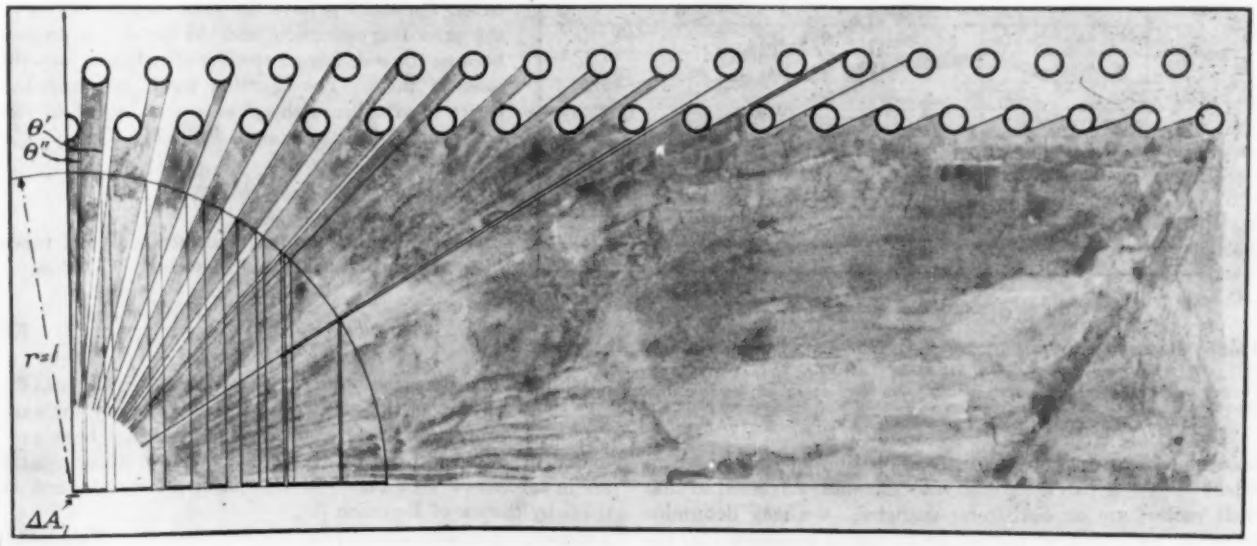

FIG. 4 RADIANT HEAT TRANSFER TO A BANK OF TUBES

picture, but simply of the cross-section through ΔA_1 and surface A_2 taken normal to the generating line of surface A_2. The angles θ' and θ'' are angles in this cross-sectional picture, made by the normal to ΔA_1 with the lines joining ΔA_1 to the edges of A_2.

A graphical solution of problems falling in this class is rapid, and frequently useful in steam-boiler, cracking-coil, and tube-circle, gives a factor F_A such that the heat interchange between the surface element ΔA_1 and the tube bank is

$$q = \sigma(T_1^4 - T_2^4)\,\Delta A_1\, F_A \quad [7]$$

This method may be used to determine quickly the distribution of heat to different rows of tubes in a setting, and to study the effect of spacing on the distribution. When only one row of

equally spaced tubes is involved and the tubes are of infinite extent in both directions (infinite number of tubes of infinite length), the solution of the problem need not be made graphically. The factor F_A for such an arrangement is given by

$$F_A = \frac{K + \tan^{-1}\sqrt{K^2-1} - \sqrt{K^2-1}}{K} \quad \ldots\ldots [7a]$$

in which K is the ratio of center-to-center distance to diameter. This factor is applicable when ΔA_1 is far enough from the tubes to make its location, whether directly under a tube or directly under the space between tubes, inconsequential; or to the whole surface A_1 regardless of its distance from the tubes.

The application of the graphical method discussed above has

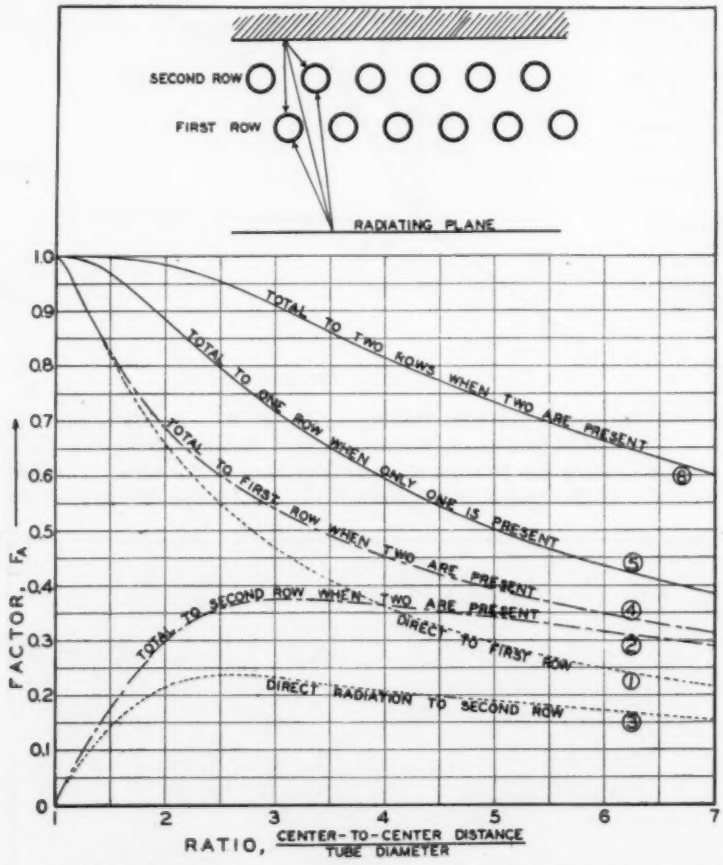

FIG. 5 RADIATION FROM A PLANE TO ONE OR TWO ROWS OF TUBES ABOVE AND PARALLEL TO THE PLANE

(Tubes on equilateral-triangular centers; non-conducting but reradiating refractory surface above tubes. Ordinate expressed on basis of heat transferred from a plane to a plane replacing the tubes, or to an infinite number of rows of tubes.)

been made to two problems in heat distribution. Let us consider the case of two horizontal rows of tubes, staggered so that their centers are on equilateral triangles. We may determine either by the graphical method or by use of Equation [7a] the fraction F_A, of the radiation from a plane below, which is intercepted by the first row of tubes. The graphical method also permits a determination of the fraction intercepted by the second row. These fractions are presented in Fig. 5, lines 3 and 1, as functions of the dimension ratio, center-to-center distance/tube diameter. We have in addition to consider the effect of the presence of a back wall above the tubes. Let F_{A1} and F_{A2} represent the fractions of the direct radiation from below which are intercepted by the first (lower) and second rows, respectively. The fraction $1 - F_{A1} - F_{A2}$ passes through both rows and is intercepted by the back wall, which assumes a temperature intermediate between that of the lower radiator and the two rows of tubes. The back wall, on the assumption of no external loss, reradiates downward an amount of radiation equal to that which it absorbs, i.e., the radiation $1 - F_{A1} - F_{A2}$. The top row, which now is the first row, intercepts the fraction F_{A1} or the amount $F_{A1}(1 - F_{A1} - F_{A2})$. The total fraction F_2 picked up by the top row is therefore $F_{A2} + F_{A1}(1 - F_{A1} - F_{A2})$; similarly, the total fraction picked up by the lower row is $F_{A1} + F_{A2}(1 - F_{A1} - F_{A2})$. These results are included in Fig. 5.

The results on a second problem in heat distribution are presented in Fig. 6. If we change from two rows of tubes, staggered, to two rows in which the tubes of the top row are directly above the lower tubes, we may expect a change in the distribution of heat. Fig. 6 presents the results, not for a variable ratio of center-to-center distance to tube diameter, but for a constant value of 2 (clearance equals diameter), with the variable taken as the distance between rows.

The results presented in Fig. 5 (or 6) are applicable to the solution of an entirely different type of problem. We have been considering radiation from a plane to rows of tubes, basing the heat transfer on the area of the plane. In the design of electric resistor furnaces, rows of rods are frequently used as resistors, and it is desirable to know the radiating power of the rods. If we consider the two rows of rods at temperature T_1 surrounded on both sides by the ultimate heat-receiving surface at temperature T_2, the radiant-heat-transfer equation would be

$$q = \sigma(T_1^4 - T_2^4)2A_p(F_{A1} + F_{A2}) \quad \ldots\ldots [8]$$

in which A_p is the area of a plane replacing the tubes, F_{A1} and F_{A2} have the same significance as in the preceding discussion, and the factor 2 is present because the rods have a receiver of radiation on both sides of them. The equation would be somewhat easier to visualize with an area term equal to the actual area of the rods, A_R. From Fig. 5,

$$A_p = A_R \frac{d}{2\pi D}$$

in which d equals center-to-center distance of tubes in a row and D equals tube diameter. Therefore

$$q = \sigma(T_1^4 - T_2^4)\, A_R \left[\frac{(F_{A1} + F_{A2})d}{\pi D}\right] \ldots\ldots [9]$$

The bracketed term may be called the "surface efficiency" of the rods. The surface efficiency for one- and two-row arrangements of rods has been presented in graphical form by Keene and Luke (5) whose results are in agreement with Fig. 5 of this paper after conversion is made by the use of Equation [9].

Case 6. Element ΔA_1 and any surface whatever. This is the general case covering all those which have preceded. Herman in his textbook on geometrical optics (1) discussed a method of graphical evaluation of the problem, depending on the fact that if a unit hemisphere is constructed above the element ΔA_1, and a straight line with one end fixed at ΔA_1 is made to move around the edge of A_2, then the projection, on the base of the hemisphere, of the area on the hemisphere marked off by the moving line, is equal to the integral $\pi \int_{A_2} d\omega \cos\theta$. Nusselt (8)

later described the same method. There is considerable difficulty, however, in making such a three-dimensional construction; and the author (11) has described a simple mechanical device to be used with a small cardboard model of the surface under consideration. The device, not made with particular care, gives results agreeing within 1 per cent with those obtained for some of those special shapes above which can be solved algebraically.

In the preceding group of surface arrangements the integration of Equation [2] was performed over the area A_2 only. In all that follow both surfaces are of considerable extent, and the integration will therefore be made over both A_1 and A_2. The simplest case is

Case 7. Infinite parallel planes. The integration of Equation [3] over the area A_1 leads to the familiar

$$q = \sigma(T_1^4 - T_2^4)\, A$$

Case 8. Two continuous surfaces, one enclosing the other. If the enclosed surface contains no negative curvature, i.e., if no elements of its surface can "see" anything but the other surface, the integration of [2a] leads simply to

$$q = \sigma(T_1^4 - T_2^4)\, A_1 \qquad \ldots\ldots [8]$$

in which A_1 is the area of the enclosed surface.

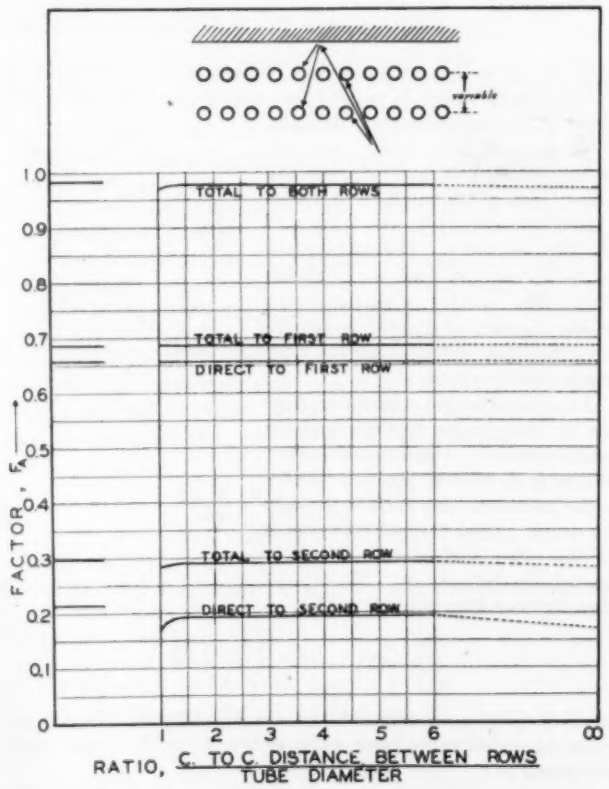

FIG. 6 EFFECT OF DISTANCE BETWEEN TUBE ROWS ON RADIANT HEAT DISTRIBUTION TO TWO ROWS OF TUBES, WHEN TUBES ARE DIRECTLY BEHIND ONE ANOTHER

(Ratio (center-to-center distance of tubes in a row)/(tube diameter) held constant at 2.0. On extreme left are given results, for comparison, on two rows, staggered, spaced with tube centers on equilateral triangles, with ratio just mentioned = 2.0.)

Case 9. Circular disks in parallel planes, with their centers on the same normal to their planes. Case 2, Equation [4], above, gave the radiation from a point to a disk. The integration of this over the circular area A_1 of radius b leads to

$$q = \sigma(T_1^4 - T_2^4) A_1 \frac{1 + \frac{a^2}{b^2} + \frac{K^2}{b^2} - \sqrt{\left(1 + \frac{a^2}{b^2} + \frac{K^2}{b^2}\right)^2 - 4\frac{a^2}{b^2}}}{2} \qquad \ldots\ldots [9]$$

This result has been given in slightly different form by H. B. Keene (2) who also pointed out that when the radii a and b of the disks are small compared to K, their distance apart, Equation [9] becomes

$$q = \sigma(T_1^4 - T_2^4) \frac{A_1 A_2}{\pi K^2} \left\{1 - \frac{a^2 + b^2}{K^2}\right\} \qquad \ldots\ldots [9a]$$

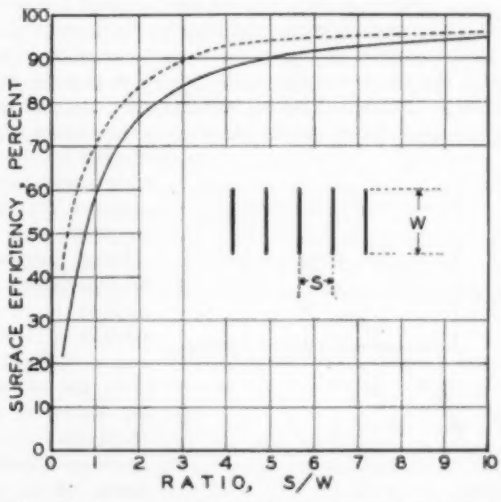

FIG. 7 CURVE OF SURFACE EFFICIENCIES FOR STRIPS

When the disks have the same radius and the ratio of diameter to distance apart is R, Equation [9] becomes

$$q = \sigma(T_1^4 - T_2^4)\, A_1 \left[1 - \frac{2}{R_2}\left(\sqrt{1 + R^2} - 1\right)\right] \qquad \ldots [10]$$

This problem has been attacked by Keller (6) in connection with the evaluation of radiation losses through furnace openings, but the approximation method there suggested for evaluating radiant-heat interchange between parallel disks is more tedious than the use of Equation [10], and less exact.

Case 10. Rectangles of equal size in parallel planes, directly opposed. By making use of Equation [5], case 3, the radiation from an element dA to a parallel rectangle with corner above dA; by applying the principle of case 4; and by integrating over the area A_1, we finally arrive at the interchange between two equal rectangles:

$$q = \sigma(T_1^4 - T_2^4) A \frac{1}{\pi}\left\{\frac{1}{XY}\log\frac{(X^2+1)(Y^2+1)}{(X^2+Y^2+1)} - \frac{2}{Y}\tan^{-1}X - \frac{2}{X}\tan^{-1}Y + 2\sqrt{1+\frac{1}{Y^2}}\tan^{-1}\frac{X}{\sqrt{Y^2+1}} + 2\sqrt{1+\frac{1}{X^2}}\tan^{-1}\frac{Y}{\sqrt{X^2+1}}\right\} \qquad \ldots [11]$$

Keene and Luke (5) in their evaluation of the surface efficiency of different arrangements of heating elements in electric furnaces included the case of parallel strips (see Fig. 7 for cross-section through strips). This case may be treated by the application of Equation [11]. One of the two dimensions is infinite. When we let $Y = \infty$, Equation [11] reduces to

$$q = \sigma(T_1^4 - T_2^4)A\left[\sqrt{1 + \frac{1}{X^2}} - \frac{1}{X}\right] \ldots\ldots [12]$$

in which X is the ratio of strip width to distance between strips and q is the interchange between adjacent strips. The bracketed term represents the fraction of the radiation from one strip intercepted by the next. The fraction not intercepted is the portion in which we are interested. The heat interchange between the strips and their surroundings is then

$$q = \sigma(T_1^4 - T_2^4)A\left[1 - \sqrt{1 + 1/X^2} + 1/X\right] \ldots [13]$$

and the bracketed term is the desired surface efficiency of the strips. It is plotted in Fig. 7 (solid line) against the ratio X. The dotted line represents the results given by Keene and Luke in the paper referred to, bases on their assumption that the fraction of the total radiation from a surface element on one strip which is intercepted by an adjacent strip is equal simply to the plane angle subtended by the strip at the surface element divided by the total plane angle above the element. The extent to which this simplifying assumption is unjustifiable is indicated by a comparison of the two curves of Fig. 7.

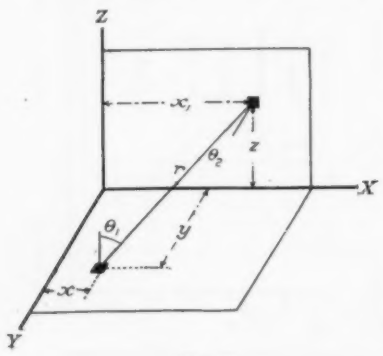

FIG. 8

In the evaluation by Keller of losses through furnace openings already referred to (6), a determination of the direct interchange between rectangles was made by an approximation method similar to that used by him for circular disks, and the conclusion was reached that the factor of interchange is the same, within 1 per cent, as that for disks, when the ratio of side of squares to distance separating them is the same as for diameter of disks to distance separating them. An exact comparison of disks and rectangles by the use of Equations [9] and [11] leads to the conclusion that when the ratio of side or diameter to distance apart is 1, the factor of interchange for squares is 16 per cent greater than that for disks; and that when the ratio is 2, the factor for squares is 8 per cent greater.

Case 11. Rectangles in perpendicular planes, the rectangles having a common side. In the accompanying Fig. 8 the rectangles, between which the heat interchange is to be evaluated are in the XZ- and XY-planes, and of dimensions X by Z and X by Y. The coordinates of the surface element dA_1 in the XY-plane are x and y; those of the surface element dA_2 in the X-Z plane are x_1 and z. Equation [2c] is most readily applicable to this case. In that equation the accompanying Fig. 8 defines the terms as follows.

$$dA_1 = dx\,dy \qquad \cos\theta_1 = z/r$$
$$dA_2 = dx_1\,dz \qquad \cos\theta_2 = y/r$$
$$r^2 = (x_1 - x)^2 + y^2 + z^2$$

Substituting, we have

$$q = \sigma(T_1^4 - T_2^4)\frac{1}{\pi}\int_0^Y\int_0^X\int_0^X\int_0^Z yz\,dz\,dx_1\,dx\,dy \ldots [14]$$

The integration, performed with respect to z, x_1, x, and y in order, leads to a solution which is slightly simplified by redefining Y and Z to refer to Y/X and Z/X, respectively, of Fig. 8. We then have

$$q = \sigma(T_1^4 - T_2^4)A_{xy}\frac{1}{\pi} \times$$

$$\left\{\frac{1}{4}\ln\frac{(1 + Y^2 + Z^2)^Y - \frac{1}{Y} + \frac{Z^2}{Y}\,(Y^2)^Y(Z^2)^{\frac{Z^2}{Y}}}{(1 + Y^2)^Y - \frac{1}{Y}\,(1 + Z^2)^{\frac{Z^2}{Y}} - \frac{1}{Y}\,(Y^2 + Z^2)^Y + \frac{Z^2}{Y}}\right.$$

$$\left. + \tan^{-1}\frac{1}{Y} + \frac{Z}{Y}\tan^{-1}\frac{1}{Z} - \sqrt{1 + \frac{Z^2}{Y^2}}\,\tan^{-1}\frac{1}{\sqrt{Y^2 + Z^2}}\right\} \ldots [15]$$

Case 12 (General). Interchange between any two surfaces of however irregular extent. If one of the two surfaces is quite small compared to the other, the mechanical device described under case 6 may be used, with its pivot point at the center of the small area. One would thus obtain a factor F_A to use in the equation

$$q = \sigma(T_1^4 - T_2^4)\,A_1F_A \ldots\ldots [16]$$

in which A_1 is the smaller area. The extension of the method to the case in which A_1 is not small compared to the mean distance to A_2 consists simply of dividing A_1 into a number of equal areas and of determining the factor F_A with the pivot point of the mechanical device placed successively at the centers of the different areas. The arithmetical mean F_A is then used in Equation [16]. The number of segments into which A_1 need be divided is usually small to obtain sufficient accuracy for engineering purposes.

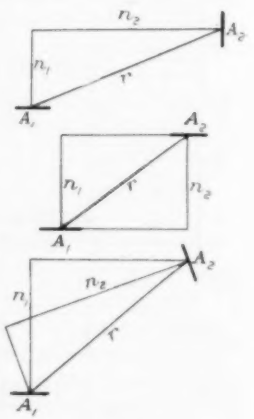

FIG. 9

An approximation method applicable to interchange between surfaces small relative to their distance apart and in such relative positions that a plane normal to one surface through its center passes through the center of the other surface has been presented by Schack (9). It follows directly from Equation [2c] and is

$$q = \sigma(T_1^4 - T_2^4)\,\frac{n_1\,n_2A_1\,A_2}{r^4}$$

in which n_1 and n_2 are defined in the sketches of Fig. 9. The method leads to considerable error when either A_1 or A_2 is not small compared to r.

EFFECT OF EMISSIVITY OF SURFACES ON RADIANT-HEAT INTERCHANGE

At the beginning of the preceding discussion of the effect of the shape of a system on radiant heat transmission in it, the assumption was made that all beams intercepted by a surface are absorbed by it. We shall now consider the effect of incomplete absorption on the equations presented.

Cases 1–6, Inclusive. In all these cases, one surface is very small compared to the distance to the other. Surface ΔA_1 will emit p_1 times as much as a black body, and surface A_2 will absorb the fraction p_2 of what ΔA_1 emits (absorptivity and emissivity are equal). The reflected portion $(1 - p_2)$ will be reflected in all directions from A_2, and since ΔA_1 is small, a negligible fraction of the reflected beam will undergo a second reflection from

ΔA_1 back to A_2. The factor p_1p_2 therefore enters directly into all the equations for cases 1 to 6, Equations [3] to [7].

Case 7—Infinite Parallel Planes. A beam leaving A_1 undergoes an infinite number of partial absorptions alternately at A_2 and A_1. The summation of the alternate members of the infinite series so formed leads to the familiar conclusion that the factor to allow for emissivity of the two surfaces is $\dfrac{1}{1/p_1 + 1/p_2 - 1}$. As long as p_1 and p_2 are not far from unity, this factor is approximately equal to p_1p_2.

Case 8—Enclosed and Enclosing Surface. Let us first consider the symmetrical cases of concentric spheres, or concentric infinite cylinders. Because the heat-transfer equations given are based on the area of the enclosed body of area A_1, we follow the history of a beam starting at A_1. If the reflection is specular,[3] every beam leaving A_1, in no matter what direction, will impinge on A_2 and A_1 alternately until completely absorbed; and the summation of terms representing absorption at surface A_2 leads to the same result as for infinite parallel planes; i.e., Equation [8] should be multiplied by $1/(1/p_1 + 1/p_2 - 1)$. This is an unexpected result and is due to our assumption of specular reflection of the unabsorbed portion of the radiation. An assumption much nearer the truth is that the reflection is completely diffuse instead of completely specular. Again we start with a beam leaving A_1; the fraction p_2 is absorbed by A_2, and $1 - p_2$ is reflected. Only a portion of the reflected beam from A_2, however, is intercepted by A_1, the other portion going directly to other parts of A_2. The calculation of the portion intercepted (not all absorbed) by A_1 may be made by proper application of the formula under case 2 for spheres, or case 5 for cylinders. In each case we find that the fraction of reflected radiation from a spot on A_2 which is intercepted by A_1 is A_1/A_2. By following the beam back and forth we form a family of infinite series, much more complicated than for the case of infinite parallel planes. Summation of terms representing absorption at A_2 leads to a fairly simple factor F_E by which [8] should be multiplied to make allowance for the emissivities of the surfaces. It is

$$F_E = \frac{1}{\dfrac{1}{p_1} + \dfrac{A_1}{A_2}\left(\dfrac{1}{p_2} - 1\right)}$$

Nusselt has given this result, but with no indication of his method of obtaining it, or of the assumption involved in deriving it. Inasmuch as actual reflection is neither completely diffuse nor completely specular, the true factor of multiplication of Equation [8] will be an intermediate value, such that

$$\frac{1}{\dfrac{1}{p_1} + \dfrac{1}{p_2} - 1} < F_E < \frac{1}{\dfrac{1}{p_1} + \dfrac{A_1}{A_2}\left(\dfrac{1}{p_2} - 1\right)}$$

The factor will be much nearer the right- than the left-hand expression.

It will be noted that the expression for F_E in terms of A_1, A_2, p_1, and p_2 reduces simply to p_1 when A_1/A_2 approaches zero, i.e., for the case of a small body enclosed in a large one.

Cases 9-12—Pairs of Surfaces Not Forming an Enclosure. Inasmuch as the whole system is not completely specified when we are considering heat interchange between two bounded surfaces, A_1 and A_2, we are in no position to consider what happens to those radiant beams from one surface not directed toward the other. They may undergo partial reflection at the unspecified surfaces and return to A_1 or A_2 for further absorption. We can only say, therefore, that the factor p_1p_2 introduced into the equations covering cases 9 to 12, inclusive, will give a result not far wrong, but always more or less low. An exact consideration of the emissivity effect in a system of many surfaces of different temperatures and emissivities would be extremely complicated.

Inasmuch as Lambert's cosine principle, which was assumed valid in deriving the equations of Section I, is no longer exact when the heat-interchanging surfaces are not black bodies, the discussion of the effect of the emissivity of surfaces on heat transmission may properly include a consideration of errors introduced by assuming the cosine principle valid. Probably the best work on the subject is that of Schmidt (7), who found that the deviation from the cosine principle was large for metallic surfaces, and that the average intensity was about $^4/_5$ the intensity measured normal to the surface. The error in using the principle is not serious, however, for oxide and other nonmetallic surfaces, and for rough surfaces. The modification of the equations here given, to make allowance for the dependence of intensity on angle of emission of radiation, must wait until we have more detailed knowledge of the departure of industrial surfaces from the cosine principle.

The engineer's task of applying many of the equations given in this paper may be greatly simplified by making use of the graphs presented in the summary, to which reference has been made (11).

[3] The angle of incidence equals the angle of reflection.

Discussion

W. J. KING.[4] The paper is a valuable contribution to the theory and practice of heat transmission. It will be welcomed by designers of the many types of apparatus in which radiant heat is a factor as providing a clear qualitative statement of the general problem, as well as giving a number of very useful and convenient formulas.

It has been the writer's experience that much confusion exists in the minds of many engineers with regard to this subject of radiant heat transmission. For example, the present paper is limited to "non-absorbing media." Of course it is generally recognized that a vacuum is non-absorbing, and for most practical purposes so is ordinary air, but what about the passage of radiation through the earth's atmosphere to the cosmic space beyond? This is an important question in connection with the cooling of outdoor apparatus exposed to the sky. If the temperature of astronomical space is somewhere near absolute zero, the radiation from a surface exposed to the sky on a clear night should be sufficient to cool it far below the ambient. As a matter of fact most terrestrial radiations are completely absorbed within a few miles of atmospheric air, so that the effective temperature T_2 in Equation [3] is never much lower than about −45 deg.

[4] Engineering General Department, General Electric Company, Schenectady, N. Y.

fahr., or 415 deg. absolute.[5] In most practical cases this temperature may be taken as that of the ambient.

Carbon dioxide and water vapor absorb considerable amounts of radiant heat. An instance of this recently came to the writer's notice, in connection with some tests on a large electric furnace for annealing copper wire. The heat was transmitted to the charge mainly by radiation from resistance strip heaters. To reduce oxidation, the air in the furnace was displaced by steam, whereupon the temperature drop from the heaters to the charge was greatly increased.

There seems to be a tendency among engineers in general to underestimate the relative importance of radiation as compared with other forms of heat transmission. Some time ago the writer was asked to design the heat-transfer features of a large sulphur-dioxide converter, in which the hot gases within a 10-ft. steel cylinder were to be cooled by a current of cool gas in the annular space between the catalyst cylinder and the outer shell. The instructions were to "neglect radiation." The temperature of the inner cylinder was about 250 deg. cent., and the amount of surface required to dissipate the heat by convection alone made the apparatus too large. It was finally found, however, that the radiation through the gas to the outer jacket amounted to about 20 per cent of the total heat transfer, which was sufficient to bring the machine down to the desired dimensions.

It might be thought that in an airplane traveling at 100 miles per hour the radiation from the engine cylinders would be negligible compared with the forced convection. However, it was noticed recently that in a certain plane the indicated engine temperature rose continually as the black paint peeled off of the cylinders, exposing the bright metal. It was thought that the low emissivity of the bright metal might account for this. Calculation showed that for a constant amount of heat dissipated, the temperature should rise from 450 to 510 deg. fahr. when the paint all came off. This was confirmed by the fact that the temperature at once dropped back to normal when the cylinders were repainted.

Even at lower temperatures, radiation may be an important factor, particularly in still air. For example, the dissipation from a plain self-cooled transformer tank is about 55 per cent radiation and 45 per cent convection.

Referring to the formula for F_E on the seventh page, the author says, "Nusselt has given this result, but with no indication of his method of obtaining it or of the assumption involved in deriving it." Apparently he has overlooked the excellent treatment of this problem by A. D. Moore in the chapter on Heat Radiation in his book on "Fundamentals of Electrical Design" (McGraw-Hill, 1927). Professor Moore also presented a paper on "Dissipation of Heat by Radiation" at the Great Lakes District Meeting of the A.I.E.E. in Chicago, in December, 1929. This included an interesting study of radiation from a slot or from a corrugated or finned surface. In all such cases the effective emissivity of the enveloping surface is higher than that of a smooth surface of the same material.

Some of the results of the present paper were given last year by O. A. Saunders in his "Notes on Some Radiation Heat Transfer Formulas," published in Vol. 41 of the Proceedings of the Physical Society (London). The case of non-concentric spheres also was treated. Some interesting conclusions are drawn from the formulas. For example, it is pointed out that "whereas coating the surface of a relatively small hot body with aluminum paint reduces the radiation heat transfer from the body to its surroundings in direct proportion to the change of surface emissivity, a similar treatment of the walls of the room in which the body is situated has no effect upon the heat loss."

A few special cases also are discussed by ten Bosch in his text, "Die Wärmeübertragung," published by Julius Springer, Berlin, 1927.

N. C. Artsay.[6] The paper is most timely, and it gives a clear exposé of the principles so vaguely understood by the vast majority of engineers. The treatment of the problem is especially valuable for the design of gas-fired furnaces where the materials are not exposed to the direct radiation of flames. The presentation of this paper seems to be an appropriate moment to discuss certain ideas on radiation. The phenomena of heat release during combustion are so complicated and, to our shame, we must say, so poorly known, that a general overhauling of our conceptions of what happens in a boiler furnace where fuel is burning is necessary. The fascination of the Stefan and Boltzmann fourth-power law begins to fade, especially when we realize that the source of radiant energy is the chemical process itself and not the high temperature of the product. The factor controlling heat exchange by radiation in cases of combustion in cavities is not on the emission side but on the absorption side. This apparent heresy may be illustrated by the following example.

Let us light a bonfire and keep it going at a steady rate in a wide open space on a clear cold night. This will be a sufficiently "black" and cold envelope for the flame. In such conditions the bonfire should relate at least 80 per cent of the total sensible heat liberated. Now let us screen the fire from all sides and gradually move the walls converging them toward the center of the fire. It is obvious that the rate of radiation emission would not decrease; it might even increase if we still entertain the idea that emission during combustion depends upon flame temperature. The temperature of gases leaving the bonfire will rise due to lowering the rate of radiation absorption. Let us cool the screens by evaporating water in them at constant temperature; the second term of the Stephan and Boltzmann formula will increase slightly due to higher metal temperature, but by no means to such an extent that the reduction of radiation absorption during the convergent approach of the walls could be explained by its new values. There is the increased flame temperature, and, if we believe that radiation emission from burning fuel depends upon the temperature then the emission and hence the absorption also should increase. All our experience with boilers tells us a different story, and the application of any formula for radiation emission during combustion is futile.

The laboratory experiments on the reflectivity of metal surfaces are usually conducted with radiation intensities far below those obtained in furnaces and mostly on wave lengths in the visible part of the spectrum. The International Critical Tables gives data on reflectivity of steel which for the infra-red range show a substantial reduction. But this is not all; determinations of reflectivity at low intensities of incidence are like nozzle tests with insufficient fluid to fill the orifice. It is high time that proper attention should be called to the absorption; under high-intensity incidence of radiation the absorbing surfaces perform as atomic mechanisms of variable efficiency, and hence a constant factor of "blackness" or "grayness" in such conditions is nonsense.

In a short discussion it is impossible to give all the consideration to support the new viewpoint, but the idea can be defined in the following simple terms:

(1) During the process of combustion the heat of chemical reaction is liberated to a great extent as radiation, and only a

[5] See "Heat Transmission," by Margaret Fishenden and A. F. Dufton, Special Report No. 11, (British) Department of Scientific and Industrial Research, H. M. Stationery Office, London, 1929.

[6] Assistant to Geo. A. Orrok, Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

small fraction, roughly 20 per cent, of it remains with the initial products of combustion.

(2) Depending upon surroundings, a part of the radiant heat will return in the product of combustion via unburned fuel, CO_2, CO, H_2O, to be further diffused into N_2.

(3) The total radiant heat absorption by the furnace envelope is fixed by the rate of heat liberation times the efficiency of absorption, the latter being a function of the load or total radiant heat per square unit of surface per unit of time.

Broido and Orrok in their empirical formulations of radiation absorption in boiler furnaces were closer to the true aspect than the majority of authors who tried to apply the fourth power law to the indefinable flame or furnace temperatures or surfaces. As Wohlenberg points out in his recent work, the radiation equilibrium of an oxidizing molecule is reached earlier than the dynamical equilibrium with the surrounding gas, and with this kept in mind we should regard the molecular chemical processes of oxidation as a source of radiant energy at a temperature (if such is needed) which is constant and dependent only upon the kind of combining molecules.

So much for the case of combustion; but there are many industrial furnaces and ovens where the treated materials are not subject to combustion radiation, and for these cases the author's work will be invaluable.

NOTE: Further discussion of this paper, together with the paper of William L. DeBaufre, by Ollison Craig, will be found following the DeBaufre paper.

AUTHOR'S CLOSURE

Some of the discussion of the paper would seem to indicate a mistaken idea of its object, which was to collect the old and to present some new material on one phase of the broad subject of radiant heat transmission. No pretense is made that the results are applicable, without modification, to problems in which the phenomena attending combustion are superimposed on the simple radiation from one surface to another. The complete treatment of radiant heat transfer under such conditions involves the use of other material not the subject matter of the present paper. The writer is in agreement with Mr. Craig that the complete analytical treatment of such a problem as the calculation of total heat absorption in a given boiler furnace would be inordinately tedious. It should be remembered, however, that although the Fuels and Steam Power Divisions are accustomed to think "boiler furnace" whenever radiant heat transmission is mentioned, there are many other types of industrial furnaces in existence, some of which are by no means incapable of analytical treatment. The author's experience with calculations on steel reheating furnaces, oil-cracking coils, and tube stills has indicated that much can be learned about probable furnace performance by the application of principles such as those discussed here, augmented of course by the use of other material included in the subject of radiant heat transmission. Even in the case of boiler furnaces certain fundamental questions of local overheating, losses through openings, distribution of heat to tube rows, etc., may be answered by a consideration of the geometrical problem involved, although the overall problem of furnace problems is at present best treated empirically.

Mr. King calls attention to the fact that Case 8, that of one body completely enclosing another, has been treated by A. D. Moore ("Fundamentals of Electrical Design," McGraw-Hill, 1927), by O. A. Saunders (Proc. Phys. Soc., vol. 41, p. 569, 1929) and by M. ten Bosch ("Die Wärmeübertragung," published by Julius Springer, 1927), in addition to the author's own treatment and that of Nusselt, to which reference has already been made. Of these treatments that of Mr. Saunders, with which the author was not familiar, is to be preferred for clarity and completeness. Mr. Saunders, considering the case of nonconcentric spheres, reaches the interesting conclusion that the maximum heat interchange occurs when the bodies are concentric, but that the decrease below this maximum as the inner sphere is moved away from the center is not of sufficient magnitude to be of much practical importance.

Mr. King further calls attention to a paper of A. D. Moore (A.I.E.E., vol. 49, p. 22, 1930) on the study of radiation from a slot or from a finned surface, in which the results of a tedious stepwise numerical calculation were presented for the special case of a slot of infinite length, with depth equal to four times its width. The author and Mr. P. V. Keyser about a year ago considered the general problem of finned-surface radiation and obtained an algebraic solution applicable to any ratio of slot depth to width and to any emissivity of the surface. The results have not been published, pending a solution of an allied problem.

Reference is made by Mr. King to the excessively high value obtained for the necessary heat-transfer area of a sulphur-dioxide converter, due to the fact that the radiation from hot sulphur dioxide was neglected. Mr. S. A. Guerrieri and the author, making use of available infra-red spectroscopic data on sulphur dioxide, have recently calculated a sulphur-dioxide radiation plot similar to those published for water vapor and carbon dioxide; and it should be possible with such a chart to make allowance for SO_2 radiation in the design of such equipment as the coolers following sulphur burners, etc.

The author cannot agree with Mr. Artsay's statement that "the factor controlling heat exchange by radiation in cases of combustion is not on the emission side, but on the absorption side," nor with his statement that "the bonfire should radiate at least 80 per cent of the total sensible heat liberated," if he means net heat of combustion by the term, "total sensible heat liberated," as the succeeding text would seem to indicate that he means. All the experimental evidence with which the author is familiar indicates that the fraction of heat radiated will be far less than 80 per cent; less, in fact, than half that figure. Experimental evidence for Mr. Artsay's unusual picture of the absorptivity of surfaces being dependent on the intensity of the radiation striking them would be welcome. Certainly there is a possibility of some such effect, but experimental evidence so far tends to deny its practical importance.

Operation of the Holland Station[1]

By E. M. GILBERT,[2] READING, PA.

The Holland Station, being among the first plants designed exclusively for high-pressure steam, is now in operation, and the experiences obtained during operation will be of interest. The main features of the plant are a 55,000-kw. cross-compound turbo-generator unit designed for variable-load operation; two similar boilers, each with its reheater built integral, designed for generating 250,000 lb. of steam per hr. each; elimination of the wall between turbine and boiler room, and control centralized on the operating floor. The operating experiences with the different elements of the plant are given, together with data showing the operating results for the six-month period. Operating results, while of short duration, show justification of the use of higher pressures from an economic standpoint.

THE Holland Station of the New Jersey Power & Light Company, a subsidiary of the Associated Gas & Electric Company, was designed and constructed by W. S. Barstow & Co., Inc. It is located on the Delaware River in New Jersey, about 13 miles below Easton, Pa. A description of the design features of the plant appeared in the February, 1929, issue of the *General Electric Review* and the March 1, 1929, issue of *Power Plant Engineering*.

The ultimate capacity of the Holland plant will be approximately 220,000 kw., the first unit of 55,000 kw. capacity having been put into operation the latter part of February, 1930.

The turbo-unit consists of a high- and a low-pressure cross-compound turbine, the low-pressure section working at variable pressure. The high-pressure turbine has a multi-valve arrangement in order to obtain high efficiency over a large load range. It receives steam of 1250 lb. gage, 750 deg. fahr., and exhausts through steam and gas reheaters at a pressure varying from 400 lb. gage to 85 lb. gage into the low-pressure turbine, the steam being reheated to 750 deg. fahr. before entering the low-pressure turbine. The high-pressure turbine operates at a speed of 3600 r.p.m. and the low-pressure at 1800 r.p.m., their maximum capacities being 11,800 kw. and 43,200 kw., respectively.

The condenser is of single-pass type having a surface of 31,600 sq. ft. The tubes are rolled at both ends, and rubber expansion joints are provided between water boxes and the shell to allow for longitudinal expansion, as the shell is hung from the turbine and the water boxes are supported from the basement floor, one box being bolted rigidly down and the other box being free to slide longitudinally.

The two boiler units, each designed for 250,000 lb. of steam per hour, are of the cross-drum type, 45 sections wide and 8 tubes high. The drums are made from solid forged billets and are 52 in. inside diameter, 4 in. thick, and 46 ft. long.

The furnaces are water-cooled except around the circular burners where refractories are used. The side walls of both furnaces and the front and rear walls of No. 1 furnace are of fin-tube construction. On No. 2 boiler the front and rear walls are of the bare-tube type, backed up by refractories. The furnace volume is 18,000 cu. ft. and the B.t.u. release about 18,000 B.t.u. per cu. ft. maximum.

Arrangement and Control

The general arrangement of equipment is shown on the plan (Fig. 1) and the cross-section (Fig. 2). All equipment operating continuously is controlled from a central station (with two turbo-units installed) located on the turbine floor, elevation 154.0, as shown in Fig. 1. The omission of the wall between the boiler and turbine rooms enables the station operator to see and control all principal equipment. With the exception of the coal-handling and milling machinery all apparatus is under the control of the station operator and can be governed automatically or by push-button devices. All equipment is regulated to maintain a constant steam pressure at the inlet of the high-pressure turbine. The water level in the boilers is automatically controlled by Smoot regulators, and feed-line pressure is regulated by combination Bailey pressure and electric control on the primary boiler-feed pump. A miniature board located at the centralized station controls all high-voltage outdoor switching equipment.

A photograph of the turbine room is shown in Fig. 3, the high-pressure unit being on the left and the low-pressure machine on the right. A photograph of the boiler room is shown in Fig. 4.

Operating Personnel

The control and operation of the plant on one floor without any wall between turbine and boiler room has made the Holland plant simpler to operate than existing low-pressure plants, and it has been found that no added personnel or higher class of labor than used in low-pressure plants is needed. The operators have all been drawn from existing plants of the Associated Gas & Electric Company's system and had no experience with plants of pressures higher than 200 to 400 lb. prior to their connection with this plant.

---

[1] The station was renamed "Gilbert" since the paper was written.

[2] President, W. S. Barstow & Co., Inc. Mem. A.S.M.E. Mr. Gilbert was born in Wilton, Conn., and after receiving his technical training in Cornell University he entered the employ of the American Stoker Company, Dayton, Ohio. In 1899 he was sent to London to install stokers in England and France, remaining abroad until 1907 as general superintendent of a parent organization that sponsored the sale and manufacture of stokers in Europe. After his return to the United States he became chief engineer for the Leadville (Colo.) Light & Power Company, and from 1909 to 1914 he was active in the operation and construction of steam- and hydroelectric-generating plants for the Colorado Power Company. He was also connected with the construction of the Boulder and Shoshone dams and power houses in Colorado. He sponsored the development of oxyacetylene welding for a steel-pipe line over 8000 ft. long used in connection with the Boulder dam. In 1916 he became general manager of the Metropolitan Edison Company and chief engineer of the properties of the General Gas & Electric Corporation. When the Associated Gas & Electric System acquired these properties, he was a director of the Metropolitan and vice-president and director of four of its subsidiaries. At present Mr. Gilbert is President of W. S. Barstow & Co., Inc., and the Utilities Purchasing & Supply Corporation. He is also director and an executive officer in several of the operating companies in the Associated Gas & Electric System.

Contributed by the Power Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

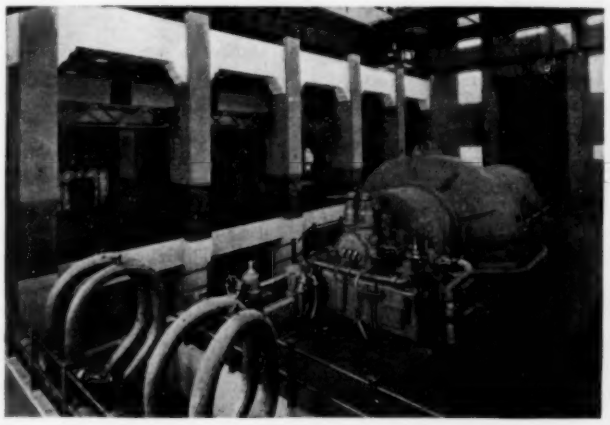

FIG. 3 TURBINE ROOM AT HOLLAND STATION

The following list of the personnel shows that the station can be operated satisfactorily with a minimum number of men:

1 superintendent
1 assistant superintendent
1 boiler foreman
1 maintenance foreman
1 chemist
1 instrument man
1 station clerk
4 switchboard operators
3 turbine operators
6 condenser and pump operators
3 firemen
3 mill operators
3 water tenders
13 maintenance men
5 coal handlers
2 janitors
6 laborers

55 total

OPERATING RESULTS

Table 1 shows operating results from February 23 to September 1. The coal consumed includes all fuel purchased for the drying out and used for all preliminary operation of the plant.

Table 2 shows average readings throughout the plant under date of August 19, 1930.

OPERATING EXPERIENCES

General. With a plant radically new in design and with many untried features it is evident that some difficulties would be encountered and would have to be rectified.

It is impossible at this time, due to the short period of operation, to report all operating problems as completely solved. Any operating difficulties stated below should not be considered as a reflection on the effort or service of the manufacturers connected with this station. Where difficulties have been encountered, the manufacturers have cooperated to the fullest extent, and if a complete remedy of any trouble cannot be given it is due to lack of time.

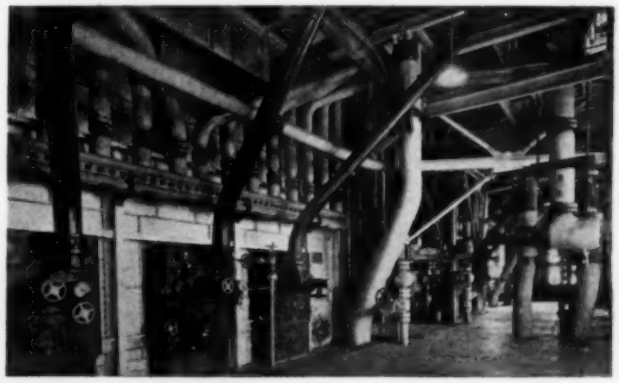

FIG. 4 BOILER ROOM OF HOLLAND STATION

FIG. 5 CENTRALIZED CONTROL

While the plant has not attained the normal expected output, sufficient information is available regarding operating costs and fixed charges to indicate the economical justification of the design and construction of the plant.

Piping. All piping joints are of the gasketed type—metal gaskets for high pressure and composition gaskets for low pressure. Flanges for the high-pressure joints were made 35 to 50 per cent stronger than the 1350-lb. standard, and special

threaded studs were used. All other flanges and boltings are of standard construction.

During the early period of operation composition gaskets used on the high-pressure lines in sizes of 2 in. and under gave trouble and were replaced by metal gaskets, which have been entirely satisfactory.

It was found that when the flanges on the high-pressure superheated lines were covered leaks developed during the change of temperature periods when a line was being brought up to

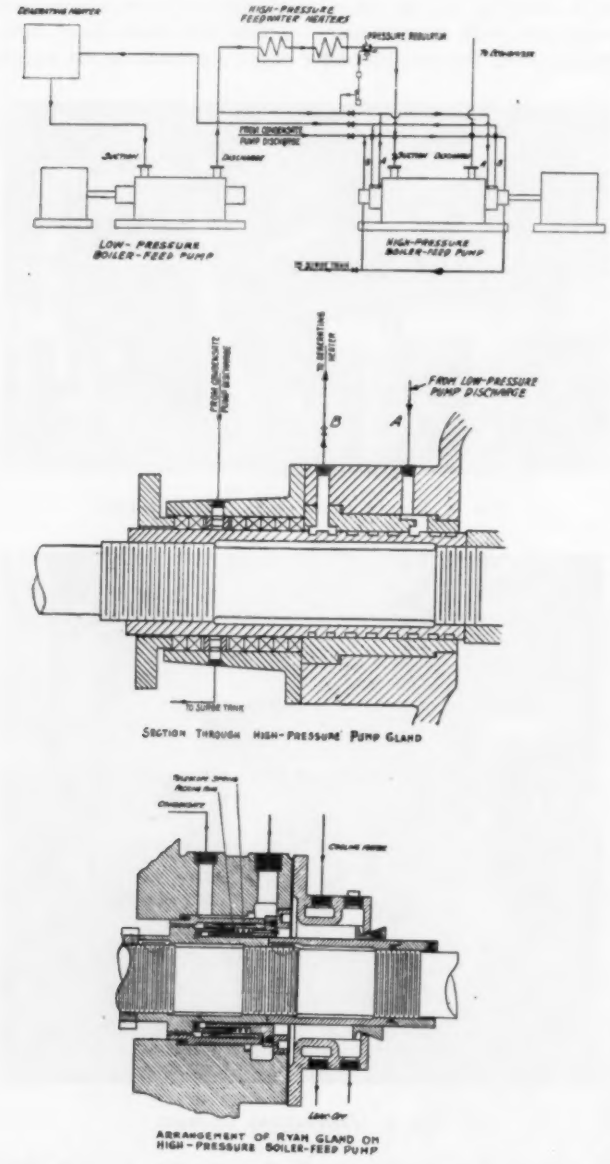

FIG. 6 HIGH-PRESSURE BOILER-FEED PUMP, ARRANGEMENT OF GLAND SEALS

pressure or the pressure was being lowered. The removal of the flange covering overcame this trouble.

Turbines. Minor trouble was experienced in the beginning on the high-pressure turbine due to condensed steam from the glands getting into the oil system. There has been considerable trouble due to sticking of the valve stems in their bushings and in the cam mechanism of the valve control, and alterations have to be made to obtain even changes of load. Leakage in the horizontal joints of the high-pressure turbine was stopped by tightening the holding-down bolts. On the low-pressure unit trouble developed with the vacuum tripper, which was due to faulty adjustment. No difficulties have been experienced with the intercepting valve, but changes are being made to give a more rigid construction.

Condensers. Leakage between the rubber expansion joint and the water box, causing the loss of the circulating system, has been overcome by a change made in the bolting arrangement. Some trouble was experienced with the reciprocating air pump during starting due to pulling water from the water seal between the first stage jet and the condenser into the cylinder, which caused cracking of the head. This has been corrected by the installation of a bypass around the first stage jets, which is used during starting up.

Boiler Feed. The secondary feed pumps were originally provided with Ryan seals. These were replaced by a combination labyrinth and stuffing box, which has proved very satisfactory. Some trouble was encountered with the oiling system, but was overcome by rearrangement of piping. A Mercon regulator is being installed between the primary and secondary feed pumps to insure bottling up of high-temperature water in the secondary pump during light load operation. This arrangement is shown in Fig. 6.

Fourth Stage Drip Pump. The plant has not operated regularly with No. 4 high-pressure heater in service. Ryan glands were originally installed on the drip pump, but these had to be replaced with labyrinth-type glands.

Superheater. The superheat obtained at the start was low, but this has been adjusted by the installation of a kicker baffle.

Gas Reheater. Reheat temperature was entirely too high during the first period of operation and required the use of a desuperheater. To remedy this trouble reheat surface has been removed from both boiler units.

Steam Reheater. Trouble has occurred in the steam reheater due to faulty welding of the high-pressure elements. This reheater has not been used regularly as the gas reheater has given more than enough temperature, and the use of the steam reheater has not been required.

Economizers. The first trouble on the economizers was due to leaky handhole caps, this having been remedied by using softer steel gaskets. Later considerable trouble developed in leaks between the tubes and the headers. Plans are in progress to correct the difficulty, but at this writing the final cure cannot be given. However, it is felt that this problem will be satisfactorily overcome.

Induced Draft Fan. At the starting period, difficulties were experienced, caused by erosion of the fan-inlet vanes, due to the high velocity when the vanes were almost entirely closed at light ratings. This trouble has been overcome by the installation of leak-in dampers which are used at light loads during starting.

Burners. With the original installation of the burners the flame went below the slag screen and changes were made to remedy this. Trouble has been experienced with the burning of the cone, and alterations are being made to overcome this difficulty. It has been impossible to operate continuously burning the mill vents in the boiler, due to the fact that the vent fan does not have sufficient excess pressure to operate satisfactorily with the high secondary air pressure required by the first design of the burners. It is expected that the changes in the burners will make the present vent fan satisfactory. If not, a vent fan of greater pressure must be installed.

Slag Trouble. In the beginning slag trouble was experienced due to faulty burner operation and the impossibility of removing

excess slag during operation where the slag screens cross. Changes in burner design and the installation of additional doors in the ashpit have overcome this trouble.

Emergency Boiler-Feed Pump. A turbine-driven emergency boiler-feed pump was installed; all other auxiliaries being motor-driven. This pump has functioned when trouble had developed with the main turbine, and its use has been felt to be justified. This emergency pump gave some trouble due to a piece of concrete being left in the suction, which threw it out of balance and caused the freezing of the runner and wearing ring.

Feedwater. The quality of the feedwater at the Holland Station was expected to be a very uncertain factor due to the fact that it is made up of water from the Delaware River, which is comparatively clean, and water from the Lehigh River, which flows into the Delaware at Easton. The pollution of the water is increased by water dumped from factories and sewerage systems between Easton and the plant. During the first months of operation the water did not cause any difficulties, but during the extreme dry season the amount of solids in the water increased very rapidly. The evaporator had to work at its full capacity, due to excessive leakage of the economizer, which also aggravated the feedwater difficulties and raised the concentration in the evaporator and boilers, causing solids to be carried over with the steam into the turbine, where they deposited and reduced the efficiency and capacity of the unit. It was decided to wash out the turbine with saturated steam, and this method has been considered satisfactory, although at this writing only the first washing has been accomplished and the final work has not been completed. Greater care is now being taken to keep down the concentration in the evaporator, and with this precaution it is expected that no further difficulties with the turbine being filled with scale will be experienced.

Discussion

SHEPPARD POWELL.[3] To evaluate adequately the various factors contributing to the success or failure of the operation of the boiler-feedwater system at this station, it will be necessary to review briefly the type of the existing system. The raw-water supply is obtained directly from the Delaware River a few miles below where the Lehigh River enters the Delaware. The Lehigh River is contaminated by mine drainage, and also receives considerable trade-waste pollution from the industries. Prior to the design of the feedwater system, a comprehensive study was made of the Delaware River as a source of supply in comparison with other available water sources. As a result of this investigation it was indicated that the Delaware River would be relatively satisfactory for the initial operation of the station provided sufficient pretreatment of the water was provided to insure a fairly good feed to the evaporator. The treatment recommended and installed consists of coagulation and subsidence, followed by filtration and final softening by the zeolite system. As a result of this treatment all water fed to the evaporator is filtered and softened. The pretreatment has undoubtedly prevented scale formation in the boilers, especially in the water walls, since without softening ahead of the evaporator the high carry-over from the evaporator would have resulted in some scale formation.

A critical study has been made of the boiler-feedwater conditions, in order to allocate the causes responsible for the carry-over from the boilers which resulted in turbine deposits. The investigation has not been completed at this time, but a study of the operating data indicates that the difficulty has been due in part to poor evaporator performance, resulting in heavy contamination of the evaporator condensate. The evaporator was guaranteed to deliver a condensate containing a maximum total solid content of 13 parts per million (0.75 grain per gallon), when the evaporator was operated at a net maximum of 15,000 lb. of distillate per hour. Actually the total solids determined have been as high as 78 parts per million (4.5 grains per gallon). It is quite probable that even a greater amount of solids was entrained at critical periods of operation, but was not recorded, since no recording devices to determine the purity of the condensate have yet been installed. In order to determine the relative extent of the contamination of the evaporator distillate, the actual concentration of salines in the evaporator shell as measured by analysis was compared with the theoretical saline concentration which should have occurred under normal operation of the equipment and under a given set of conditions. This study, based upon the actual operating conditions, indicated that about 10 lb. of solids per day, or more, were introduced into the boilers from the make-up evaporator. As a result of these conditions the concentrated boiler salines determined were as high as 2000 parts per million (117 grains per gallon). It has been clearly demonstrated that concentration of solids approaching these quantities cannot be carried without serious contamination of the steam leaving the boilers.

A number of factors have been responsible for the unsatisfactory evaporator performance, although the importance of each factor has not been allocated. The following conditions have probably contributed to failure to produce a good evaporator distillate at all times:

(1) Probably high water in the evaporator shell
(2) Rapid fluctuation in evaporator output, due to the necessity of hand regulation of the drips, which in turn was due to failure of the existing traps on the drip line
(3) Relatively high concentrations of the salines in the evaporator shell
(4) Possible clogging of the vanes in the vapor purifiers, and clogging of the drip line from the vapor-purifier section
(5) No baffle plate ahead of the vapor-purifier section.

Based upon the foregoing analysis of these operating problems a number of changes in the evaporator construction and operation are indicated. A summary of these proposed improvements is listed as follows:

(1) The installation of a baffle plate to prevent surging of water into the vapor-purifier elements, and the relocation of the drip from the vapor purifiers so as to discharge the water removed by the vanes outside of the shell
(2) Continuous blowing down of the concentrated salines in the evaporator shell, limiting the maximum total solids of the salines to 1200 parts per million, or lower if found necessary to produce a satisfactory distillate
(3) Operation of the evaporator at ratings sufficiently high so that it is not necessary to flood the coils; effective automatic operation of the drip trap will be provided as a means of accomplishing this end, since past operation of the trap has not been satisfactory
(4) The installation of recording conductivity apparatus to determine the purity of the distillate and the concentration of salines in the evaporator shell; this will insure a continuous record to indicate desired changes in the control of the evaporator, thus providing a distillate of high purity.

A condition of zero carry-over is not likely to be met in practice, so the following study of boiler concentrations has been based upon the assumption that the carry-over from the evaporator

[3] Baltimore, Md.

can be limited to 13 p.p.m. of total solids in the distillate (the evaporator guarantee). The further assumption has been made that these various solids are present in the evaporator distillate in the same proportion as exists between these various solids in the evaporator salines.

When the boilers are operating at full load (500,000 lb. of steam per hour), with 1.5 per cent evaporated make-up and no condenser leakage, there will be introduced into the boilers 2.34 lb. of solids per day as carry-over from the evaporator under these conditions. Since these solids are alkaline in character, their content of sodium sulphate is added to give the desired ratio, and the total introduction of solids per day, counting both the carry-over and the added sodium sulphate, would be 3.25 lb. Assuming a saline content of 60,000 lb. per boiler with no carry-over therefrom, the total solids in the boiler salines would be increased about 27 p.p.m. per day by the evaporator carry-over plus the added sodium sulphate. It can thus be seen that if the boilers be blown enough to decrease the concentration 100 p.p.m., about four days would elapse before they would have to be so blown again. This schedule of blowdown is in marked contrast to existing conditions where it is often necessary to blow the boilers every six hours. It can be seen that, even with the limit of 13 p.p.m. total solids in the evaporator distillate, satisfactory blowdown conditions of the boilers could be maintained, and that with purer distillate the boiler concentration would be even less of an operating detail. It should be remarked here that an evaporator distillate containing 13 p.p.m. total solids is unsatisfactory, and conditions should be established whereby a much purer distillate can be obtained.

G. C. Derry.[4] Erosion is a rather difficult problem to deal with and has become increasingly so the last few years. During this time the designers of power stations have been very materially increasing the capacities of their plants, and with the insertion of reheaters, economizers, air heaters, and cinder catchers, the draft loss has mounted steadily, so that it is now quite common to receive requests for draft loss varying from 12 in. up to 20 in. This draft loss necessitates a much higher speed of the fan than heretofore, accompanied by a more rapid velocity of the cinder-laden gases across the face of the fan blades. We have kept pace with the designers so far as strength of the material is concerned, although the stresses are becoming very high.

These high stresses require the use of heat-treated alloy steels. It was thought at one time that through the use of these steels the problem of erosion might be solved. However, we have in the course of the last 10 years experimented with practically all of the alloy steels and have been greatly disappointed to have been forced to the conclusion that none of the alloys at present on the market has any virtue whatever in resisting the erosion encountered in induced-draft service.

We have been agreeably surprised at a change in the character of the erosion accomplished by our vane-control, spiral-inlet, induced-draft fans. This design was worked out to secure an even distribution of the gases to the inlet of the fan, and we found when the fans were put in service that there was also an even distribution of the dust. The result is that such erosion as occurs on the wheel is distributed across the whole face of the blade and at the outer periphery, so that the resulting erosion of metal does not seriously impair the strength of the wheel.

In some cases the wear has been almost exactly uniform across the width of the blade, and in no case has there been the sharp file-like cutting that we used to run into with the old square inlet box. It is possible to operate these fans at high tip speeds with the delivery edge, or portions of the delivery edge, worn feather thin. Where the fans are operated at high speeds and low capacities with the adjustable inlet vanes very nearly closed, wear results on these inlet vanes. This wear can be minimized by the use of Stellite or by a leak-in damper, in some such manner as the author suggests.

Wear on these stationary inlet vanes is a much less serious matter than wear on the wheel. They are much less expensive to replace, and the danger of wheel failure during operation is avoided. To sum up the matter of the new type of fan briefly, it may be said that the wear has been transferred from the wheel to the inlet vanes, which we consider is a very desirable transfer.

We have noticed in many plants a tendency to weld material to the wheel blades at the first sign of erosion. This practice cannot be recommended. The duty required from this modern induced-draft fan requires the use of alloy steels, and alloy steels cannot be subjected to the acetylene torch or the electric arc without seriously impairing their structure. The best procedure is to operate the fan with the maximum allowable wear on the blade, and then to reblade. The plant operator is too apt to consider that the slightest bit of erosion requires immediate attention. Such is not the case. Where erosion is occurring only at the outer periphery of the wheel, the impairment of the strength of the wheel is very slight, even for a large degree of erosion. The inner portion being of the original thickness and strength, together with the reasonable allowance for safety made in the design of modern fans, eliminates entirely any necessity for rapid and quick repairs.

We have also found in the old type of rectangular inlet box that the way in which the gases come into these boxes made a great deal of difference in performance and fan guarantees. We have proved through tests that with these rectangular inlet boxes the performance can be changed as much as 50 per cent, depending on whether the gas comes in on one side or the other of the fan inlet box. This is one of the reasons that caused us to design our spiral-inlet boxes, and we have found that it

Fig. 7 View of the Gilbert Station

makes no difference which way the designer leads his air into this particular type of fan, for he can be assured of his expected performance from the beginning of the inlet box to the outlet flange of the fan.

[Note: Further discussion of this paper, together with the paper of K. M. Irwin, by H. J. Kerr and W. S. Johnston will be found following the Irwin paper.]

Author's Closure

It may be of interest to hear what troubles have been encountered in the first six or seven months of operation of this new

[4] Manager, Power Apparatus Department, B. F. Sturtevant Co., Inc., Hyde Park, Boston, Mass.

1250-lb. pressure steam plant. Some months of continuous operation have passed since the data originally submitted in the paper were printed, and some changes have taken place and some additional experience has been gained. A view of the plant is shown in Fig. 7.

Piping. All piping joints are of the gasket type, special metal gaskets being used on the high-pressure and composition on the low-pressure joints. All flanges for the high-pressure joints are made with from 35 to 50 per cent added thickness above the 1350-lb. standard, this being done to prevent distortion of the flanges. Threads on the studs are considerably finer than those used under the standard. The high-pressure joints have all been satisfactory, with the exception of two which have given first. These bushings were replaced with nitralloy, and present operation shows this to be a decided improvement, but it is too early to state whether this is a complete cure. Very poor regulation was obtained at first with loads from 28,000 to 34,000 kw. This trouble was thought to be due to the springing of the camshaft under load, all operating arms being keyed to a steel shaft. This arrangement was changed so as to apply the load directly to new steel cam arms, merely using the shaft as a bearing and thus eliminating any strain on it. This appears to be satisfactory to date.

Considerable trouble has been experienced with oil leakage from No. 1 bearing of the high-pressure turbine. The loss from this bearing has been as much as 100 gal. per day in its worst

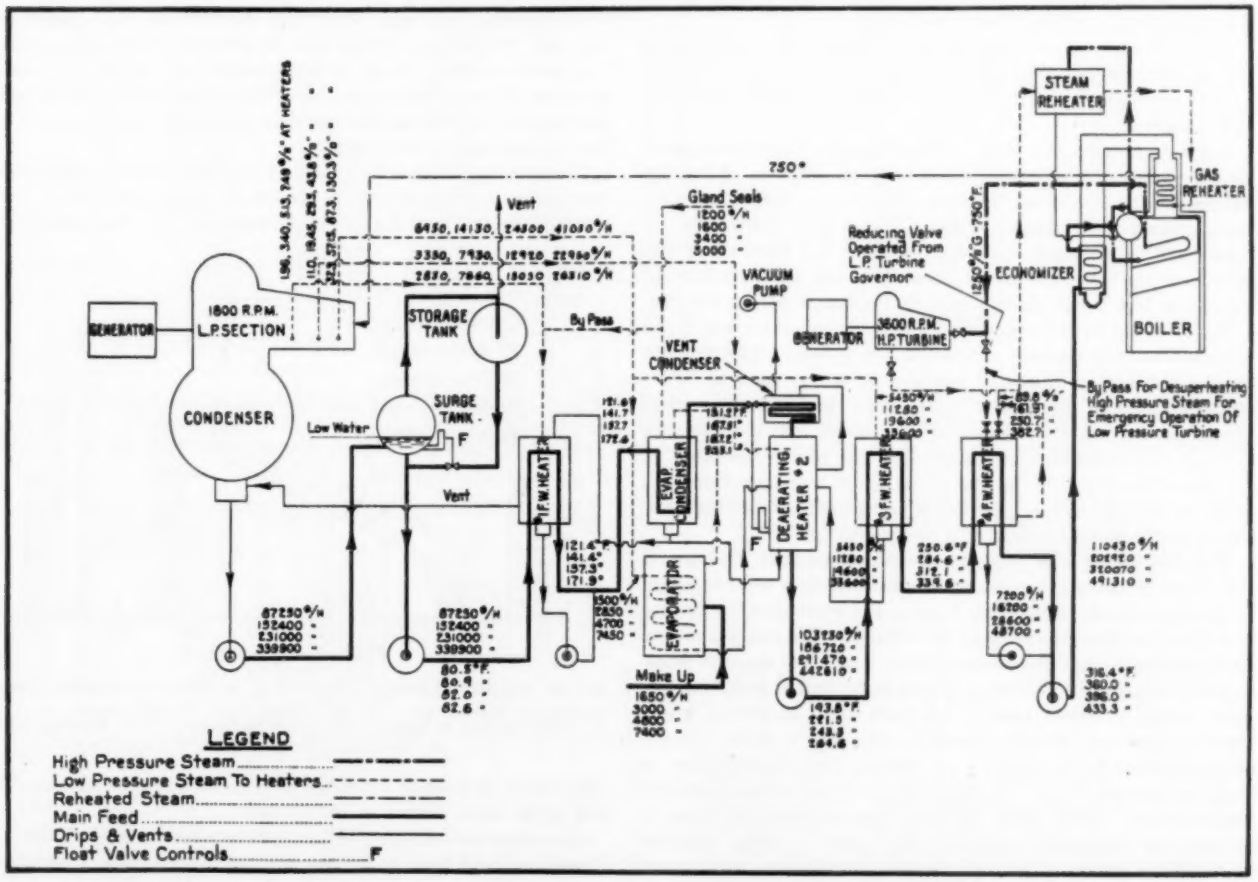

FIG. 8 GILBERT STATION HEAT-CYCLE DIAGRAM

trouble several times. It was decided that these two leaks were due to lack of flexibility in the piping, and added flexibility is being arranged for at these points.

On high-pressure piping less than 2 in. in diameter, where the joints are subjected alternately to high and low temperatures, leakage has been encountered even with the metal gaskets. Experience in the plant with small forged fittings, which are screwed on to the pipe and then welded, has been highly satisfactory, and where necessary on this smaller piping this method will be used.

On low-pressure joints composition gaskets are being used and standard flanges and bolting. Fig. 8 is a diagram of the heat cycle.

Turbine. Sticking of the valve stems in their cast-iron bushings on the high-pressure turbine occurred frequently at condition. A new bearing has just been installed, but results are not yet known.

A great deal of care must be exercised in starting the machine to prevent the bursting of the lead diaphragm on the turbine used in connection with the vacuum tripper. If too much non-condensible gas or air remains in the shell at the time of opening of the throttle, the pressure in the turbine may increase enough to burst the diaphragm. The removal of this air before starting is difficult to accomplish as the turbine gland seals are practically inoperative until the turbine is moving.

Trouble was experienced during the lightning season by the low-pressure turbine tripping off with a sudden large change of load. This was caused by the governor controlling the intercepting valve not acting quickly enough to prevent the steam contained in the piping, reheaters, etc., from entering the low-

pressure turbine and causing overspeeding. This governor was set to act more quickly.

It was noted that the capacity of the turbine, when operating under full steam flow, gradually dropped from 56,000 kw., which had been the high point of operation, to 46,000 kw. Investigation, by the comparison of pressures under the turbine shell, etc., led to the belief that the turbine blading was choking with foreign material. The turbine was not opened, so that the exact point of clogging was not determined. Washing of the turbine with saturated steam was resorted to in an endeavor to see whether this scale formation could be dissolved and removed this way. The result was satisfactory, and the capacity of the machine was gradually brought back. This scaling of the turbine has been traced to the evaporator, and changes in this piece of apparatus are being made.

Boiler Feed. As stated originally, there was considerable trouble encountered with Ryan seals, which were later replaced by labyrinth gland and stuffing box. This has greatly improved this condition.

Some time after starting, leakage in the boiler-feed pump casings developed, requiring that they be welded. After the welding, leaking occurred between diaphragms, this apparently being caused by a warped casing. These have since been rebored, and it is hoped that this condition has been corrected, as no similar trouble was experienced in the pumps where no distortion has taken place nor in these pumps before welding.

It was noted in the paper that a Mercon regulator was being installed between primary and secondary pumps. This has not been a satisfactory piece of equipment, so no data as to its operation can be given, but it has been determined by hand operation of a valve between the two pumps that maintenance of constant differential will accomplish the results desired.

Induced-Draft Fans. In the paper there was mentioned the wear on the inlet vanes. Stellite is being used in repairing these vanes, and it seems to materially increase their life.

The fan casing has been lined with removable steel plates which can be easily taken out and replaced as they wear through.

The floats on the fan, which wear at the outer tips, are having new metal welded into place as this occurs. The operators have been cautioned that the present floats, which are made of heat-treated steel, can be welded only to a very limited extent on the outer tips. It seems that a fan built from materials which prevent rapid and simple repairs is not what is desired in the average power plant, and we are asking the manufacturer to look into the question of building these wheels so as to simplify maintenance. Their great problem apparently is to effect a satisfactory compromise between the class of metal required to stand the strain of the high tip velocity and that which most satisfactorily resists erosion.

Burners. All experiments to reduce secondary air pressure to allow use of present vent fans have been without success, and new vent fans of higher pressure are now being installed. Some maintenance still remains on the burner cones, and there is some slag trouble in the ashpit and on the boiler tubes when the boilers are operating continuously at the higher ratings.

Evaporators. During the first months of operation a great amount of leakage occurred in the economizers, the result being that the make-up for the system increased very materially and the evaporator was working at unusual capacities. It was also found that the method of operating the evaporator was irregular, which still further increased its overload at times. Under normal conditions, however, the evaporator was not meeting its guarantees, too great a quantity of solids being carried over into the distilled water. Various changes were decided upon covering operating procedure, alterations of steam baffle, limit to steam supply lines, etc., and these were explained in the discussion by Mr. Sheppard Powell. As these changes are not all completed it is too early to state definitely whether the solids carried over will be reduced to the required point, but operation has already been materially improved.

Feedwater Treatment. The feedwater treatment which is being used was discussed by Mr. Powell, who is responsible for the layout.

As to heaters, reheaters, economizers, etc., nothing need be added to the text originally prepared. Such troubles as existed have been overcome except for leaking in the rolled joint of the economizer, and that is in the hands of the manufacturers.

No trouble with the boilers, water walls, or brickwork has been encountered; not a brick has been replaced in the furnaces and no boiler or water-wall leaks have occurred.

Conclusions. It may be safely stated that the operators feel that very little trouble can be ascribed to pressures and temperature used. Most of the troubles are similar to those occurring in any new plant, especially where newly developed machines or apparatus arrangements are being tried out, and a cure is apparent in each case.

The quality and quantity of labor required for plant operation has not been increased due to the use of higher pressures. The chart shown in Fig. 9 is a sort of yardstick used to compare plant

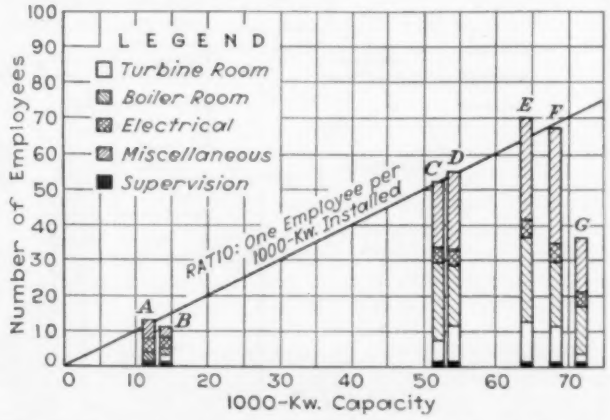

FIG. 9 CLASSIFICATION OF EMPLOYEES AT STEAM POWER STATIONS (*A*, Benson Springs, Fla.; *B*, Avon Park, Fla.; *C*, Binghamton, N. Y.; *D*, Gilbert Station at Holland, N. J.; *E*, Middletown, Pa.; *F*, Reading, Pa.; *G*, Parr, S. C., standby for hydro.)

labor costs, and while not considered as an accurate measure, it still gives some degree of comparison.

Operating statistics for the plant to date are shown in Table 3. These coal and heat quantities are based on shipper's weights and include all coal used for heating, testing, numerous shutdowns and restarting, and also without any benefit from No. 4 heater. The B.t.u. per kw-hr. will be reduced somewhat when all unusual troubles are removed and steady operation is possible.

It is interesting to note that this plant was built within the estimate, and cost about 7 per cent more than the 350-lb. Middletown plant.

Fig. 10 gives the relative costs between various stations which have lately been built by the Barstow Company, these costs being placed so as to compare the different stations under each construction heading. It will be noted that in several of the divisions the 1200-lb. plant was not by any means the most expensive.

Before installing the bin system at the Gilbert Station a careful analysis of costs for both bin and unit systems was made. The figures for these comparisons were furnished by the manufacturers, and the result was that there was practically no difference in investment cost of the two systems. This analysis

[a] Estimated. [b] Based on mine weights.

included the cost of and space required for the pulverized-coal bunkers. Of course it may make some difference on what basis these comparisons are made, and ample mill capacity is one point that should be insisted upon in making comparisons The reason for this may be illustrated as follows:

At the Middletown plant pulverizing mills were installed

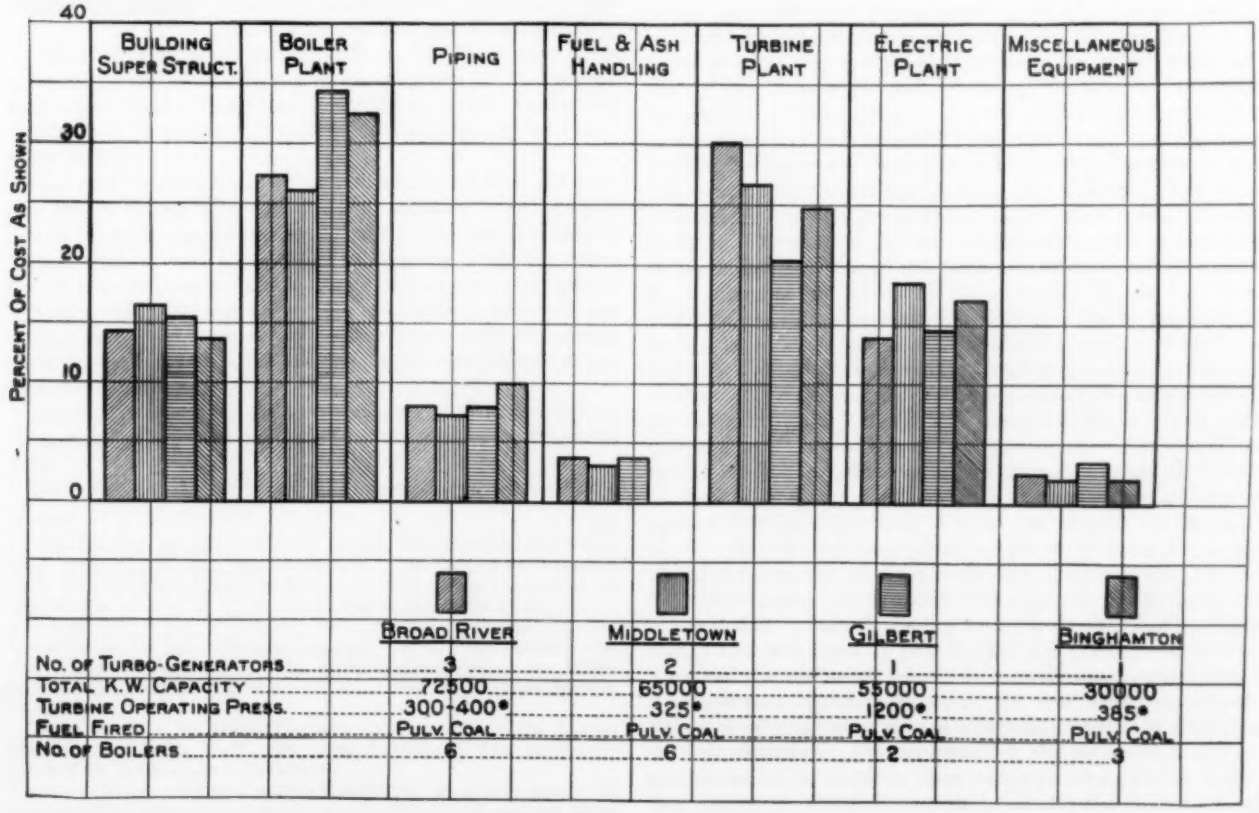

FIG. 10 COMPARATIVE COSTS OF FOUR STEAM-ELECTRIC STATIONS

which gave sufficient capacity, milling 16 hours a day, to run the station at its maximum load. During a strike which occurred about two years ago it was necessary for several months to obtain coal other than that ordinarily used, the result being that owing to the reduction in friability of this fuel the capacity of the mills was reduced by about 40 per cent, and it was necessary to operate these mills 24 hours a day, including Sundays, to keep the plant running at all. If this had been a unit system, with the same capacity in mills, nearly half the capacity of the plant would have been out of service.

Therefore when a unit system is installed it is felt that the mills used should be of greater capacity than would be necessary with a bin system in order to care for emergencies which may occur at any time due to strikes or failures, from any cause, of the mines or railways supplying the fuel.

There is a preference for the flexibility obtained by a limited bin system built in such a way that the benefit of mill drying and burning of vent dust is accomplished as it is in the Gilbert Station. There is also the ability to shut down the mills on the peak hours or in cases of emergency.

As to the matter of turbine scaling, this is in no way peculiar to high-pressure stations, but occurs in low-pressure plants as well.

As to the availability of the feed pumps there are as yet no definite figures on this. Generally speaking, the author may say that it never has been necessary to shut down the plant or to reduce the capacity because of trouble with the pumps. Of course there is a spare pump which always can be cut in. Availability factors may be obtained after all changes are made and the pumps are definitely on a permanent operating basis.

FSP-53-20b

Operating Experiences, Deepwater Station

By K. M. IRWIN,[1] PHILADELPHIA, PA.

The physical characteristics of the Deepwater Plant are described, emphasizing only those details which are relatively new or those which have had a distinct bearing upon operating experiences. The paper gives a history of the operations from the time the plant was first started in March, 1930, up until the present, summarizing the difficulties that have been encountered and attempting to segregate them between those that are directly chargeable to the pressure or temperature and those which have been encountered due to other features of design. Due to the fact that a large portion of the plant has been in what might be termed commercial operating service only since June 1, or for three months at the time this paper was prepared, very little authentic data on operating efficiencies can be given.

PART I GENERAL

THE Deepwater Plant was built by the American Gas and Electric Company and The United Gas Improvement Company for their respective subsidiaries, and is centrally located for these properties on the Delaware River in the southern part of New Jersey. The initial installation consists of two General Electric Company compound turbines, which have a nominal manufacturer's rating of 53,000 kw., but have been operated satisfactorily up to 58,000 kw., and one high-pressure turbine, which is an exact duplicate of the high-pressure elements of the beforementioned compound machines, but which is used for the benefit of the du Pont company, whose plant is adjacent to the Deepwater Station.

The boiler room has six boilers, which are so arranged that two are to supply each high-pressure machine. Out of each pair of boilers supplying the compound turbines, one is equipped with a reheater and a small-size economizer, while the other has no reheater, but a large-surface steaming-type economizer. The two boilers opposite the du Pont turbine, however, are equipped only with economizers. All six boilers have air heaters, those on the reheater boilers having 14 per cent larger surface than those on the boilers with steaming economizers.

The fuel is fired in pulverized form, the direct-fired system being installed on three boilers and a bin system on the other three.

The boilers are designed for 1350 lb. operating pressure and the turbines for 1200 lb. The initial temperature admitted to the high-pressure cylinder is 725 deg. fahr., and at the exhaust to the high-pressure cylinder this steam is reheated in the flue-gas reheaters to 750 deg.

Arrangement of du Pont Apparatus

It is necessary to describe briefly the arrangement of the equipment which was installed for the benefit of the du Pont company before going into a description of the plant heat cycle, as the design is contingent upon the working in of the separate cycle which was necessary in order to supply the industrial demand.

The du Pont turbine is a duplicate of the high-pressure elements of the compound machines, and if in the future it is found desirable by either party to discontinue the arrangement with du Pont, a low-pressure element may be added, so that this portion of the plant becomes a duplicate of the other two portions devoted to the power companies.

The turbine exhausts into evaporators in order to condense the plant steam and permit this to be saved and pumped back into the boiler plant. Raw water at 180 deg. is delivered to the evaporators by the du Pont company, and is converted into steam at 180 lb. gage pressure and superheated 40 deg. in the steam superheaters. The condensed plant steam or evaporator drips are picked up in individual hot wells on each evaporator and pumped forward by drip pumps into the suction of the boiler-feed pumps, which are also duplicates in size and characteristics of the boiler-feed pumps on the power companies' units. All boiler-feed pumps discharge into a common header. A considerable problem has presented itself in the operation of the evaporator drip pumps, as the pressure at full load is approximately 400 lb. and the temperature of the drips at saturated temperature of this pressure. A great deal of the pump trouble in the plant has been caused by the difficulty of maintaining a level in the hot wells of the evaporators sufficiently high to give the pumps their proper submergence and sufficiently low to be able to properly vent the entrained oxygen from these hot wells. Flashing difficulties in the drip pumps are quickly transmitted to the boiler-feed pumps and have caused considerable trouble in maintaining the boiler-feed pump seals. It has only been with considerable experience and skill that the operators have been able to maintain an equilibrium in this portion of the cycle and at the same time keep the discharge of the boiler-feed pumps at the same pressure as the discharge pressure of the feed pumps for the other units. If the feed pumps on the du Pont cycle deliver a higher pressure in the boiler-feed mains than the pumps on the compound-turbine systems, this would cause the boilers to draw the majority of the water from the du Pont boiler-feed pumps, draining this system of water and backing up the water in the other two systems, while, on the other hand, if the discharge head in the du Pont boiler-feed pumps is too low, the boiler-feed pumps of the other two systems which supply all of the feedwater shut off the flow from the du Pont boiler feeders, and in that way back up into the hot wells of the evaporators. As all of the pumps of the du Pont cycle are constant speed, it is necessary therefore to adjust the final discharge pressure either by varying the number of drip pumps used or by throttling on their discharge. As later described, the pumps on the power companies' units, however, have variable-speed primary boiler-feed pumps, so that it is possible to control the discharge head on these pumps.

---

[1] Mechanical Engineer of The United Gas Improvement Company, Philadelphia, Pa. Mem. A.S.M.E. Mr. Irwin was graduated from Yale Sheffield Scientific School in 1915. The same year he entered the employ of B. F. Sturtevant Co., Hyde Park, Mass.; later was with Stone & Webster, Boston, Mass. He served in the Navy during the war. He has been with The United Gas Improvement Company since 1919. Mr. Irwin is Chairman of the Philadelphia Local Section, A.S.M.E., and a member of the Prime Movers Committee, N.E.L.A.

Contributed by the Power Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

At the present time, the regulating is done by using water-level regulating valves on the evaporator hot wells, which allow a small portion of the water from the discharge of the boiler-feed pump to be bypassed back into the evaporator hot well. The designers now are considering installing considerably larger hot wells on the drips from the evaporators, in order to supply greater storage at a given head elevation over the drip pumps.

Heat Cycle, Power Companies' Units

The low-pressure cylinders are bled at three points, and a fourth bleed point is provided at the exhaust of the high-pressure unit. The condensate pumps discharge through the first stage of bleeder heating into a deaerator. This deaerator also receives the various plant drips and the make-up water from the plant evaporators. Connections are provided to the deaerator from the second and third bleed points, which are controlled by thermostat-operated valves in order to maintain 214 deg. fahr. to insure complete deaeration. Immediately below the deaerator, a large storage tank is provided, and from this tank the primary boiler-feed pumps or tank pumps take their suction and discharge through the second, third, and fourth bleeder heaters into the suction of the boiler-feed pumps. These tank pumps are variable speed, and all of the boiler-feed pumps are constant speed, so that the pressure in the boiler-feed main is maintained by varying the speed of the tank pumps, and in that way varying the suction head of the boiler-feed pumps.

The first-stage bleeder heater is provided with a drip pump which discharges into the deaerator. The fourth-stage bleeder heater, which takes its steam from the exhaust of the high-pressure turbine, is also equipped with a drip pump which discharges into the line leaving the fourth-stage heater. The drips from the second- and third-stage bleeder heaters are cascaded back into the deaerator.

The only modification which has been made to this system since the plant has been put into operation has been to supply additional cold-water storage by installing a storage tank on the discharge of the condenser condensate pumps. These storage tanks float on the line, and admit water to the system when the float valve opens up on the tank below the deaerator and receive water from the system as this float valve closes.

Boiler and Furnaces

The boilers are all of the Babcock & Wilcox Company cross-drum type, nine tubes high, without baffles, the gas passing straight up through the boiler directly into the economizers on four of the boilers and into the reheaters on the other two boilers. The boilers which are equipped with reheaters also have a small economizer below the reheater in order to reduce the temperature of the gases before entering the air heaters.

All four sides of the furnaces are equipped with water walls, consisting of bare tubes on 6 in. centers backed up with refractory walls. The bottoms of the furnaces are flat, and are designed for slag tapping. Originally, two of the furnace bottoms were lined with dolomite, two with mica schist, and two with cans filled with coke.

Pulverized-Fuel System

The owners felt at the time the plant was designed that the advisability of utilizing either the bin or the direct-fired system had not been definitely determined, and it was therefore thought advisable to equip half of the plant with a bin system and the other half of the plant with a direct-fired system. It seemed that each system had very distinct advantages and that this would offer an opportunity for the two owning companies to gain experience which would prove of value to them in their other stations.

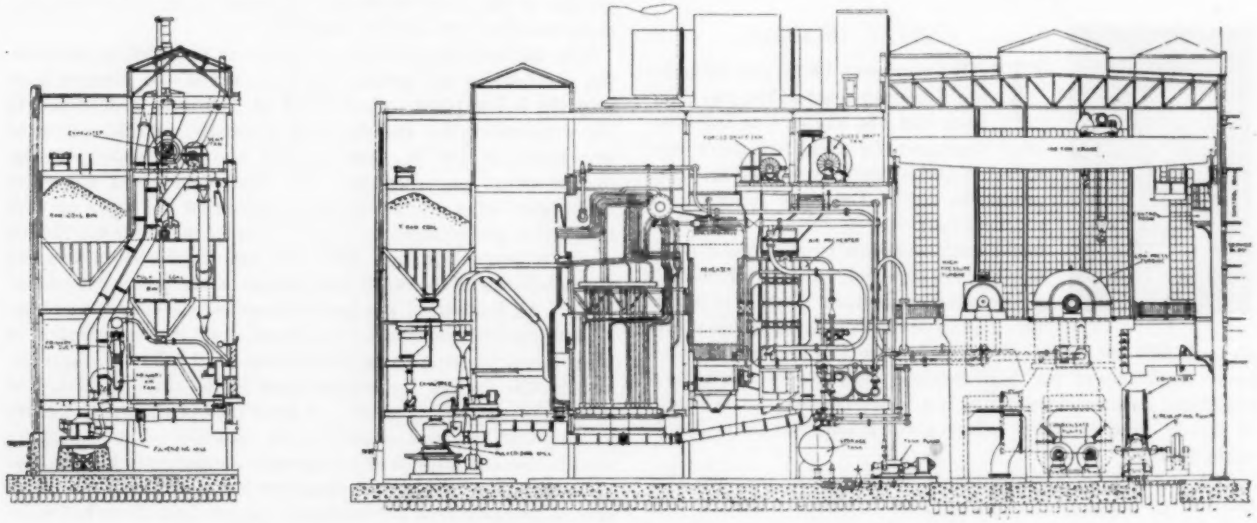

Fig. 1 Elevation of Boiler and Turbine Room in the Deepwater Power Station
(At left, elevation through bin system; at right, elevation through direct-fired system.)

This plan was adopted, the three boilers on the bin system having one mill each of 20-ton capacity. The mill exhausters take their suction out of the mill cyclones in place of discharging into them, as was the more general practice at the time the plant was designed. Mill drying is done by taking a portion of the air out of the preheated-air ducts into the mills, and providing a vent or leak off fan to take a portion of the air out of the mill system beyond the discharge of the cyclone exhauster, and discharge this air into the secondary-air chamber around the burners. It is felt that, with this arrangement, two of the most serious objections to the bin system had been overcome—namely, the elimination of driers and the elimination of cyclone vents, which have in the past proved a dust nuisance. The cyclones on each mill discharge directly into the powdered-coal bins in front of the boiler. A screw conveyor has been provided so that it is possible to utilize any mill on any boiler. Each of the

bin-system boilers is equipped with six burners, which are fed by the feeders directly below the powdered-coal bunkers. The burners are of the Combustion Engineering Couch type.

On the direct-fired system, two mills of 10 tons capacity are provided on each boiler, each mill discharging up to three burners. The burners are the Fuller-Lehigh Calumet cross-tube type.

The designers laid out the building and required the manufacturers of the two respective systems to work their equipment into exactly the same space requirements, so that there can be charged no additional investment for building space against either system. The final installed cost of the two systems, including all necessary wiring and control equipment, was very close, so that the ultimate choice between these two systems must lie in features of flexibility, reliability, efficiency, and general appearance, including such items as light and ventilation.

Ash-Handling System

The slag is tapped from the boilers into a disintegrating chamber, with high-pressure water jets to break up the slag stream and quench it. A Coghlan ejector is provided to draw the water and slag out of the disintegrating box and discharge into a 10-in. pipe line, which carries the slag out to the yard.

placed by either soft-steel or corrugated Monel-metal gaskets. Difficulty was also encountered with leaks on the bonnets of some of the valves, and again it was found due to the disintegration of composition gaskets, which have been replaced.

The economizers, which have been subjected to as high as 1800 lb. pressure, are the B. & W. return-bend type with copper gasket joints. In general, it may be stated that these have been satisfactory, in that only one of the boilers has been troublesome with leaks, and on this boiler it was found that most of the leaks have been due to the gaskets being improperly installed or that the faces have not been properly prepared to receive the gasket. It has not been necessary to repair any one joint more than once. Generally, the same observation has been made of the water-wall tubes. Some of the boilers have had a number of leaks, but in nearly all cases after these had been rerolled, no further difficulty has been experienced. In a few cases where there has been a repetition of the difficulty, it was found to be traceable to the fact that the water from the quenching on the slag-tap system has slopped over on these tubes before the covering was completed.

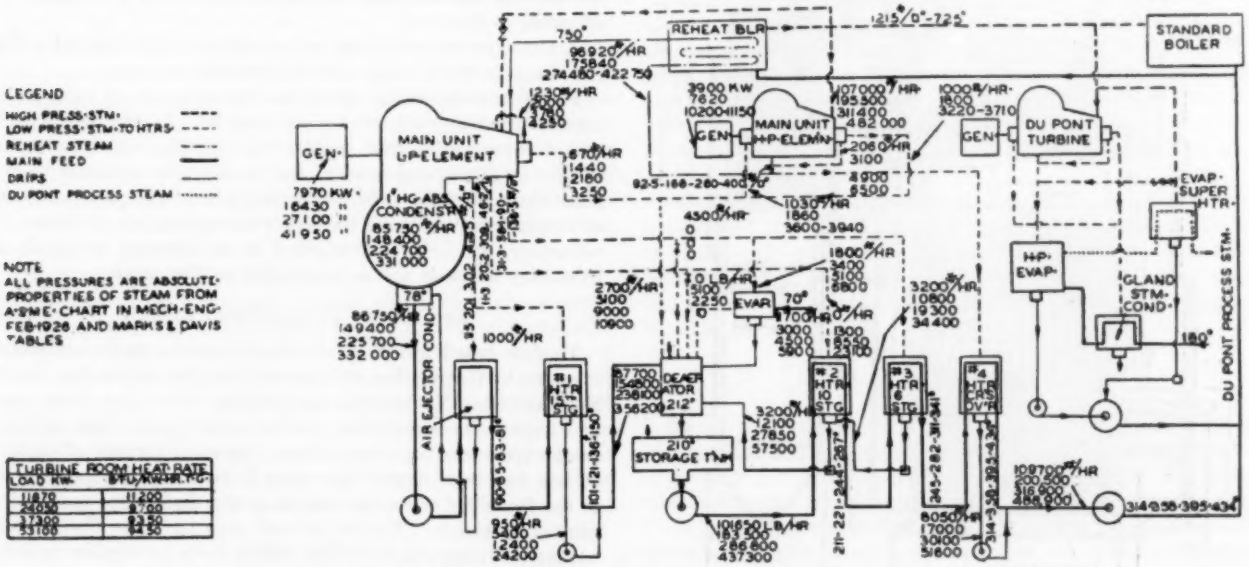

Fig. 2 Heat Balance Diagram of Deepwater Power Station

PART II OPERATING EXPERIENCES

The author wishes to again emphasize the fact that at the time this paper was prepared the plant had been in commercial operation only a little over three months, and therefore had not had a long enough running period to give definite figures on the economies obtained or on the operating efficiencies of the various parts of equipment.

Many difficulties, such as are encountered in new plants and especially those with novel features of design, have come up, for some of which remedies have been provided, and others are still being treated.

Many of the fears of 1200 lb. have been centered around the piping, and it can be stated that, to date, there have been no leaks on the larger sizes of high-pressure piping, which is equipped with the Sarlun joints. Some difficulties have been encountered with the smaller size pipe, which has been used for drips and instrument connections. Most of this is chargeable to the use of composition gaskets, nearly all of which have now been re-

The reheaters and the superheaters have been entirely satisfactory, both as to their operating characteristics and types. The temperatures at the outlets of both the superheaters and reheaters have been very close to the guaranteed condition. Summing up, it might be stated that there had been no difficulties in the boiler room traceable to 1200 lb. pressure selected.

Operating Difficulties Not Traceable to Pressure

Other difficulties encountered in the boiler room which are entirely foreign to the pressure or temperature have been with the slag-tap furnace bottoms, boiler side and rear walls, and the pulverized-fuel system.

Since this plant was designed, a great deal of development work and knowledge have been gained on slag-tap furnace floors at other stations, and difficulties which are gradually growing, but of which the operators of other plants were not cognizant, have come to light. The first of these was that boilers which are taken off of the line and put back at fairly frequent intervals had their furnace floors grow and push the side walls out. It was found on inspection that this was due to having the bottoms crack in cooling down, and the cracks and interstices fill

with molten slag when the boilers are again heated up. The repetition of this operation gradually pushes the walls out, so that it is necessary to cut back the furnace bottoms adjacent to the side walls and to allow the walls to spring back or to be pushed back into shape, and to start over again.

This was brought to the attention of the owners of the Deepwater plant after two of the boilers had been installed with dolomite bottoms similar to other installations, so that the next two boilers were changed, and mica schist was used in place of dolomite. At one other plant with a slight amount of experience with mica schist, it appeared that the slag did not penetrate in the same manner that it did in the dolomite. Later operating experience at Deepwater, however, has proved that dolomite bottom is much superior to the mica schist. To date there have been only two cases of leakage of slag from the furnace bottoms covered with dolomite. Neither one of these

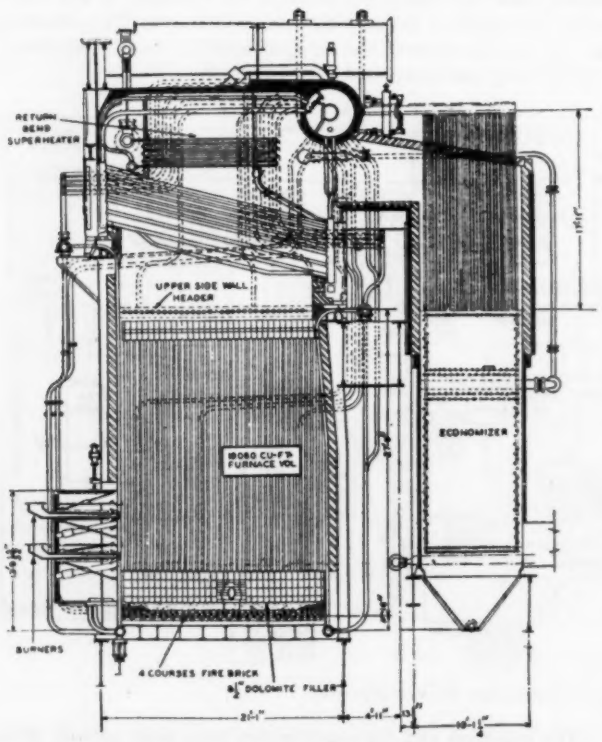

FIG. 3 SECTION THROUGH ONE OF THE STANDARD BOILERS IN THE DEEPWATER POWER STATION
(There are four standard and two reheat boilers installed in the plant.)

was serious, and both were immediately stopped by chilling the slag leak with water, and after the furnace was shut down, cutting back the floor approximately 6 in. along the two sides, allowing the walls to assume their normal position, filling again with silica sand (a sand used in glass making) and dolomite. Summing up, it might be stated that bottoms of this type can be operated without a great amount of trouble if the side walls are carefully watched for deflection and if the boilers are not taken off and on the line too frequently, and operating periods of a year or more may be obtained without any serious maintenance work to the bottoms.

About the time the first four boilers mentioned went into operation, the owners were advised by the manufacturers that, on the basis of laboratory tests where they had used slag tapped from furnaces of other companies, they had found that coke or carbon was a material which the slag would not penetrate. This was also confirmed by investigation of practice in the metallurgical furnaces. Therefore, the last two boilers were designed with bottoms of radically different design, and coke cans were placed on top of 5 in. of silica sand, and above this additional coke and coking coal were spread, in order to form a solid coke bottom. In other plants carbon bricks are used. It is now found that these last two boilers with their coke bottoms have been the least satisfactory of any of those installed. The slag contains a large amount of iron sulphide, which, due to its weight, sinks to the bottom of the slag bath and is therefore never drawn out through the slag tap. This material is very heavy, penetrating down through the coke and entirely consuming it, so that on one boiler with this design of bottom, which has been taken off the line and cut into, it was found that all remnants of the cans of coke had entirely disappeared, and the only thing that was left was approximately 22 in. of iron sulphide and approximately $^3/_4$ in. of the silica sand over the steel-plate bottoms.

The different performance of these bottoms in practice over the laboratory tests is accounted for by the fact that the tests were run with slag taken out of other boilers, and therefore did not contain the iron sulphide which is actually obtained in an operating boiler.

It has now been decided to reconstruct with magnesite the two furnaces which originally had the coke bottoms.

The side walls earlier described are made up of bare plain tubes backed up with refractory material. It has been found that the rear wall, that is, the wall opposite the burners, is subject to severe slag erosion, and it has been necessary to replace three of these walls. Combinations of the particular ash of the fuel that is being burned, with various compositions of refractory, are being investigated in an attempt to obtain a refractory which is not so susceptible to slag erosion.

BIN VERSUS DIRECT-FIRED SYSTEM

To date it is impossible from the records to make any statement as to the relative efficiency of the bin versus the direct-fired system. No careful evaporating tests have been run, and from normal operating data it would appear that the systems were operating practically at the same furnace efficiency. It has also been found that there is no marked improvement in the flexibility of the bin system over a direct-fired system for normal operation. The bin system does have the distinct advantage of being able to cut the boilers down to very low ratings. This feature was taken advantage of at the time the plant was originally put into operation, and only small quantities of steam were required for turning turbines over for drying out, operating auxiliaries, etc. The direct-fired system has a distinct low-rating limitation.

It is well to mention here that, due to not being able to run the furnaces at extremely low ratings, it was necessary to utilize oil in drying out the boilers after erection. This difficulty which was experienced with this oil has received considerable publicity, and for that reason it seems advisable to describe the accidents which occurred.

Apparently the oil fire was so small for such a large black surface furnace that the oil was not entirely consumed, and unburned oil vapors passed on up through the boiler and condensed in the breechings and stacks, forming a heavy, greasy soot. On two occasions the soot in the stacks and breeching caught fire, and on one of these occasions two men were fatally burned.

The direct-fired end of the plant presents a very much more desirable appearance, in that the pulverized bins of the bin system are bulky and cut off considerable light and air, so that a visitor to the plant is much more favorably impressed by the general arrangement at the direct-fired system end. The one counterbalancing feature, however, has been the more reliable operating

condition existing at the bin end of the plant. On a number of occasions it has been necessary to cut back the load which the plant was carrying, due to failure of coal supply to furnaces from the direct-fired system. A number of these interruptions were caused by small adjustments which were needed on the mills themselves. These have been made, and on one of the boilers which caused a drop in load four times during the month of April. due to a faulty lubrication system on the mill and which was corrected at that time, no interruptions have occurred since. On three of the mills which are of the Fuller-Lehigh table B type, trouble is still being experienced with the loss of fuel. It is felt that one of the difficulties with these three mills is that in normal operation they are extremely quiet and do not become noisy even when the coal feed fails, as is the case with the other mills. Therefore the operators are not cognizant of this condition as quickly, and a tie-up in the fuel actually causes loss of steam pressure at times before the condition can be corrected. It should be emphasized, however, that this again is a matter of operating experience, and it is believed in time that a great deal better record will be obtained.

Difficulty has been experienced with the coal hanging up in the raw-coal bunkers and sticking in the connections between the raw-coal bunkers and the scales which are installed between the raw-coal bunkers and the mills, jamming in the scales or in the magnetic separators and catching small particles of wood or foreign material on the Star feeders of the mills themselves. Two cases occurred where a failure in the mill of wearing parts was not caught in sufficient time to prevent the mill from failing while in service. The records show that difficulties have been steadily decreasing, however, and it is hoped that very soon they will be entirely eliminated.

As the author is a representative of the company which advocated putting in the bin system, any prejudice can be excused, for he now is of the opinion that it is safer and more comfortable to have a small supply of powdered coal on hand in order to take care of unforeseen difficulties which may happen in the fuel-supply system which will be absolutely no fault of the particular mill which is being used, and that in the Deepwater plant ten hours' supply of powdered coal is probably far more than is necessary. The recommendation would be that a two to three hours' supply would make an ideal practice.

Turbine Room

Difficulty has been experienced in the turbine room with silica scale deposited on the last rows of blading and nozzles in the high-pressure turbine which is used in the du Pont system. This difficulty has been entirely peculiar to this one machine out of the three high-pressure machines. To date no evidence of scale has been found in the other two high-pressure units. It has been necessary to shut this machine down for periods of two weeks in order to scrape the scale off the nozzles and blading by hand. This has been a laborious and expensive job. In order to correct this condition, purifiers have been installed on the vapor outlets of the house evaporators to cut down the carry-over silicate in the make-up water. Since these have been installed, the purity of the vapor in the evaporators has been considerably increased, and the turbine has operated for a period of several weeks without showing any symptoms of scaling. Similar difficulty has been experienced at other plants, and it has been found that the scale can be taken off the blades by admitting water to the steam in the high-pressure throttle to the extent of having the steam in a completely saturated condition. After operating for several hours under this condition, it is found that the scale can be entirely washed off, so that while it is felt that this difficulty has been overcome at Deepwater, it is comforting to know that, if a repetition of this should occur, a remedy has been found. This is one of the troubles which can be directly charged against the pressure utilized in this plant, as the other plants which have experienced this trouble are also operating at 1200 lb.

Silica is soluble in water at superheated temperatures, as is evidenced in many low-pressure plants by the eating away of gage glasses on the boilers, which is a common phenomenon. Apparently as water temperatures increase, it increases the solubility of the silica, so that at temperature corresponding to saturated temperature of 1350 lb., which is 582 deg. fahr., this action is extremely pronounced.

Each of the high-pressure elements on the compound units has developed leaks on the horizontal joint. These leaks occurred on successive days and did not occur on the high-pressure unit of the du Pont system at any time, and the du Pont machine was not operating two days that the difficulty was encountered.

Considerable difficulty has also been encountered with the government mechanism and control valves on the high-pressure turbines. The manufacturers have made certain changes, and it is now felt that this has also been overcome.

On several occasions the operators have attempted to run the low-pressure element of the compound machines without the high-pressure, utilizing a control valve which was provided with the turbines to admit the high-pressure steam directly into the low-pressure elements. It has been necessary for the manufacturer to redesign this valve, as to date it has been impossible to operate in this manner without breaking the stem on the controlling valve.

In closing, it may be stated that very little difficulty has been experienced due to the pressure and temperature conditions selected for this plant, and of the difficulties which have occurred, the operators feel that they are well along on the road for remedies and corrections, which, it is hoped, can be outlined in better detail in the near future.

Discussion

Grant Campbell.[2] The problem presented by The Allied Engineers was to maintain a safe minimum water level in seven evaporator hot wells, each having a constant-speed drip pump which delivers the condensate to the boiler-feed pump suction.

Owing to the variable demand for process steam, there are times when the condensate is very much less than the capacity of the drip pumps, and this condition led to insufficient suction head, subjected the drip and feed pumps to failure, and otherwise affected the plant operation. It is also true that too high a level of water in the evaporator system lowered the efficiency of the evaporators and of the high-pressure turbine.

The plan adopted by the engineers provides for bypassing water from the boiler-feed pump discharge to each hot well when its water level is below a definite level. Seven Campbell water-level regulators of the boiler-feedwater type were installed, one for each hot well, as indicated in the diagram of connections and general arrangement, Fig. 4.

The principle upon which the operation of this regulator is based is that when a mixture of steam and hot water under pressure passes continuously to atmosphere through a system of matched orifices, the intermediate pressure between any two orifices will vary with the moisture content of the mixture.

A suitably treated sampling pipe is set in a water column with the open end below the desired average water level, and there is a continuous minute flow up the pipe to the orifice system. This flow obviously will be all steam at extreme low-water level or all steam at extreme high-water level or all water at extreme high-water level. Between these limits the moisture content of the

[2] Atlas Valve Company, Newark, N. J. Mem. A.S.M.E.

fluid mixture will increase as the water level rises, and vice versa.

The regulating element is shown in the diagram, Fig. 5, connected to the water column and with a tapping for receiving the sampling pipe.

In the element is a pair of orifices scientifically proportioned so that as the mixture of steam and water passes through the orifices to atmosphere the pressure in the element will increase or decrease as the percentage of moisture increases or decreases, or as the water level rises or falls.

The chart, Fig. 6, showing a relation between the element pressure and the water level, gives a typical condition taken from an actual boiler test.

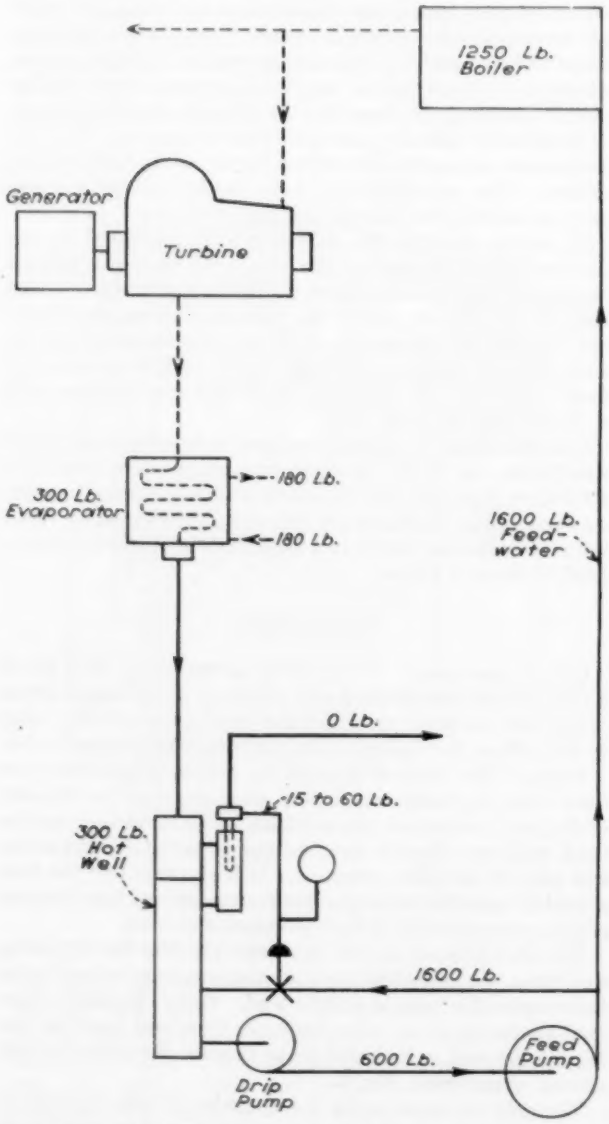

FIG. 4 INSTALLATION OF WATER-LEVEL REGULATORS

Since there is a definite pressure change in the element with any water-level change, this variable pressure applied to a pressure-actuated valve regulates the flow of input water in accordance with the water level.

In the control valves installed at Deepwater this pressure has been imposed upon a spring-loaded diaphragm which actuates a pilot stem, as shown. This arrangement leaves little for the pressure to do but to lower the pilot stem with increased water level, and vice versa.

This pilot stem, rising and falling inversely with the water

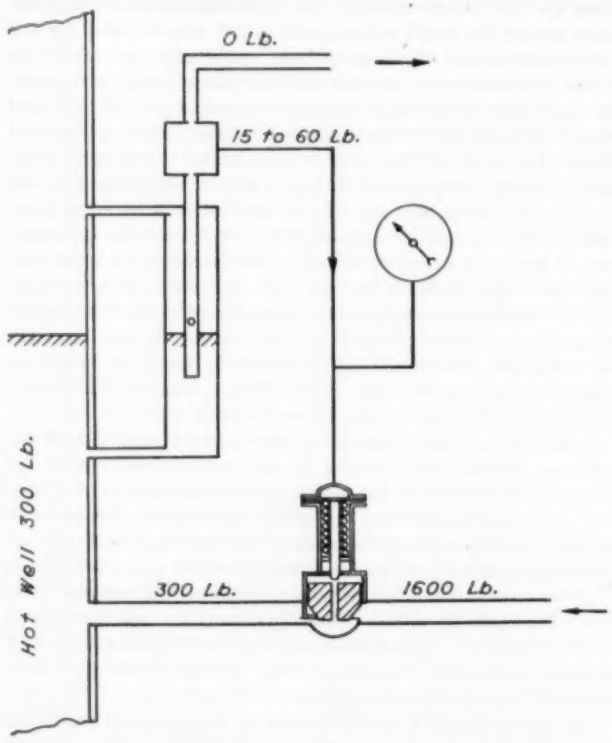

FIG. 5 REGULATING ELEMENT CONNECTED TO WATER COLUMN

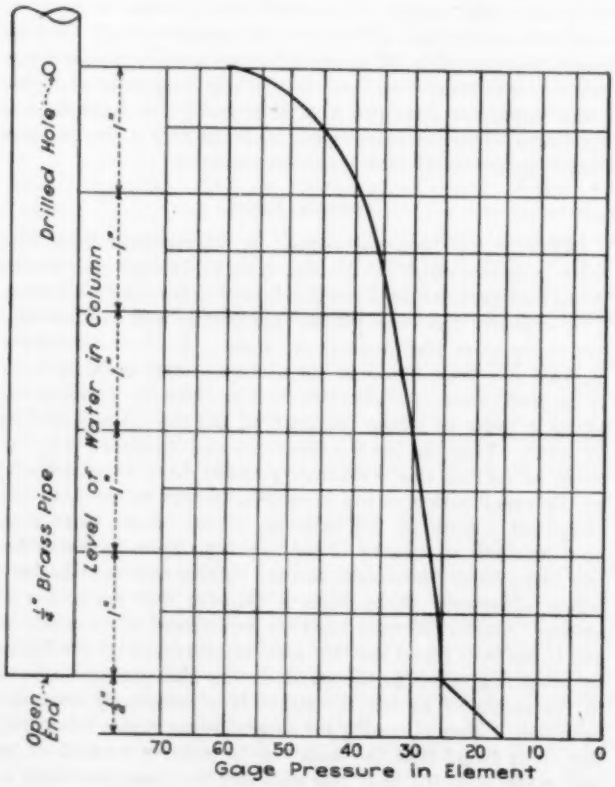

FIG. 6 RELATION BETWEEN ELEMENT PRESSURE AND WATER LEVEL

level, is aligned with a poppet loosely fitted in the valve body at the upper end and having a conical surface at the bottom end to contact with the seat and close the main valve port and with a vertical pilot port opening at the bottom into the discharge side of the valve but subject to restriction at the top by the pilot stem.

The areas and the balances used in the design are such that in operation the valve poppet always follows closely the movement of the pilot stem without offering resistance to it, the valve port opening or closing as the water level lowers or rises.

It will be seen that the regulator combination admits water to the hot well when the level of water is lowered, but provides a tightly closed valve port at high water, the valve in operation being always in perfect balance.

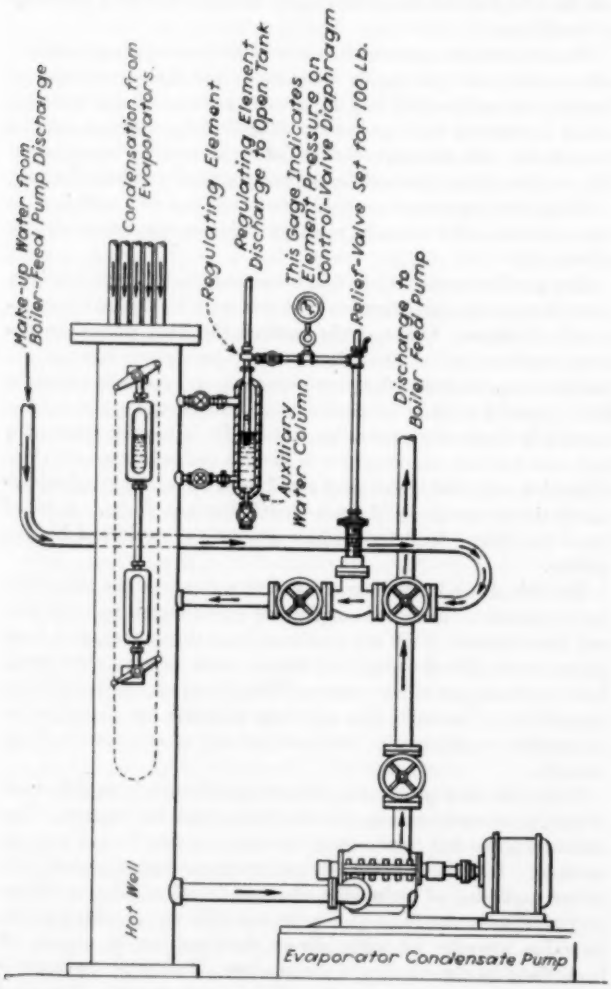

FIG. 7 WATER-LEVEL CONTROL CONNECTIONS AT DEEPWATER STATION

The conditions encountered in the Deepwater operation are different in many respects from those met in boiler-feedwater regulation, but the principles are the same. The diagram of connections at Deepwater Station is shown in Fig. 7.

The hot wells are 18 in. in diameter and hold very little water, so that the regulators have been made to respond accurately and rapidly to maintain the level within a few inches.

The steam pressure in the hot wells is varied from 250 to 350 lb., and the boiler-feedwater pressure may be from 1500 to 1800 lb., so that the control valves have been constructed to be capable of adapting themselves to widely varying loads and drops in pressure and still retain their accuracy.

For the best operation of these level-control units it is essential that there be a true water level in the water column to regulate by, and that at all times there be water in sufficient quantity and at adequate pressure to hold the desired minimum level.

For several months these level-control units have successfully maintained a safe low-water level in the hot wells materially assisting in the operation of the power station and thereby have justified the designing engineers in selecting the type of equipment used in this pioneer level-control operation.

JAMES M. TAGGART.[3] The author is to be congratulated on his frank and clear statement of the troubles encountered during operation. It is especially noteworthy that none of the real troubles was due to the high pressure of operation. The performance of certain equipment and arrangements covered in the paper merits careful consideration. Further information is, however, required before reaching a judgment as to the results obtained. The writer is taking up a few points that impressed him, with this in view, not in a spirit of criticism.

Pumping hot water at or near saturated-steam temperatures is a common source of trouble where it has been attempted in central stations. Judging by the numerous troubles encountered and from statements made to the writer, there seems to be an extended lack of comprehension of the factors involved. At the Deepwater Station, according to the paper, no trouble occurred so long as the proper water level was maintained. The requirements are of course that the head shall be sufficient to maintain a pressure in the pump above the flash point. The amount of head required therefore depends on the design of the pump and piping connection. The pressure of the liquid pumped is immaterial except as it affects the design with respect to strength and leakage. Provided a suitable type of propeller pump or pump with the first stage of the propeller type be used, similar to certain types of condenser hot-well pumps, much lower heads can be used with safety. Some types of high-speed centrifugal pumps require excessively high heads on the suction side. It would be informative to know the type and arrangement of the drain pumps used on the evaporators at Deepwater and also the minimum head at which they operated successfully. The lack of provision for maintaining a constant head in the evaporator hot well would seem to have been an oversight. The large temperature difference required for maximum load in the evaporator, namely, 72 deg. fahr., would seem to be excessive. It is possible that the maximum noted is more in the nature of an emergency loading. Otherwise either there is apparently an undue restriction in first cost or the evaporator efficiency is very low. A temperature difference of 30 deg. fahr. would give an approximate increase in power output of 20 per cent. With a good design of evaporator this temperature difference would not require excessive surface compared to the value of the return. A short description of the type size and temperature difference required for various loadings would be instructive.

The slag erosion of the rear boiler-wall refractory between the tubes was apparently due to flame impingement, since the side walls did not suffer. The form of burners and fineness of pulverization would determine the amount of impingement to a large extent. It would be interesting to know the fineness used and what, if anything, was done to shorten the flame. Running slag will wash away any ordinary refractory. Normal changes in refractory would at the best only prolong the life slightly unless greater cooling effect is obtained. In this respect carborundum brick pressed against the back of the tubes might give the extra cooling action needed.

[3] Consulting Engineer, New York, N. Y. Assoc-Mem. A.S.M.E.

Slag-tapping furnaces, judging from the experiences at Deepwater and elsewhere, are still somewhat in the experimental stage. Some method of taking care of the expansion is evidently needed. Bumping or bagging the furnace floor, combined with provision for restraining the side flow, might divert the expansion so as to prevent any continued enlargement.

The author's comments on the relative merits of the unit and bin system for pulverized coal possibly apply more especially to the conditions at Deepwater. There are unit systems where the reliability factor is high. However, it is the writer's opinion that the merits of both systems might be combined by the use of relatively small bins, either in parallel with direct feed or as feed bins. It is certain that this arrangement would provide for the low load operation and would give better combustion control at all loads than the unit system alone.

E. G. Bailey.[4] The Deepwater Station is a very interesting group of equipment, and the author has presented the picture up to date in a very frank and fair manner.

The interesting feature of this station is that it represents a fairly true cross-section of the diversity of engineering opinion in regard to certain phases of power-plant equipment. It is to be expected that there should be a diversity of opinion when developments are in progress. Some engineers are inclined to stay by the true and tried, while others are always reaching for the newest equipment offered, and still others endeavor to follow the old adage, "Be not the first by whom the new is tried, nor yet the last to lay the old aside."

As to the relative merits of the direct-fired and the bin systems, this question will not be finally settled to the satisfaction of all engineers throughout the country from results of this one station, because operating conditions, load factor, and the details of crushing and feeding coal have a great deal to do with the correct conclusions under different circumstances.

There are a great many stations as large or larger than Deepwater which are operating entirely satisfactorily on completely direct-fired units and handling an even worse grade of coal than is supplied to this station.

As to relative cost of bin system versus direct firing, the author states that the final cost was very close. This is not always the case. Sometimes the problem works out to an additional cost of 25 to 100 per cent for the bin system over the direct firing. Under certain circumstances the advantages of flexibility and other features may make this increased investment advisable, while in others there is certainly no justification for it.

As to the building space occupied, while the two systems were adapted to go into the same space, yet a glance at the two views of Fig. 1 indicates that building space could have been reduced for the direct-fired system.

The statement that it was necessary to replace three of the furnace walls due to slag erosion should be explained a little more fully; that is, the replacement consisted of the refractory back of the bare tubes. These tubes are $3^1/_4$ in. in diameter on 6-in. centers and have blocks extending up a short distance above the slag line. There has been no trouble with the portion of the wall covered by blocks. Above this, however, the fusing temperature of ash and the rate of combustion, which is approximately 20,000 B.t.u. per cu. ft., have resulted in a combination a little below the proper safety factor for continuous operation without erosion and expensive maintenance.

This bare-tube and tile type of furnace-wall construction has worked out satisfactorily under other conditions, but its unsatisfactoriness for this particular place indicates again what small differences in operating conditions are often magnified in the final result.

[4] President, Fuller-Lehigh Company, Fullerton, Pa. Mem. A.S.M.E.

As to the slag-tap furnace floors, these were installed at a time when this story was in the state of flux and the opinions of different engineers were evident from the variety of materials tried. Here is a case where the original design of brick and dolomite has worked out best, and the expected improvements in the way of mica schist and carbon were unsatisfactory, although under other slightly different conditions both of those materials have given better results. The problem, of course, for an engineer is to find a type of construction that will meet all conditions, or else if there is too great a difference in cost in applying this standard to some cases where punishment is not so severe, then he should have very definite facts and knowledge available so as to use discretion in selecting the proper construction for a given set of conditions.

Those who have operated furnaces of different arrangement for ash removal are practically unanimous for the advantages of tapping out molten slag and are greatly in favor of this method, and it is believed that temporary difficulties in working out the best design will not appreciably deter the coming adoption of this method of ash removal for the great majority of installations.

While our experience on this problem is not yet sufficient to be conclusive, a few remarks covering a diverse experience may be of interest.

The usual comment when first encountering this problem is to go to the metallurgical furnace man and copy his design for open-hearth furnaces. One quickly realizes the vast difference between the two sets of conditions. The open-hearth furnace, for instance, is provided with a very expensive and carefully prepared floor, sintered in place by gas heat; all heating and cooling of the furnace is done very gradually, and its life is mostly spent at a high and uniform temperature; while in a boiler furnace the rates of heating and cooling are very rapid, and the areas involved are many times the areas of open-hearth furnace floors. Both of these conditions tend to produce growth, as explained by the author.

The Illinois coals produce an ash which has been the most difficult to handle. From it considerable quantities of metallic iron and iron sulphide (FeS) are produced from the pyrites, and these do not mix with the slag, but due to their gravity they settle into the lower part of the furnace, filling the cracks and producing expansion. If metallic iron and iron sulphide are permitted to accumulate continuously, the conductivity of the bottom is increased.

While the floor problem is somewhat different from side walls of refractory construction, yet they have much in common. The side-wall story has been solved by water-cooling in one form or another. It therefore seems that water-cooling, together with proper surfacing of magnesite, chrome, or other suitable refractory, will solve the furnace floor in a similar way, making a construction whereby all materials on the floor can be tapped off from time to time and not accumulate. Basically the trouble has been that too cheap a floor has been installed. The kind of floors on several of the first jobs indicated that this was ample, but later experience indicates that a little more expensive construction is required. It is not a problem to require more than a relatively short period of intensive study and trying out of different materials in practice under a sufficiently wide variety of conditions as to rating, kind of coal, and method of operation to determine the various factors and limitations for use in future engineering study and application.

H. J. Kerr.[5] The authors, Messrs. Irwin and Gilbert, should be thanked for their valuable papers and are to be congratulated upon the success of the two plants which they represent.

[5] Chief Engineer, Service Department, Babcock & Wilcox Company, New York, N. Y. Mem. A.S.M.E.

Approximately five years have elapsed since the starting up of the first 1200-lb. unit at Edgar Station, Boston, and these two papers refer to two additional high-pressure plants, making in all six stations now operating successfully above 1200 lb. pressure. In addition there are two industrial plants.

While some difficulties have been experienced with the higher pressure, it can be fairly stated that the boiler rooms of such stations have developed no problems for which the solution was not readily available.

As a result, units are being built and plans are being made for many additional installations to operate above 1200 lb. pressure. In general, the tendency is to design the boilers for approximately 1400 lb., with the turbines operating at about 1250 to 1300 lb. Some consideration is being given to somewhat higher pressures, and it is as yet too soon to conclude that steam pressures will not extend to a pressure of the order of, say, 2500 lb. This question also involves the limit of superheat temperature which will be commercially permissible.

The use of high pressures has necessitated changing the designs of parts ordinarily used for low-pressure plants. The future will no doubt bring about changes in many construction details which will simplify the present designs; to name one detail—pipe flanges. In going over a high-pressure station one is impressed with the amount of material and the cost of pipe flanges sufficiently strong to withstand these pressures. A material simplification would be possible with a satisfactorily welded joint.

In general, high-pressure designs should tend to the elimination of all possible joints. In this connection, central power plants in this country have developed feedwater conditions to an extent where it is almost possible, and some day it may be possible, to eliminate all joints.

Both papers call attention to a problem which has developed in more recent years with the increase in pressure and temperature; namely, the deposit on turbine blading.

With low pressures and low steam temperatures, it was customary to discuss steam conditions in terms of 1 or $1^1/_2$ per cent of moisture, and under which conditions, except in the cases of very difficult waters, quite satisfactory results were obtained from the turbine. In later years considerable effort has been expended in obtaining the driest possible steam from boilers, and we today discuss steam conditions of the order of $^1/_4$ of 1 per cent of moisture, or in terms of four or five parts per million, or perhaps in terms of the electrical resistance of the condensate.

With boilers discharging steam of this purity, deposits on turbine blading are taking place, the annoyance depending largely on the nature of the material which deposits. Of these materials, the one which has caused the most difficulty is silica. In some instances the deposited material analyzed as high as 95 per cent of silica, so that the only practical way for its removal seems to be the actual scraping of the turbine blades.

In other cases where the material has been a combination of sodium hydrate and other salts, its removal from the turbine periodically by either washing the turbine or by dropping the steam temperature to saturation has proved practical.

It should be borne in mind that this deposit on turbine blading is taking place with a steam which is purer than distilled water obtained in a drug store. It should also be borne in mind that passing through a 60,000-kw. machine we have something of the order of 600,000 lb. of steam an hour, so that for 1 p.p.m. we have 0.6 lb. of material passing through the turbine an hour, or 430 lb. a month. If, due to pressure-temperature changes, in passing through the turbine 10 per cent of this material deposits on the blading, it is self-evident that a loss in load will result.

The writer is not prepared to say that we have gone the absolute limit in securing clean and dry steam from boilers. We still have hopes for further improvement, but the evidence is such that designs of high-pressure–temperature plants should contemplate maintaining the best possible conditions of water, and a silica water should be avoided wherever possible.

W. S. Johnston.[6] These two papers by Messrs. Gilbert and Irwin are invaluable to the membership of the Society and the public-utility industry of the country.

Both stations were designed and developed at about the same time after an exhaustive analysis of the economic possibilities by two engineering organizations working independently of each other. That they both came to substantially the same conclusion is indicative of their thoroughness in, first, sensing the fundamental factors the problem presented and, second, the economic solution thereof.

Both authors are to be commended for their frank statements regarding the operating troubles experienced in starting the equipment in service and the changes necessary to overcome them. It is to be hoped the manufacturers involved will profit by this practical experience when called upon to supply equipment for similar duty. After reading these papers and in the light of experiences at other 1400-lb. stations, one can safely assume that high-pressure steam is practical wherever the economics of the situation justifies its use. It is not too much to expect that the authors may publish in later papers more operating experiences and performance data when the stations have been in longer service.

The application of pulverized fuel is worthy of note. The Holland Station uses the storage system, while at Deepwater both the storage and direct-fired systems are employed. Mr. Irwin reports some operating troubles with the direct-fired system, but it is thought these can be overcome. Coal hanging up above the mills can be prevented by making the slope of the raw-coal bunker walls and coal chutes steeper to permit gravity movement of wet coal. The feeders might be changed from the star to the drag type. While the suggestion of incorporating a small storage bin of pulverized fuel between the mills and burners may be worth while at Deepwater, yet it is believed that after the initial period of operation has passed and the operators have become thoroughly familiar with the service characteristics of the equipment, it will be found that the direct-fired system affords the same degree of reliability now secured from the storage system.

A combination of the regenerative and reheat cycles has been incorporated in both plants. There can be no question that the regenerative cycle is a permanent feature that will be retained in station design for many years. On the other hand, the reheat cycle is felt to be transitory. It will not be necessary to resort to it when we can use higher initial steam temperatures. With 1350 lb. pressure at the turbine throttle, a steam temperature of 1000 deg. fahr. will not give greater moisture in the exhaust end than is permissible with present-day machines. At least one manufacturer will supply superheaters for this temperature. Turbine builders will now countenance the use of steam at 825 deg. fahr. with the proper arrangement of engine cylinders. Before long they will design for yet higher temperatures. Steel makers must prepare to furnish materials for piping and valves that will complement the superheaters and turbines. Then it will be possible to save on fixed charges by eliminating the investment in reheater equipment. At that time it will be interesting to compare extensions to the Holland and Deepwater Stations with the initial design.

Author's Closure

All of the high-pressure steam leaks which have occurred in the Deepwater Station have been on the small lines, with the

[6] Stone & Webster Engineering Corporation, Boston, Mass.

exception of one or two leaks which have developed on the boiler-feed lines where they connect to equipment and where the joints are not welded. The following gasket practice has been followed:

Boiler manholes—corrugated Monel metal.
Rehater manholes—folded asbestos.
Boiler, water-wall, and superheater handholes—steel-covered asbestos gasket. On this particular type of gasket to date only one failure has occurred, and that was on a handhole plate on one superheater. The gaskets on the water columns are corrugated Monel metal. Copper, soft-steel, and sheet packing have been tried, but with little success, and the Monel metal is at present giving good service.
Economizer return bends and flange connection on economizer supply pipes to the boiler drum—a stainless-steel gasket is being used in place of the original copper gaskets, and seems to be some improvement.

The stainless-steel gasket has one fault, in that if a leak does occur the fitting faces show more signs of being cut than they do when a copper gasket is used. This is probably due to the fact that the stainless steel resists wear more than the fitting faces.

As previously reported, the operating experience with the economizers may generally be stated to be satisfactory, although during the months of September, October, and November on six occasions it has been necessary to shut down one of the boilers in order to replace gaskets on the economizer U-bend. This is the same boiler on which difficulty was cited in the original report. Only three leaks have developed on the other five boilers during the same months.

No further difficulty has been experienced with slag-type furnace bottoms. No. 6 boiler, in which the magnesite bottom was installed the end of August, has been operating satisfactorily without undue expansion and without developing leaks. No. 4 boiler, which originally had a floor made up of cans of coke, but which have now entirely disappeared, has shown no change and is operating with the floor made up of slag. This floor caused the operators some concern for a week or two as the steel plates on the bottom of the floor became heated to a dull-red glow, but by raising the slag depth in the furnace the bottom was chilled and has been giving satisfactory service ever since. The measurements of the growth of this floor show that it has the least expansion. It is the intention not to make any changes in this floor unless some unforeseen difficulties arise.

The statement that iron sulphite was responsible for the using up of the coke in the bottoms of boilers 4 and 6 should be changed. This conclusion was reached due to the fact that the manufacturer advised that this trouble had occurred at other plants where no coke bottoms were installed. However, an analysis of the material cut out of the floor of No. 6 boiler shows that the material is similar to the slag which is tapped off in the normal course of operation.

One Distinct Advantage of Bin System. The last three months have borne out the earlier conclusion that there is a distinct advantage in reliability to be obtained from a bin system of fuel firing over the unit system. During the past three months, on seven occasions, it has been necessary to reduce the load on the plant from 5000 to 12,000 kw. due to difficulty with the mills used on the direct system. This has at times been due to breakage of mill parts because of wear, and may be overcome after the operators are better able to judge a proper maintenance and overhaul schedule. Even with prearranged periodic maintenance it is of course necessary to reduce the output unless it is possible to synchronize mill and boiler outage.

In the last few weeks a Pittsburgh seam coal, which it was possible to purchase at a relatively low price, has been burned in small quantities for test purposes, and it was found that using this much harder coal on the direct-fired mills takes considerably more power and reduces output and necessitates overloading the mill motors in order to keep the boilers up to capacity. It is a condition which could not persist over a long period of time, as there is danger of burning the motors from continuous overload, and it is difficult to keep the boilers up to rating. Using the same coal on the bin system, the mill capacity is also seriously decreased, but by operating the mills longer hours it is possible to maintain the boilers at any desired rating. This feature of flexible boiler capacity with varying qualities of coal should be taken into consideration when deciding the relative merits of the two systems.

Other difficulties with the mills have been due to operating conditions, such as plugging of the feeding system to the mill or the plugging of coal in the mills themselves. There have been outages of the mills on the bin system, but it has never been necessary to reduce plant load on the bin-system boilers on account of lack of mill capacity.

Refractory Erosion Most Serious Problem. Difficulty with erosion of the refractory material which backs up the bare-tube water walls on the back wall of the furnaces opposite the burner has increased and is now the most serious trouble being encountered in the boiler room. The operators are experimenting on the bin-system end of the plant by varying the secondary and primary air pressures in the hopes of shortening the flames to the extent where they do not throw the slag from the coal against the rear walls and wash them down, and still keeping the flame travel sufficiently long to prevent the flames from carrying this slag up into the lower row of boiler tubes and slagging these over. It is felt that with careful adjustment it may be possible to find the point where a balance between these two extremes will leave a satisfactory condition.

On the direct-fired end the manufacturers are experimenting with deflector blocks to be put into the burners, in order to get better control of the flame travel. On a rear wall now being rebuilt a 70 per cent alumina brick is being used in place of straight refractory, in the hope that this will reduce the washing action of the slag. If the present experiments are not successful, it may be necessary to resort to an all-metal wall, by using either fin tubes or blocks on the present bare tubes.

Silica Deposit on Turbine Blades Reduced. There is a misstatement in the original report in that it was assumed that other plants were having similar difficulty with silica deposit on the blading. We were led astray by an article in *Power Plant Engineering* (February 15, 1928), written by John Anderson, in which he stated that the analysis of the deposit found on the high-pressure turbine blading on the 1200-lb. machine at Lakeside, Milwaukee, contained 56 per cent silica, and that by injecting 10,000 lb. of water per hour into 15,000 lb. of steam per hour entering the turbine throttle when the machine was rolling at 400 r.p.m., they were able to wash off this scale so that the machine could be restored to its full-load capacity.

TABLE 1

	Net output, 1000 kw-hr.	B.t.u. per kw-hr.
April	19,975	16,752
May	35,373	14,036
June	44,707	13,828
July	43,169	14,114
August	63,775	13,341
September	63,842	12,749
October	66,989	12,419
November 1 to 15	35,520	12,244

Deepwater Economy Increased to 12,244 B.t.u. per Kw-hr. It should be borne in mind in evaluating the advantages of 1200 lb. against these particular results that a load was carried for 24 hours of the day during the past 3½ months, which necessitated

operating all turbines and five of the six boilers at their maximum capacities, which is a point beyond the maximum efficiency point on the turbines. See Table 1.

The scale on the blading at Deepwater plant has been analyzed on several occasions and varies between 75 and 95 per cent silica. An attempt to wash this off apparently had no effect, as it did not increase the machine capacity. However, when the machine was taken down for inspection, no scale was found on the blading, but the last stage diaphragm had a thin coating which was sufficient to increase the pressure drop across this diaphragm to the extent of reducing the turbine capacity.

Since the installation of purifiers on the vapor outlets of the house evaporators, the quantity of silica in the water is so small that it has been practically impossible to separate it or even to find it on laboratory analysis. It is believed, however, that some of this must be carried into the pure-water system from leaks in large-size evaporators installed for the du Pont system. The tubes in these evaporators are being rerolled. During the period when evaporators are cracked the pressure conditions which exist in the shell would tend to force raw water into the condensed-water side of the system. A 1-in. steam line has also been installed on this turbine to take steam from the first stage into the fourteenth stage, in an attempt to increase the temperature in the last stage of this machine nearer to the temperature existing in the last stages of the high-pressure elements of the compound machine. It would appear that the higher exhaust temperature on these machines must prevent the scale deposit.

One of the low-pressure turbines has developed vibration early in operation when the steam was carried at the contractual temperature. Until such time as it is possible to take this machine down it is necessary to operate it with steam at 700 deg. in place of 750 deg., which of course reduces the efficiency of this one unit. It is expected that when the machine is overhauled and a more economic loading is imposed on the plant, station economy will be improved by 400 to 500 B.t.u. per kw-hr. This condition of maintaining five boilers at their maximum loading continuously has also brought to the fore more forcibly than in other locations the necessity for continuous availability of the fuel-burning equipment and has showed reduction of load due to short-time outages of the direct-fired mills. Normally, this condition of course would not be introduced, as other boilers in the plant would be able to take the small deficiencies.

FSP-53-21

Comparative Resistance of Refractories to Coal-Ash Slags

By R. K. HURSH,[1] URBANA, ILL.

The results contained herein were obtained in an investigation conducted by the Engineering Experiment Station of the University of Illinois. Tests have been made in the laboratory slagging-test furnace of various commercial refractories and of a series of special mixtures representing clays from three manufacturing districts, as well as differences in the method of fabrication, the firing treatment, and the fineness of grinding of the materials. The slags used were ashes from coals of five different districts. The comparative resistance of refractories varied with the character of the coal ash. Dry-pressed and stiff mud bricks were more resistant than hand-made refractories. A moderate degree of firing treatment was preferable to hard burning when the brick were subjected to high furnace temperatures and slag action.

THE slagging of refractories by coal ash in boiler furnaces is due to a combination of corrosion and erosion. The molten slag attacks the refractory at the contact surface, taking some of the material into solution. More or less penetration may occur, with the result that the refractory surface subject to corrosive action is greatly increased. The piling up of the liquid slag on the refractory produces a flow due to gravity, which may be increased by the velocity of the furnace gases. The flowing away of the slag removes the dissolved material and maintains an unsaturated slag deposit on the refractory surface. At the same time particles of undissolved refractory, loosened by solution of the bonding material, are washed away with the slag. This latter action is found with refractories containing coarse grog particles, which are usually more resistant to slag action than the bonding material of the brick. It is especially noticeable with bricks which are appreciably penetrated by the fluid slag.

Effect of Slag Composition

The comparative severity of attack by the slag is dependent on the composition, temperature, and viscosity of the slag, as well as the amount deposited on the refractory. Slags high in fluxes, such as lime, magnesia, alkalies, and iron, generally have low fusion temperatures and are more fluid at the temperatures of furnace operation than are slags with higher contents of alumina and silica. The composition of these low-fusing slags is such that their reactivity with refractory compositions is also greater than that of more refractory ashes. Both factors, high flux content, and high fluidity, result in greater corrosive action at given temperatures, and the degree of attack increases markedly with temperature increase.

Effect of Furnace-Gas Composition

The composition of the furnace gases with respect to reducing or oxidizing conditions is considered as an important factor in the action of ferruginous slags. Under reducing conditions the iron will be in the ferrous form, which has a much greater corrosive action than ferric iron. However, the operating temperatures of boiler furnaces are generally high enough to produce a considerable amount of ferrous iron or magnetic oxide regardless of atmospheric conditions. Results in the laboratory slagging tests have shown little effect of differing degrees of reduction, as indicated by the tests with slag from coal used at the Cahokia station (see Table 1).

TABLE 1 EFFECT OF FURNACE-GAS COMPOSITION ON SLAGGING ACTION

Test No.	Aver. temp., °F.	Aver., % Co	Time, hr.	Slag used, lb.	Average depth of erosion, in cm. — Brick brand						
					21	18	16	19	14	17	27
36...	2900	6.2	24	170	0.75	0.78	0.72	0.71	0.76	0.55	0.63
37...	2900	2.5	24	165	0.83	0.90	0.72	0.75	0.83	0.70	0.72

Effect of Temperature Gradient in Refractory

The temperature gradient in the refractory may be a considerable factor in the slag action. If the furnace wall is well insulated so as to maintain a high temperature in the refractory somewhat back from the surface, the slag in contact with the brick will be kept fluid, and more active corrosion takes place. There is the further possibility that the high temperature will cause more or less fusion and glass formation in the refractory back of the slag interface which will have a lower resistance to slag action than the unfused material. In some cases, however, crystallization of mullite from this glass in the body might conceivably increase the resistance to slag action.

When there is a high temperature gradient through the refractory, heat is taken away from the surface fast enough to somewhat cool the slag at the contact and thus increase its viscosity. Its activity is thus reduced, and its tendency to penetrate the refractory is much decreased. This may be a considerable factor in the resistance of silicon-carbide refractories because their high thermal conductivity reduces surface temperatures and slag penetration is slight, even though the body itself may be quite porous.

Refractories Factors

The corrosion by slags will vary with refractories of different chemical or mineralogical constitution. Where the body is composed of different clays or materials, the slag attack may be especially marked on one of the constituents, resulting in rapid attack and washing away of the more resistant particles.

---

[1] Department of Ceramic Engineering, University of Illinois. Professor Hursh was graduated from the University of Illinois in 1908 with the B.S. degree in Mechanical Engineering. He spent a year as a graduate student in Ceramic Engineering and was for two years in the Clay Products Division of the U. S. Bureau of Standards. Since 1911 he has been a member of the staff of the Department of Ceramic Engineering. He is a member of Sigma Xi and was for several years Treasurer of the American Ceramic Society. Professor Hursh has been principally interested in the lines of structural clay products and refractories. He has contributed various papers in the publications of the American Ceramic Society, the National Brick Manufacturers Association, and the University of Illinois Engineering Experiment Station.

Contributed by the Special Research Committee on Boiler Furnace Refractories and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[a] No erosion.

Inferior bonding materials in clay refractories are thus likely to materially decrease the life in boiler furnaces.

Bodies of low refractoriness do not withstand service conditions well because of the combined fusion effect in the body due to high temperature and the corrosion by the slag. Materials of high fusion or softening point may show equally poor service because they remain porous enough at furnace temperatures to permit penetration by the slag to much greater depth than do some of lower refractoriness. This is quite noticeable in the case of some of the high-alumina bricks.

Many of the fireclay refractories develop a vitreous, porcelain-like layer back of the slag contact and become so impervious that there is little, if any, penetration. Such materials offer a minimum surface for slag attack, and hence good service.

The physical structure of the body is an important factor in slagging effects. Coarse-grained bodies which permit penetration of the slag are severely attacked. Cracks, fissures, and laminations afford weaknesses in resistance to slag action. In some bodies the grog particles shrink excessively and become loosened from the bonding material. These particles are washed away readily as corrosion of the bond takes place, and the coarse grog is therefore of little effect in resistance to the slag.

The physical structure is also reflected in the method of fabrication. The dense skin-effect of stiff-mud molding would seem to offer an advantage in resistance to erosion, but this may be offset by lamination. Dry-pressed bricks are likely to be dense, providing the material is not too coarse. Maximum density should be a highly desirable factor in slag resistance. Hand-molded refractories are likely to be coarse grained and of minimum density, and therefore less resistant than either stiff-mud or dry-pressed bricks.

Laboratory Slagging Test

A laboratory slagging test has been described[2] in which the test bricks form the lining of a rotating furnace into which powdered slag is fed at a uniform rate through the gas-burner. The molten slag flows down the surface of the brick, producing the combined corrosion and erosion effects, while temperature and atmospheric conditions are controlled. Uniform treatment of each test brick is obtained and comparison of slag action is made by determining the volume loss per unit area exposed, or the average depth of erosion.

A series of commercial brands of brick, including those in use during service tests by the U. S. Bureau of Mines at the several boiler plants, have been made with different coal-ash slags. In part of these tests the same temperature has been used for each of the slags. In a further series the temperatures for the respective slags were approximately the maximums found in service in the plants.

Comparison of Refractories With Different Slags

In Table 2 the comparative effect of the different slags, based on a 24-hr. test at 2900 deg. fahr., is shown for several brands of bricks. The figures represent the relative amount of depth of erosion, using that of brand 18 as a basis of comparison. In each case the data represent an average of two separate tests, two bricks of a brand being used in each test except in one or two cases where there was a limited supply. The ash from the East Peoria coal shows a distinctly different degree of activity on many of the bricks from that of other slags. This is an ash of much higher lime content than the others, but of somewhat lower iron content than the Chicago and Cleveland slags. It has the lowest fusion or P.C.E. value of the group of slags. It is of interest to note that the stiff-mud bricks, representing materials from two different districts, showed a somewhat better resistance than that of dry-pressed bricks, while the hand-molded refractory was much the poorest. The high-alumina brick showed inferior resistance to that of standard grades of fireclay. This is possibly due to the action of lime on the alumina to produce compounds and mixtures of lower fusibility than those of higher silica content.

The Chicago slag ranks next to East Peoria in lime content and has a greater iron content. With this slag, the high-alumina brick showed a slightly better resistance than the fireclay brick. The stiff-mud bricks show a slight advantage over the dry-pressed refractories. There is, however, little actual advantage of any brand over the others with this slag.

The Cahokia and Cleveland slags have about the same lime content, but the Cleveland ash is the highest in iron content of the group. The resistance of the high-alumina brick was appreciably better with these slags than of brand 18, indicating that such refractories might show considerably better service with slags of low-lime and high-iron contents than do the standard fireclay bricks. It is to be noted, however, that the physical characteristics of the brick may, and probably will, have an increased significance in this case.

Effect of Temperature on Slag Action

Marked increase in slag action is the result of increased furnace temperatures with the more fusible slags, as shown by the data in Table 3. The three brands of fireclay brick, made by different processes and at different plants, show a fairly consistent relationship between loss and furnace temperature. This is better indicated by the curves of Fig. 1, in which the slopes differ somewhat for the respective brick, but the comparative resistances are about the same at the three temperatures.

Comparison of Special Mixtures

In order to compare the effects of various manufacturing processes and materials on the resistance of firebrick to different coal-ash slags, eight lots of brick were made up by a single manufacturer. These represented the following variations in processing:

Brand	Material	Fabrication	Grind	Firing treatment
St 1	Dist. 1	Dry-pressed	Fine	Cone 6
St 2	Dist. 1	Dry-pressed	Fine	Cone 12
St 3	Dist. 1	Dry-pressed	Fine	Cone 14
St 4	Dist. 1	Dry-pressed	Very fine	Cone 12
St 5	Dist. 1	Stiff-mud	Fine	Cone 12
St 6	Dist. 1	Hand-made	Fine	Cone 12
St 7	Dist. 2	Dry-pressed	Fine	Cone 12
St 8	Dist. 3	Dry-pressed	Fine	Cone 12

These were tested in the laboratory slagging furnaces with slag from five different coals sent from plants at which tests were made by the U. S. Bureau of Mines. (Tests with a sixth coal are yet to be made.) The tests were arranged to make direct comparison of method of fabrication, grind, firing treatment, and materials from the three producing districts. The tests with the several slags were conducted at temperatures comparable with those found in the service tests at the respective plants. In the case of the East Peoria coal ash the test temperature was somewhat above the average found in the boiler furnaces, but approximated the maximum. This higher temperature was chosen in order to obtain a larger amount of erosion in the testing period and more satisfactorily comparable results. It has been indicated previously that the order of resistance of fireclay brick is not changed by the increase in temperature. The results of this series of tests are shown in Table 4. The values for erosion losses represent averages of determinations on three brick of each mixture used in a test. The porosity and bulk specific gravity values are averages on five brick of each lot as received.

TABLE 4 COMPARISON OF REFRACTORY MIXTURES WITH DIFFERENT SLAGS

(Based on average of three tests)

Brand	Description	Grind	Porosity, %	Bulk, specific gravity	Average depth of erosion in cm. — Kind of slag used and temperature in deg. fahr. — East Peoria 2600	Ca-hokia 2800	Chicago 2800	Lowellville 2600	Detroit 2800
Comparison of fabrication method

St 8	DP	Dist. 3	22.4	2.04	0.89	0.65	1.66	0	0.37

In the comparison of bricks made by the three molding processes the hand-made were distinctly inferior in resistance to all the slags. Dry-pressed brick showed the best resistance in all cases except that with the Chicago slag, but the advantage over stiff-mud brick appears to be slight in any case. The density of the dry-pressed and stiff-mud bricks is nearly the same, while that of the hand-molded bricks is lower. This may account, in part, for the differences shown in resistance to slag attack.

There is no appreciable difference in the action on bricks with different fineness of grinding in any of the tests. The difference in grind was not great, as the density values and the appearance of the bricks indicated.

In the comparison of firing treatment the brick fired at the lowest temperature showed less erosion in each test except that with East Peoria coal ash. The explanation for this was found in examination of the slagged brick. Slag penetration by the three slags used in tests at 2800 deg. fahr., was deeper in the cone 12 and cone 14 brick than in those fired at cone 6 but there was no noticeable difference in the case of East Peoria slag at 2600 deg. fahr. Apparently the higher firing temperature has developed a greater amount of glass in the body with possibly a higher thermal conductivity. At a furnace temperature of 2800 deg. fahr. the slag diffuses into this glass more readily than into the lower fired body and corrosion is therefore increased. A higher thermal conductivity, which is indicated by the greater depth of vitrified body back of the slag contact in the higher-fired brick, would result in higher temperature and more fluid glass in the body. This contributes still further to diffusion of the slag into the body and to corrosive effect.

In the cone 6 brick the development of glass in the body has not been sufficient to aid diffusion of slag into the body. Consequently, a thin vitreous layer is formed back of the slag contact which offers greater resistance to slag penetration. A greater temperature gradient, hence a smaller depth of high-temperature conditions, is evident in the appearance of the brick.

In the case of the East Peoria tests, the temperature, 2600 deg. fahr., is not high enough to soften the glassy portion of

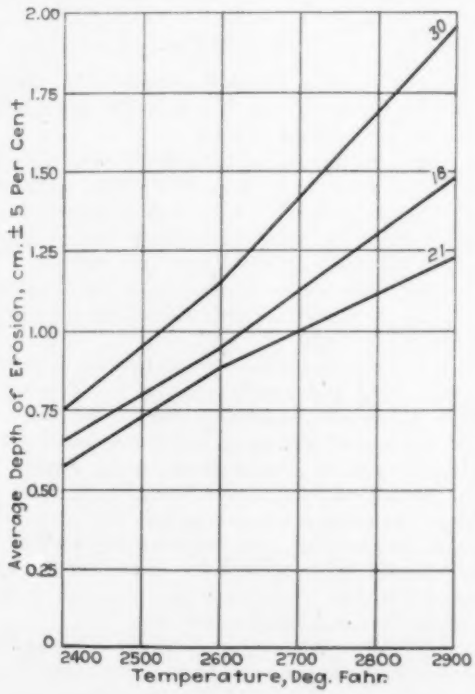

FIG. 1 EFFECT OF FURNACE TEMPERATURE ON SLAG ACTION
(The numbers at end of curves indicate brand of brick.)

the body to any appreciable degree. Hence, no noticeable difference is seen in the erosion, nor was any evident in examination of the several brick tested.

It is evident that high firing temperature is not desirable for these fireclay brick when subjected to furnace temperatures at which the glass in the body softens appreciably. The results might also be interpreted as indicating that the proper firing treatment for a refractory for boiler-furnace use is below that at which glass is formed in the body. The temperatures encountered in service will produce a vitreous coating on the brick to prevent appreciable slag penetration, and the softer burned body provides an insulation to limit the depth at which temperatures will develop.

The order of resistance of brick made in the three districts which are represented in these mixtures is somewhat variable with the different slags. (It is to be observed that these brick represent specific clays from the given districts and may not be at all representative of the region from which they come. It would be decidedly unfair to generalize in comparing the materials from various clay-producing districts on the basis of a single mixture from each; hence, the district is referred to by number only.) The brick from district 2 show a distinct advantage in the East Peoria tests and, possibly, are slightly

better with Cahokia and Chicago slags, but inferior with Detroit ash. In the latter case there is quite a marked difference in the resistance of the three mixtures. The amount of erosion by this slag is, however, small, and is less than that of the others. The relative differences between the mixtures might be lessened with a greater amount of erosion. The conclusion may be made from these data that various clays or mixtures do offer different degrees of resistance to different slags or under different furnace-operating conditions. A choice of fireclay refractories may therefore be made on the basis of specific performance with a certain coal ash and set of furnace conditions. A brick which gave good service in one place might be definitely inferior with a different coal ash.

Summary

The effect of varying reducing conditions in the furnace on the corrosive action of slag from Cahokia coal ash is slight in the tests in the laboratory furnace.

The temperature gradient in the refractory is an important factor in slagging action in two ways. With refractories of very high thermal conductivity the rate of heat loss through the body is sufficient to maintain a viscous slag at or near the contact, thus reducing slag penetration and corrosion. In the case of fireclay brick the conduction is not sufficient to have this effect, but materials of lower conductivity show somewhat better resistance to slags.

Materials of low refractoriness or fired at too high temperatures have reduced resistance to slag action, due apparently to diffusion of slag into the glassy portion of the body.

The development of a vitreous and impervious layer of the body, without excess of glass, next to the slag contact reduces corrosion. Bodies of very high refractoriness, which do not so vitrify at furnace temperatures, permit slag penetration and are more affected by slags than less refractory bodies.

A high-alumina brick showed less resistance to high-lime slags than did fireclay brick, but a greater degree of resistance to slags of low-lime and high-iron contents.

Increase of furnace temperature produces a marked increase in the erosion of refractories by coal ash. The order of resistance of fireclay brick was not changed with temperature variation.

Tests of special mixtures indicated an advantage for dry-pressed and stiff-mud bricks over hand-made, somewhat proportionate to their comparative densities.

High firing temperature tended to increase slag action of one fireclay mixture when subjected to slag action at a furnace temperature of 2800 deg. fahr. At 2600 deg. fahr. no difference due to firing treatment was observed.

A fireclay brick may afford better comparative resistance to one slag or set of operating conditions than to another; a selection may therefore be based on specific performance with respect to a given slag.

[Note: Discussion of this paper, jointly with the paper by T. A. Klinefelter and E. P. Rexford, by Ralph A. Sherman and by Harold E. Simpson will be found following the Klinefelter and Rexford paper.]

Author's Closure

In general, the results of the two methods of testing the action of the coal-ash slags on the refractories are similar. The Bureau of Standards method indicates the temperature range within which erosion losses are moderate and above which the attack of the slag becomes severe. The Illinois test indicates the relative activity of the slags on refractories under conditions simulative of those in service, as well as the comparative resistance of different refractories to a given slag under these conditions. With the slags shown by Messrs. Klinefelter and Rexford to have a low critical range, the slagging losses were generally high. The Lowellville ash, with a high critical range, produced little or no erosion in tests at 2900 deg. fahr. Some discrepancy appears in comparison of East Peoria and Cahokia slags, for which the critical ranges of temperature were found to be about the same. The results in Table 3 show greater losses due to the East Peoria slag at 2600 deg. fahr. than with the Cahokia slag at 2800 deg. fahr. From this it would seem that the temperature-viscosity relationship of a slag above its critical range is extremely important. The viscosity of the East Peoria slag decreases much more rapidly with increase in temperature than does that of the Cahokia ash. Hence its activity at temperatures above the critical range is much greater. The Chicago ash, which shows a high critical range, produced the most severe erosion in the whole series of tests at 2800 deg. fahr., considerably greater than that of the Cahokia ash, which showed a lower critical temperature range.

It is a question whether the average operating temperature in the boiler furnace is as important in relation to slag action as is the maximum temperature. The marked increase in erosion with higher temperatures indicates that the action during short periods above the average may cause greater losses than in long periods at the usual furnace temperatures.

In answer to Mr. Sherman's question concerning the differences in erosion losses on the same brand of brick in different tests, shown in Table 4, there were some differences in the temperatures and amounts of slag used in this series. No especial effort was made to duplicate the conditions exactly in the several tests with a given ash, since in each one all the brick brands were included which were to be directly compared. By correction of the figures for these variables the erosion losses of the St-2 brick in the separate tests with a given slag are practically equalized. Previous results have shown that tests can be satisfactorily duplicated, when desired, without difficulty.

Referring to the question of Dr. Simpson concerning relative slag penetration in brick fired at different temperatures, it was shown that less penetration and lower erosion loss of cone 6 brick was evident only in the test made at 2600 deg. fahr. A considerably greater amount of glass was apparent throughout the body of brick fired at cones 12 and 14, as well as deeper slag penetration. No slag was evident beyond the thin vitrified surface layer of the cone 6 brick. The heat treatment apparently was not sufficient to develop a glass of the amount or fluidity that would permit appreciable diffusion of the slag. In tests at 2800 deg. fahr., the slag penetration and the erosion losses were the same for all three firing treatments.

FSP-53-22

Action of Slags on Firebrick and Boiler Furnace Settings[1]

By T. A. KLINEFELTER[2] and E. P. REXFORD,[3] COLUMBUS, OHIO

The results contained in this paper were obtained in an investigation conducted by the Columbus branch of the U. S. Bureau of Standards for the A.S.M.E. Special Research Committee on Boiler Furnace Refractories. The paper presents a rational discussion of the action of coal ash upon boiler-furnace refractory walls and shows the consistency of results from the authors' laboratory slag tests with firebrick under actual service conditions in boiler furnaces.

WITHIN the last year the laboratory examinations made in connection with the boiler-furnace slags have developed what seems to be a practical test for predicting the action of slags on firebrick. The preliminary work leading up to this phase of the investigation will be found in previous reports.[4,5]

T. A. Klinefelter

In the latter report a description was given of the methods and the general procedure for the study of the principal components found in slags. This study remains the most fundamental on the program outlined, but one or two interesting developments have appeared from the examination of the field samples first sent in, resulting in a test which seems to have considerable practical application.

The work on the multiple component system brought out the fact that to obtain a true picture of the phases and conditions present at any given temperature it is necessary to quench the slag from that temperature. This led to a complete re-examination of all samples sent in by the Bureau of Mines field crew.

As a result of these examinations there was presented a rather different picture. Quenchings were first made from about the average operating temperatures to which the boiler settings had been subjected. It was noticed that, in those cases where the refractories had been giving fair or good service, the slag appeared to be saturated with a solid phase or phases, and in those cases where poor service had been reported the slag consisted mostly of glass with only a small amount of mullite present, particularly along the interface with the refractory.

Development of Working Hypothesis

On correlating these observations it was noted that in every case the slag and refractory interaction could be separated into three fairly distinct stages or ranges, as follows:

E. P. Rexford

Lower Range. At the relatively lower temperatures very little penetration into the refractory was apparent, the amount of glassy matrix was small, and the whole slag was saturated with the solid phase which very evidently originated from the components of the slag solution itself. These solids in most cases were skeleton magnetite and mullite, but fayalite, anorthite, akermanite, etc., were also found, depending on the composition of the coal ash.

Critical Range. As the temperature was gradually raised the following changes were noted: The skeleton magnetite dissolved first, and also the quantity of glassy matrix increased and became darker, thus apparently indicating solution of the magnetite into the liquid glass. At the same time the quantity of mullite or other solid phase decreased and the grains became smaller and finer, due probably to solution. Penetration of the glass or liquid into the refractory was more apparent, while along the edges of the refractory and in the glassy veinlets impregnating it fine needles of mullite appeared, very evidently growing from a combination of the refractory material and the coal ash, thus showing the start of severe corrosion.

This condition continued as the temperature increased until an interval or range was reached where the glassy matrix or liquid seemed to be at a maximum, the solid phases at a minimum, and the penetration into the brick was not great. For convenience this has been termed the "critical range," as at temperatures above this range severe corrosion appeared. This interval was not particularly sharp in any case, although in one or two cases an interval of 25 deg. fahr. showed a much more decided change than usual.

Upper Range. At temperatures above the "critical range" an increase in the solid phase again appeared, showing most abundantly along the interface with the refractory. In the cases examined, all of which were clay firebrick, this solid phase was mullite. Solid phases other than mullite would be expected with refractories of essentially different composition. The penetration into the brick became more and more pronounced, and the penetrating veinlets became a mass of unoriented mullite needles.

In general, then, it appears that, if the temperature and conditions in the boiler furnace are such that the slag solution is saturated with the solid phase recrystallizing from its own

constituents, that slag is relatively less corrosive than a slag containing little or no solid phase. In the latter case the molten unsaturated solution present is capable of more or less continuous corrosion of the refractories, if there is not enough material in the slag to form a saturated solution of that solid phase required by the particular section of the multiple component system in which the solution lies for that temperature. Then in order to bring about a saturation the necessary constituents are absorbed from the brick, causing intense corrosion and the ultimate breakdown of the setting. Equilibrium is never reached, of course, as new slag is being constantly supplied by the gas currents. At low temperatures some of the dissolved material will be crystallized out as a solid if the melt has been saturated at a higher temperature. On heating, this dissolves, and if more is placed in the solution it, too, will dissolve within limits as the temperature is increased. In the case of the boiler setting, the slag, which is more or less viscous, is plastered against the refractory wall. If the temperature and composition of the slag are such that the liquid is capable of rapid corrosion, it flows or drips away. In doing so, whole particles of brick, especially the more refractory portions such as the grog, are floated away bodily. This condition was noted in the preliminary examinations. No doubt the so-called "washing" effect of the furnace gases aids in this process to greater or lesser extent, but only after the refractory has been softened by excess temperature or fluxing action of the slag.

It is entirely possible that, in the case of certain brick where the binding matrix is less refractory than the grog or solid particles, the boiler temperature and conditions may be such that softening and even liquefaction of the brick matrix occurs, thus causing failure without any reaction between the brick and slag. However, the evidence so far does not point to this as a factor of much importance in the case of good grades of brick at prevailing conditions. But this may be a factor which, coupled with the thermochemical action of the slag, causes failure with even the best of refractories. There has not been sufficient time to investigate this angle.

The investigation upon which the preceding discussion is based has been carried out under neutral to oxidizing conditions. While the work so far seems to check up quite well with the results shown in the commercial settings, it is felt that some of the findings will be modified for settings where the atmospheric conditions are strongly reducing. Commercial settings are of course known to be much harder on refractories when the furnace is operated under such conditions.

Method of Test

Assuming as a working hypothesis that, to obtain a relatively low corrosive slag, conditions should be such that the slag solution is well saturated at all times with one or more solid phases formed from constituents of only the slag solution, it becomes necessary to work out the three ranges mentioned for any given coal ash and refractory. With the "critical range" established, it is only necessary to keep the temperature of the boiler furnace below the "critical range" to obtain as good practical service from that refractory and slag combination as is possible from the thermochemical standpoint.

In order to work out these ranges readily, the following method and technique are suggested. As referred to, it has been found entirely impossible to study these slag and refractory combinations properly unless they are quenched from temperatures at which slag action took place in actual service. This requires the use of a control board for maintaining accurate and constant temperatures over any desired range. The furnace should be so constructed that the sample may be quickly quenched. This can be done readily by having the furnace core or heating chamber in a vertical position with a removable plug at the bottom.

By fusing the fine platinum wire by which the specimen is suspended it may be dropped into a mercury bath held close under the furnace.

A refractory to be investigated has a $^3/_8$-in. hole drilled near a corner to a depth of about $^1/_2$ in. A section including the drilled hole is now sawed or broken off and roughly shaped into a crucible about 1 in. in diameter and 1 in. in depth. This work requires only a few moments, as the drilling can be done with a corundum or periclase clip which works rapidly and cuts cleanly. The final shaping is done with a rough silicon-carbide stone.

This miniature crucible is filled with sintered coal ash and coal, or a piece of slag from the boiler setting under investigation, and then suspended in the furnace with a thermocouple next to it. Two samples can be handled almost as readily as one, the hot junction of the thermocouple being located between the two. This gives a temperature control of more than necessary accuracy, since it has been found in the work so far that in practically all cases there is no necessity for obtaining quenchings at intervals closer than 25 deg. fahr. In rare instances a closer interval in the so-called "critical range" has given a little better knowledge of conditions.

The furnace is heated rapidly to the desired temperature and is held there for from 4 to 24 hours, and the sample is then quenched. In general, the longer heat treatment gives crystals which are larger and much more easily identified than those produced in the short treatment, the proportionate amounts of phases present running practically the same.

Discussion of Preliminary Results

This hypothesis will be applied in the study of Table 1. It will be noted in this table that in every case where the service of the refractory is reported as "good" the average operating temperature is below that of the "critical range," and conversely where the service is "poor" the average operating temperature is above the critical range.

The average operating temperatures were arrived at by a study of the furnace and refractory temperatures observed at

TABLE 1 FIELD AND LABORATORY DATA OF BOILER FURNACES INVESTIGATED

Station	Equipment	Fuel	Average temperature for average rating, deg. fahr.	Critical range, deg. fahr.	Service of refractory in boiler setting	Crystalline compounds present in slag
Lowellville, Ohio	Underfeed stoker	Bituminous coal	2000–2300	2700–2750	Very good	Mullite
Trenton Channel, Detroit, Mich.	Long flame burner	Powdered bituminous coal	2600–2700	2700–2800	Good	Mullite, magnetite

Crawford Avenue, Chicago, Ill.	Chain grate	Bituminous coal	2800–2900	2500–2550	Poor	Mullite
Cahokia, Ill.	Long flame burner	Powdered bituminous coal	2600–2700	2200–2250	Very poor	Mullite, magnetite

the time the samples were collected.[6] Temperatures were taken within the bricks themselves at varying distances from the hot face, and extrapolations were made to obtain the temperature of the hot face. At the same time temperatures were taken within the furnace itself at varying distances from the hot face. As the latter temperatures, particularly those 2 ft. from the side walls, were somewhat higher than those obtained by the gradient established from the temperatures within the brick, they have been used. The readings taken under average boiler ratings, generally 150 to 175 per cent, were shown rather than the extremes. While the maximum temperatures and conditions affect the thermochemical reactions more or less, it is thought that average operating conditions are the ones of greatest value.

The installation reported as giving probably the best refractory service was that of Lowellville, with low-sulphur coal. The laboratory study of the fuel ash plus the refractory indicated a critical range of 2700 to 2750 deg. fahr., while the average operating temperature was from 2000 to 2300 deg. fahr. This suggested a prediction of good service from the refractories, and the reports stated the average life at this station to be about two years.

In case the average operating temperature is just below or falls within the critical range, one would expect only fair service from the refractories, depending upon certain conditions. If, for instance, the boiler were operated at or somewhat below average rating, the refractories would probably do quite well, while if operated at higher ratings considerable portions of the time, the operating temperatures thus exceeding the critical range, the refractories would fail much more quickly. Both the East Peoria Station and the Fisk Street Station of Chicago fall in this class. Fair results were reported from the field in both cases.

On the other hand, the cases of Cahokia and Crawford Avenue Station, Chicago, showed very poor service from the refractories as compared to the cases cited. The Cahokia critical ranges showed 2250 deg. fahr. as the upper limit, and the average operating temperature was from 2600 to 2700 deg. fahr., which is well within the "upper range" of the coal-ash refractory combination. Hence, severe corrosion was to be expected, and the field reports showed this to have been true. The Crawford Avenue Station was a similar case. It reported an average life of about 36 days for its refractories in positions receiving the maximum punishment, and the laboratory tests show this combination as having a critical range 300 to 400 deg. fahr. below the average operating temperature.

The laboratory studies show that in some cases the boiler temperature could be increased without serious detriment to the refractories in use, while in other cases considerable improvement might be expected if other combinations of coal ash and refractory were used.

Some investigating was done along this line in the case of Cahokia and Trenton Channel coal-ash refractory combinations. The Cahokia refractory was tried with the Trenton Channel coal ash and resulted in a decided raising of the critical range. Likewise, the Cahokia coal ash in combination with the Trenton Channel refractory also resulted in an increase, although not to the same extent. In this case the coal ash was a more deciding factor than the refractory.

For any given boiler furnace certain coals and refractories are available or economical to use. If a study can be made of the various ashes with the various refractories along the lines indicated, one or more combinations can probably be found where the critical range is above the average operating temperature. It is thought that by using the method outlined one will be able to obtain results with an accuracy and speed hitherto unobtainable.

[6] "A Study of Refractories Service Conditions in Boiler Furnaces," Ralph A. Sherman, Bulletin of the Bureau of Mines.

Summary

The following working hypothesis has been developed for predicting the action of slags on firebrick: To obtain a relatively low corrosive slag, conditions should be such that the slag solution is well saturated at all times with solid phases formed from constituents of the slag only. This involves working out three ranges or conditions for any given combination of coal ash and refractory, as follows:

1 The lower temperature range, where the slag is saturated with the solid phase originating from its own components and is considered to be a safe working range for the combination of coal ash and refractory.

2 A critical temperature range, where most of the crystalline phases from the slag components have come into solution and the slag is mostly liquid. The temperature should be kept below this range, as immediately above it severe corrosion of the refractory begins.

3 The upper temperature range, where the temperature is high enough to permit the brick components to unite with those of the slag to cause supersaturation and recrystallization of a solid phase. In this range severe refractory corrosion begins, increasing rapidly with further increase in temperature.

A technique is suggested for determining these ranges by the use of a quenching furnace and control board, giving on the whole a precise and accurate simulative test method.

Discussion

Ralph A. Sherman.[7] Manufacturers and users of refractories have long sought an accurate test by which the resistance of refractories to slags could be measured. The authors have presented in these two papers two methods which are widely different, but which have been developed concurrently and have had the advantage of comparison one with another and with rather carefully conducted field tests. With the completion of the trials of the two methods on the special series of firebricks which the Special Research Committee of the Society has had manufactured and the trials of panels of these bricks in actual boiler furnaces a definite evaluation of the relative merits of the two methods can be made. Mr. Hursh has reported the results of his method on all of the bricks with all but one of the slags to be used, and Battelle Memorial Institute is now engaged in a year's work which it is contributing to the problem in studying the series of combinations by the quenching method of the Bureau of Standards; Dr. Harold E. Simpson is conducting the investigation.

Both types of test may be retained as each has its particular advantages. The quenching method is undoubtedly the more fundamental of the two and gives an accurate picture of what occurs in the action of a slag on a refractory. The use of the control board allows much closer regulation of temperature than can be obtained in the rotating-furnace method. The cost of the equipment for the quenching method is greater than for the rotating furnace, and a more highly trained operator is required to conduct the tests and make the observations. A particular advantage of the rotating-furnace method is that the results are quantitative and a curve of the relation of the rate of erosion to the temperature can be plotted.

Although some idea of the increase in the rate of attack with temperature can be obtained by the quenching method, it has not yet been possible to plot a curve of the results. Another advantage of the rotating-furnace method is that different

[7] Fuel Engineer, Battelle Memorial Institute, Columbus, Ohio.

furnace atmospheres may be obtained with some degree of facility. Although it does not seem impossible to subject the specimens in the quenching furnace to different atmospheres and it is intended to attempt this phase of the work, it is probable that certain difficulties will arise, particularly in connection with the attack of reducing gases on the platinum winding of the furnace.

The authors of the paper on the quenching method have emphasized the fact that the "critical range" cannot always be determined within narrow limits, and the writer wishes to place further emphasis on this point. With one of the slags which has been studied at Battelle Institute the range was determined within limits of 25 deg. fahr., but with another slag the range could not be defined more closely than 200 deg. fahr. This is not at all serious, as without special studies the temperatures at various points in a boiler furnace at various ratings cannot be controlled more closely than 200 deg. fahr.

In closing, the writer wishes to ask Professor Hursh to clarify one point in connection with the results shown in Table 4 of his paper. The refractory ST-2 was used as a comparative specimen in the study of the four factors of burn, grind, method of fabrication, and district, but the erosion reported for this refractory for the same ash is not always the same. For example, the average depth of erosion with the Detroit ash under the comparison of the effect of the method of fabrication was 0.70 cm., while for the same refractory and the same temperature under the comparison of the effect of grind it was 0.27 cm. It is presumed that these were different tests and the length of run and amount of slag used were different, but without explanation it would appear that the results could not be closely duplicated.

HAROLD E. SIMPSON.[8] The development of a satisfactory service test for boiler-furnace refractories is one of vital interest to both user and manufacturer of such products. Such refractories are not only called upon to withstand high temperatures, but also they must withstand the corrosive action of the coal-ash slag.

The two tests given in these papers, while developed along different lines, have as their common goal a means for observing the effect of coal-ash slags on refractories. The one method inherently lends itself to careful control and precision, giving the fundamental relations existing between coal-ash slags and refractories, while the other lends itself to use in the average size laboratory and gives a comparative estimate of slag attack on refractory.

In Professor Hursh's paper, the writer would like to see the results of tests carried out at a series of temperatures, say, from 2200 to 2800 deg. fahr. at 100 deg. fahr. intervals for a particular coal ash and refractory. He would also like to ask why the author believes slag penetration to be greater in a vitrified body. If the development of glass is conducive to slag penetration in the high-fired refractories (cone 12 and 14), why does the development of thin vitreous coating in cone 6 body hinder slag penetration?

In the paper by Messrs. Klinefelter and Rexford, the writer would like to add that it has been his experience that rather severe corrosion may occur even if the slag still contains considerable solid phase. As a rule, however, the presence of a great amount of glass in the slag is an indication of considerable attack of refractory by slag.

E. G. BAILEY.[9] It would seem that the conclusions to be drawn from the paper by Messrs. Klinefelter and Rexford are about as follows:

1 Select coal with as high a fusing temperature of ash as possible
2 Select refractories to produce a high "critical range"
3 Keep the furnace temperature below this "critical range" by means of low rate of combustion, high excess air, or other means, most of which are inefficient.

In this day of high steam pressures and temperatures and high electric voltages, it seems rather reactionary to call for low furnace temperatures.

If low furnace temperatures are required, water-cooling of the furnace walls is the best way to do it, and the question might be asked, "Why use refractories anyhow?"

While water-cooling is undoubtedly here to stay, the writer still can see some good in refractories and is very much interested in studies such as those brought out in this paper. High furnace temperatures are necessary in many cases; they are desirable in all cases for the most complete combustion at high rates of liberation. At low rating a cold furnace leads to inefficiency, smoke, and oftentimes absolute failure to maintain ignition.

The essential point of this paper is the "critical range" between a given refractory and a given ash. This points toward a refractory-lined furnace, with the advantage of high temperatures, yet cooling behind this refractory that keeps the refractory and slag mixture at its surface below the "critical range" by means of the water-cooling and the high temperature gradient from the furnace to the water tubes. Further studies along the line of this paper are well worth while in this field.

With slag-tap furnaces and relatively hot refractory walls and perhaps additional refractory in other places, the recovery of ash in the furnace and its economical elimination in the early stages of gas flow are all desirable goals which can only be brought about by further knowledge of the ash-refractory fluxes and the use of a proper refractory throughout the furnace.

P. NICHOLLS.[10] In the investigations on the life and the failures of refractories it has often been disappointing that one could not make assured explanations for what occurs; also the usefulness of laboratory determinations of the characteristics of refractories has seemed to have such a limited application. For these reasons, in the committee work, the writer has been quite enthusiastic about the explanatory theory advanced in the paper by Messrs. Klinefelter and Rexford. It is the first time that an attempt has been made to connect tendency to slag with a fundamental measurement, and to generalize from it.

One must expect, however, that, by itself, this new indicator will not be a measure of the relative wastage of furnace walls. Even assuming that all imposed conditions are determinable, yet at least the viscosity of the resultant slag will be another fundamental, as will also the relationship of viscosity to temperature. The writer believes that measures of the tendency to slag will have to include these. In addition, the prediction for probable actual slagging will have to allow for the quantitative measures of the imposed conditions such as quantity of deposited ash and gas velocity and composition.

The interpretation of the work of the authors is therefore that their indicator gives a relationship between "tendency to corrode" and temperature up to their critical temperature; that the "tendency of the rate of corrosion" against temperature will have to include the additional factors of the viscosity of the liquid and some measure involving the texture of the solid refractory; and that the "rate of corrosion" will be compounded of the latter (what may be termed the fundamental) constant and the imposed conditions.

[9] President, Fuller Lehigh Company, Fullerton, Pa. Mem. A.S.M.E.
[10] Supervising Fuel Engineer, Pittsburgh Experiment Station, U. S. Bureau of Mines.

The line of study being conducted by the authors is, however, well worth continuing, and it is to be hoped that they will not be content to leave it in its present state, as is so often the necessity, and also perhaps the tendency, of investigators, but that the study will be continued to the stage where it can be embodied in a definite testing specification or other form available for practical application, instead of being carried no further than a special investigation.

Authors' Closure

In the paper there are mentioned a number of points on which considerable work is necessary before some of the criticisms brought out in this discussion may be answered more fully.

The three conclusions which Mr. Bailey drew are correct so far as the first two are concerned, but in the case of the third the assumption drawn is decidedly incorrect. It would follow of course, if the life of the refractory were the sole factor to be considered. This is not the case, and we certainly had no intention of giving the impression that other factors in boiler operation should be subordinated to that of life of the refractories.

The laboratory was given the task of analyzing the causes and processes involved in the failure of the refractories. This is what we have endeavored to do in the paper, and since some refractory and coal-ash combinations give better service than others, we have gone a step further and suggested a method of finding the best combination for an installation. There is not the faintest inclination on the part of the authors to advocate any changes in any installation which will lessen the final efficiency of the whole station operation. It is all a matter of how important a factor the life of the refractory may be in the cost accounts of any given installation. It may or may not be worth while to lengthen the periods between repairs. To do so might mean such an increase in the cost of coal alone sufficient to offset the benefits gained, or as Mr. Bailey suggested, such low temperatures with resulting inefficiency as not to be worth while. It is a matter of simple arithmetic for the individual station to be worked out by the cost accountant.

There are cases noted in Table 1 accompanying the paper where there is no doubt that a different combination of refractory and coal ash would lengthen the life of the refractory; but whether it would actually pay that station to change or not can be answered only by the station's bookkeeper, not by us. It is our personal opinion in the matter in general that there exist a good many stations which could use another coal-refractory combination to advantage, and also we believe that a precise method of determining varying degrees of corrosion with various combinations will enable a power station to write specifications for both their coal and refractories in a much more intelligent fashion than heretofore.

In regard to Dr. Simpson's finding that rather severe corrosion may take place even while containing large amounts of glass and of solid phase, we should like to caution that one must never lose sight of the fact that all these slags are corrosive in all ranges, but relatively less so in the lower and the critical than in the upper. Also that the amount of corrosion in a given range for any given combination may be less or greater than for some other combinations.

In the same way the length of the critical range varies considerably, as Mr. Sherman points out, and while we have not sufficient data as yet to correlate any property with it, we believe this will develop. We suggest that it possibly ties in directly with the viscosity of the slag, and may be something of an index of relative corrosion. In the studies mentioned in the main paper it was noticed that the most violently corrosive slags had a shorter critical range than those of less corrosion. It is a phase which calls for much further study, particularly with regard to the factor of viscosity, as Mr. Nicholls points out.

FSP-53-23

High-Pressure Chemical System for Boiler-Water Conditioning

By A. A. MARKSON,[1] NEW YORK, N. Y.

In this paper the author describes the high-pressure phosphate system for boiler-water conditioning as used at the Kips Bay Station of the New York Steam Corporation. He believes that it solves the problem of economizer deposition, and while the primary object is to avoid deposition of scale in economizers and feed lines, it is apparent that it gives a flexibility of control superior to that obtained by adding the chemical directly to the feedwater heaters or hot wells. The paper does not discuss the chemical phases of the problem.

THE PURPOSE of any system of boiler-water conditioning is to maintain such conditions in the boiler water that the production of steam will not cause the formation of deposits on the heating surfaces. If in the accomplishment of the primary object, secondary difficulties develop, these latter must be eliminated without interfering with the accomplishment of the main objective. At Kips Bay Station of the New York Steam Corporation the phosphate system of boiler-water conditioning was found to be extremely satisfactory in the elimination of deposit from the heating surfaces, but in its original application secondary difficulties either existed or arose, which had to be traced down and eliminated. These difficulties were as follows: (1) The boilers produced wet steam, (2) heavy deposits formed in the economizers, and (3) it was not possible to maintain low alkalinities in the boiler water while maintaining economizer-corrosion protection.

The problem of wet steam at Kips Bay, and its solution, has been fully discussed in a paper by A. R. Mumford, "A Study of Moisture at High Rates of Evaporation," published in Vol. 51, No. 22, of the A.S.M.E. Transactions. Study of this problem developed the following facts:

a That there was a critical value of the concentration of boiler caustic alkalinity, above which it was practically impossible to accomplish the mechanical removal of entrained moisture, and below which mechanical purification was entirely practicable.

b That the concentration of other dissolved substances and suspended matters had a negligible influence on the quality of steam delivered from the boilers, within the concentration ranges covered in the experiments.

The caustic concentration was kept below the critical value by increasing the blowdown, until its control by chemical means could be effected. The sources of the caustic were two: That added to inhibit the economizer corrosion, and that formed by the breakdown of the carbonates in the boiler water. Some caustic alkalinity is necessary in the boiler water to insure the maintenance of conditions called for by the phosphate system for the formation of non-adherent precipitates. Obviously the economizers would be subjected to accelerated corrosion by the elimination of the caustic added to the feedwater. Furthermore, the presence of carbonates in the make-up insured a constantly increasing concentration of caustic soda in the boiler water.

Because of the fact that no deposits formed in the economizers before the phosphate system was adopted it was rather obvious that the adding of conditioning chemical directly to the boiler would eliminate completely the zones unfavorable to conditioning by the phosphate system. By using a less alkaline sodium phosphate than was previously employed advantage could also be taken of the possibilities of keeping the boiler alkalinity under control by partial neutralization in the boiler, rather than by excessive blowdown.

The author has noted considerable interest on the subject of economizer and feed-line scale deposition, as evidenced by several recent contributions on the subject, both of an experimental and a speculative nature, to the Society's committee on feedwater treatment.

One theory advanced seems to hold that the product formed when phosphate is added to the feedwater is in a supersaturated condition until it hits the heat-absorbing surface, at which point equilibrium is suddenly induced by the sharp change of temperature. The product carried along in a state of supersaturation then precipitates. Another hypothesis developed to explain the formation of deposits where none should occur, is that there is a film effect at the heating surfaces in which film precipitation occurs. Based on the experiences with economizers and feed lines at both stations A and Kips Bay, a theory is advanced which differs from those mentioned.

It appears that there is much to be learned as to the exact physico-chemical nature of substances in solution. The economizers scaled up very heavily, and the deposits were not limited to the tubes, but seemed, if anything, to be worse in the headers and on the plugs. This point was enough to question the specific validity of the supersaturation and film theories for these conditions. It is the author's belief that the answer to the question of such depositions will be found in the existence of products which are more basic in nature than those which are conventionally supposed. These products, of which there may be several, may have the general formula:

$$(Ca)\ w\ (OH)\ x\ (PO_4)\ y\ (H_2O)\ z$$

instead of being straight calcium phosphates. Some of the experimental facts in support of this contention are weak, but they may be summarized as follows:

1 If the boiler-water environment is not kept at a causticity materially greater than that theoretically required to insure tricalcic phosphate, adherent deposits form.

2 If a sample of boiler water is allowed to stand without being

---

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

filtered and the clear liquid above the sludge is analyzed on successive days, the concentration of phosphate in the clear liquid will be found to increase, apparently due to the slow action of caustic soda on the calcium phosphate.

3 At the time the high-pressure system was first put into operation at Kips Bay, it so happened that on two boilers the internal feed lines terminated in open-ended pipes above the upcomers. It was noticed when these boilers were taken off the line for inspection 30 days after the system had been in operation, that there were well-defined circular patches under the feed-line discharge pipes, which were of the same composition as the material which was formerly deposited in the economizers.

The author believed at the time of the inspection that the cause of these patches was that the incoming feedwater had no chance to mix with the boiler water to more than a slight extent, thus resulting in a solution weak in phosphate and alkali being directly localized under the feed pipes. If this theory were true, it would follow, so it seemed, that securing a uniform distribution of feedwater in the drum would not merely spread the deposit over a greater area, but would actually cause such deposition to disappear. This proved to be true.

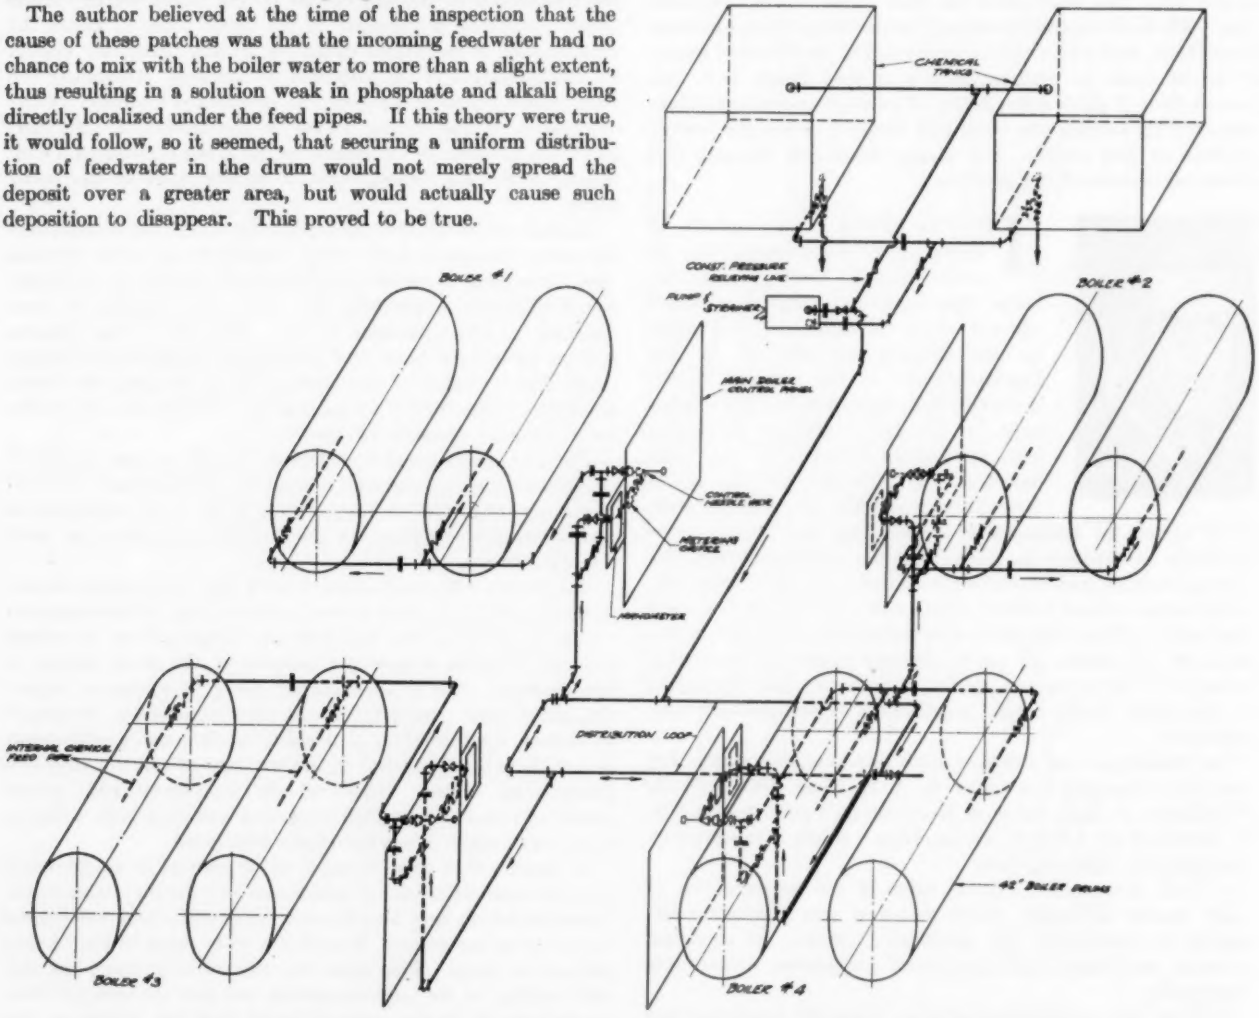

FIG. 1 SCHEMATIC LAYOUT OF HIGH-PRESSURE CHEMICAL SYSTEM AT KIPS BAY STATION

To recapitulate, the cause of economizer and feed-line scale deposition is essentially due to the maintenance of lower alkalinity in the feedwater than is required to prevent the formation of nonadherent precipitates. This required alkalinity is in excess of 100 parts per million of OH, fivefold higher than the maximum which could be economically added because of the resultant high blowdown required.

DEVELOPMENT OF THE HIGH-PRESSURE SYSTEM

In developing the system which was installed at Kips Bay, and later at Station A, certain mechanical conditions were set forth which must be met by the general scheme. In the first place, any such system ought to be simple to operate, to adjust, and to maintain. Secondly, the amount of special attendance necessary for the functioning of such a system ought to be a minimum. Third, the system ought to be under complete and accurate control at all times, with visible and positive indication of its functioning.

It is believed that the system which is to be described met these requirements very well. The general simplicity of the design is evidenced by the fact that both of the installed systems have shown no fundamental defects in 10 months of operation at Kips Bay Station and in five months at Station A.

The principle of the system may be thus briefly described: If a chemical charge of calculated strength be fed into the boilers in exact proportion to either the feedwater entering the boilers or the steam generated by the boilers, the optimum condition for internal treatment of boiler water will be attained. The assumption that the amount of treatment is proportional to the steam generated is probably true for most cases. The system accomplishes this in the following manner. A high-pressure pump maintains a constant head of chemical solution in the distribution loop. Feeds to individual boilers are taken off this loop. A metering orifice is placed in each boiler chemical line and the flow from the loop into the individual boiler is manually

controlled by means of a needle valve placed after the metering orifice. The metering orifice indicates the flow of chemical by means of a graduated manometer which is under the observation of the boiler operator. The manometer scale is graduated to correspond with the boiler-meter flow reading. The operator, therefore, has merely to adjust the control needle valve until the correct indication is obtained on the manometer, at which time treatment requirements will be satisfied.

The system is composed of the following component parts, shown schematically in Fig. 1: (*a*) Supply tank, (*b*) suction strainer, (*c*) high-pressure pump with constant-head bypass, (*d*) main feed loop, (*e*) metering orifices, (*f*) control needle valves, (*g*) indicating manometers, and (*h*) distribution pipe in boiler. The design of the metering and control system will be discussed first.

Design of the Orifice

In the design of the orifices for use in metering the chemical, the limiting factors are the available supply-tank capacity, the number of boilers to which it is desired to apply the system, and the question of probable accuracy obtainable in meteri g

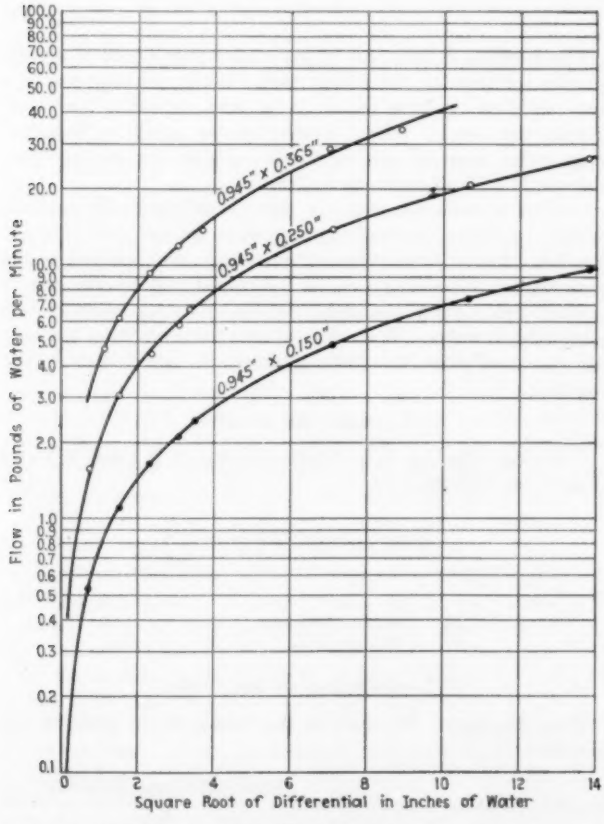

Fig. 2 Calibration Curves for Three Different Sizes of Orifices

small quantities. There is a limit of minimum flow below which metering difficulties, such as the use of orifice plates having microscopic holes, are apt to appear. Furthermore, since the total amount of solution fed into the system depends to a large extent on the number of boilers in the station, it follows that the chemical-solution tanks will have to be larger in capacity as the number of boilers goes up, in order that the tanks may not empty in too short a time. Where the number of boilers is relatively large, as in Station A, where there are now 14 boilers, a single large tank may be used, and a very small auxiliary tank employed to feed the system while the large tank is out of service for recharging. The tanks are equipped with air agitation so that outage is minimized.

At Kips Bay Station there were two 7000-gal. tanks available for holding the chemical charge. The maximum daily load on

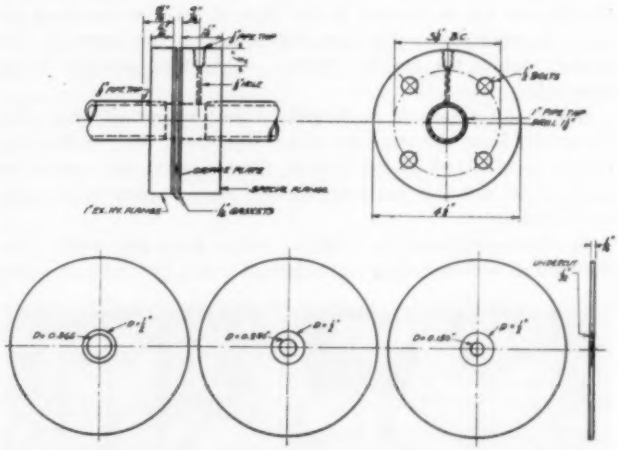

Fig. 3 Orifice Assembly and Three Orifice Plates Used

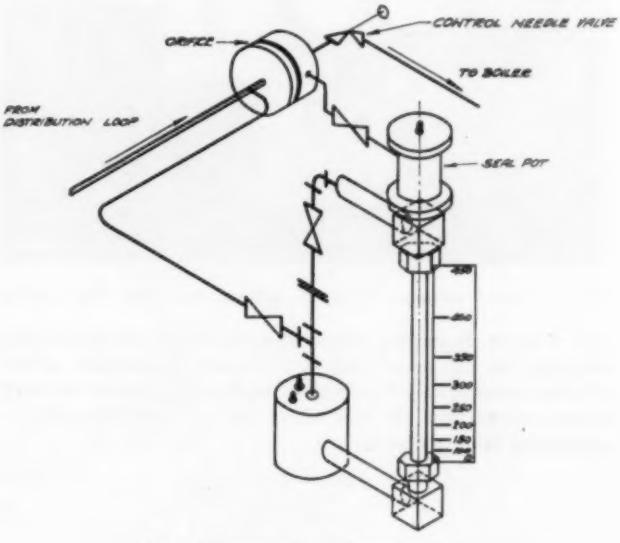

Fig. 4 Indicating Manometer

the station at that time was about 24,000,000 lb. Feeding from alternate tanks it was desirable that recharging intervals should not be shorter than 48 hr. at the maximum station load. This means that the average hourly feed would be 7000 divided by 48, or about 145 gal. per hr., which corresponds to an average hourly steam generation of 1,000,000 lb. per hr. It was therefore necessary to feed chemical at the rate of 2.4 gal. per min. for an hourly evaporative rate of 1,000,000 lb. As the maximum load per boiler is somewhat over 400,000 lb. per hr., the figure which was used in designing the metering system was 1 gal. per min. chemical flow when the steam-flow meter indicated 400,000 lb. per hr. generation.

Those familiar with orifice work will immediately appreciate the difficulties of obtaining close metering accuracy under these conditions. Nevertheless, Fig. 2 gives a calibration curve for three different sizes of orifices under a complete range of heads

If these orifices be used in the standard orifice carriers, their reproducibility will be well within 3 per cent.

Actual coefficients of discharge of these orifices were determined by numerous weighed tests on water, and the results of these tests may possibly be the subject of a contribution to the Fluid Meters Committee of the Society.

Since the calibration curve is based upon water of density 62.4 lb. per cu. ft. flowing in the pipe, it may be corrected for other densities by multiplying the values on the curve by the square root of the specific gravity of the fluid actually being metered.

If for any reason it is desired to use orifices differing very materially from the standard plates described, their coefficients should be obtained by calibration, since existent data on orifice coefficients and tap spacings are not very applicable to such small orifices.

In this installation the 0.365-in. orifice plate was used. The differential corresponding to a flow of 1 gal. per min. is about

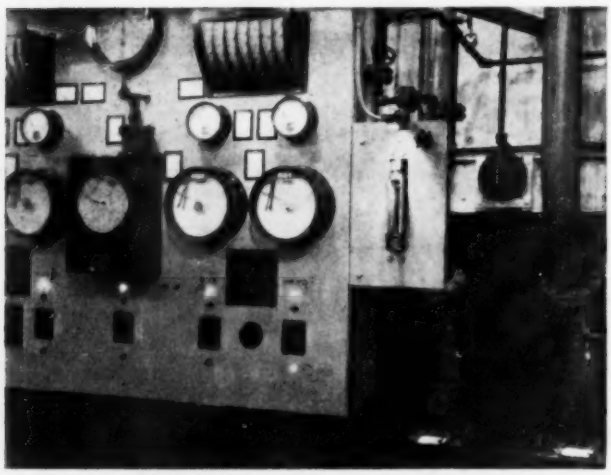

FIG. 5 THE CONTROL VALVE IS LOCATED AT THE MANOMETER

4 in. of water, depending somewhat on the density of the chemical solution. In the event that it be desired to compute orifices differing considerably from those employed by means of coefficients derived from the calibration curve, a useful formula for computing these plates is:

$$F = \frac{CD_1^2 Y^{1/2} H^{1/2}}{Q} \times 5.99$$

$$F = \left[\left(\frac{D_1}{D_2}\right)^4 - 1\right]^{1/2}$$

D_1 = Pipe diameter in inches
D_2 = Orifice hole diameter in inches
C = Coefficient of discharge
Y = Density of the solution, lb. per cu. ft.
H = Differential in inches of water of specific gravity 1.00
Q = Flow, lb. per min.

A curve giving values of $\frac{D_2}{D_1}$ against values of F makes a very convenient device for getting values quickly. In the formula the density of water at room temperature has been taken at 62.4 lb. per cu. ft.

For low values of $\frac{D_2}{D_1}$, F is sensibly equal to $\left(\frac{D_1}{D_2}\right)^2$ and the orifice-hole diameter is then given by

$$D_2^2 = \frac{Q}{5.99\, CY^{1/2} H^{1/2}}$$

THE INDICATING DEVICE

The design of the indicating device is shown in Fig. 4. It is nothing more than a high-pressure cistern manometer of somewhat special construction. Attention may be directed to the fact that it uses a $^3/_8$-in. standard boiler-gage glass and has a cup on the top combination which acts as a safety-seal pot.

GAGE COEFFICIENT

In a manometer using a heavy liquid as the indicating liquid, in contact with a lighter liquid as the medium of pressure transmission, the true differential, in terms of water of specific gravity 1.00, corresponding to the observed total deflection, is given by the observed deflection times $\gamma_1 - \gamma$, in which γ_1 = specific gravity of the gage liquid; γ = specific gravity of the lighter liquid.

If the gravity of the chemical being fed is sensibly equal to unity, this reduces to:

Differential in inches of water = deflection in inches $\times (\gamma_1 - 1)$ ..... [1]

The question is then that of selecting a gage liquid of specific gravity suitable for the orifice used. While mercury makes a very satisfactory gage liquid, it is very expensive and may require the use of orifices which are too small in diameter. Some other gage liquids which are suitable are carbon tetrachloride (1.58) and bromoform (2.9).

Carbon tetrachloride magnifies the true differential by approximately 1.7 times; bromoform reduces it by half, and mercury by 12.6. For orifices carbon tetrachloride was selected as the gage liquid. This was colored a brilliant red by the use of "pyloil" red, a dye (commonly used for coloring gasoline) which is insoluble in water. It is apparent that the necessity of knowing the gage coefficient accurately increases as lighter gage liquids are used.

CISTERN COEFFICIENT

The true deflection in a cistern manometer is given in terms of observed deflection by

$$\text{T.D.} = \text{O.D.} \times \left(1 + \frac{A_1}{A_2}\right) \text{.....} [2]$$

in which

A_1 = Gage glass area
A_2 = Cistern area

CONSTRUCTION OF THE SCALE

From Equations [1] and [2], the length of the scale can be obtained.

$$\text{Length of scale in actual inches} = \frac{\text{Max. differential in inches } H_2O}{\left(1 + \frac{A_1}{A_2}\right)(\gamma_1 - \gamma)} \text{.....} [3]$$

This gives a fixed length of scale corresponding to the fixed maximum rate of generation, the assumed differential, and the assumed amount of chemical flow. It is obvious that the intermediate scale values can be constructed geometrically or otherwise to take into account the variation of the discharge coefficient as well as the square root function of flow. The scale may be graduated, of course, in any other set of arbitrary units desired.

The Control Valve

As shown in Fig. 5, the control valve is placed at the manometer, so that the operator's duty consists of maintaining the manometer reading at the scale point corresponding to the reading of either his feedwater or steam meter in a manner analogous to controlling the air-flow pen on the boiler meter. The control valve should be placed after the orifice for obvious reasons. For the control valves it has been found that $^1/_4$-in. steel needle valves function perfectly for the conditions and have given no trouble since installation.

The Loop

In designing the loop a maximum velocity should be chosen which tends to make the loop act as a pressure reservoir. One or two feet per second is satisfactory. Welded joints are preferable, although there has been no trouble with screwed or flanged pipe in this service at the pressure of 400 lb. Check valves should be employed where necessary, and all valves and fittings ought to be of iron or steel and of the best quality obtainable.

The Pump

The pump, as might be expected, is the point in the system upon the satisfactory functioning of which practical operation depends. The first pump selected was a reciprocating triplex type driven by a 5-hp. motor. The functioning of this pump was quite satisfactory, although when it came to selecting a change-over pump, it was felt that this could be improved upon considerably in the matter of maintenance, which was a little more than would ordinarily be required because of the necessity for a steady flow curve.

A rotary pump was installed which gave some promise at first, but later developed so much trouble that the makers took it back. Final choice was a low-capacity high-head centrifugal pump driven by a small turbine. This appears to have all the ideal characteristics required for the work. The power consumption is about 25 hp., which is considerably in excess of the power requirement of a reciprocating pump. Since the exhaust steam may be used and since the amount of water treated by this system is so large, this power requirement is easily justified. Two manufacturers, at present, are prepared to supply this type of pump in heads up to 600 lb. from stock patterns.

Constant Pressure Relief

A spring-loaded relief valve is used to bypass the excess of fluid pumped back to the supply tanks and to maintain a fairly constant head on the discharge loop. The constancy of this head is very important, in order that the control needle valve will not require readjustment at constant rating. A suitable all-iron valve for the service could not be obtained, but it was found that a standard bronze valve, when chromium plated, was satisfactory. If a pump is selected of ample excess capacity, a durable needle valve may be used instead of a loaded relief valve.

In the operation of the system the pump pressure should be set at a point which will insure a negligible effect of variations of boiler pressure on the flow through the boiler-control needle valve. For example, if the boiler pressure varies 5 lb. from the usual operating point it will only affect the indication of the manometer very slightly when a drop of 100 lb. is induced across the control valve, but rather seriously if the drop induced across the control valve is, say, in the neighborhood of only 10 lb.

The suction strainer is a duplex strainer of our own making, having strainer baskets of 40-mesh monel cloth. The assembly is arranged so that a strainer can be cleaned in about 10 min. without interrupting the service.

Conclusion

In conclusion, the advantages of a high-pressure system such as the one described are:

1 It solves the question of economizer deposition due to the nature of the conditioning chemical used. The author has no available data on whether stage heaters show the same deposition, but it is obvious that the high-pressure system also solves this question.

2 While the primary object of the high-pressure system is to avoid deposition of scale in economizers and feed lines, it is apparent that it gives a flexibility of control which is far superior to adding the chemical directly to the feedwater heaters or hot wells.

3 The cost of installation of such a system is very moderate. Some limitations that occur to the writer are: (1) It is not as adaptable to the needs of a very small plant as it is to a very large plant, and (2) it requires technical supervision of a better order than is required by the other method.

This paper does not attempt to go into all the chemical phases of the problem. There is an abundance of literature on the subject of boiler-water conditioning by means of the phosphate system, which has been published by the various societies. The author wishes to express his indebtedness for the cooperation of both the operating and design deparments of the corporation which made this development possible.

Appendix No. 1

Cost figures show that a good estimate of the cost of installation of a complete system as described is about \$8000 + \$250 per boiler. This figure includes two high-pressure pumps and supply tanks and is derived from costs on four and twelve boilers.

Appendix No. 2

Average discharge coefficients for small orifices:

Upstream tap—one pipe diameter.
Downstream tap—0.8 pipe diameter.

Ratio D_2/D_1	Ave. C
0.16	0.66
0.26	0.66
0.39	0.62

Data obtained on 1-in. extra-heavy iron pipe of ordinary roughness.

Discussion

H. A. Jackson.[2] The paper presents the difficulties that arise from addition of sodium phosphate to boiler feed in order that proper boiler-water conditions may be obtained for the elimination of boiler scale. The author has concisely pointed out that to prevent feed-line and economizer corrosion the feedwater must have a definite alkalinity, and that as this alkalinity increases enormously in the boiler due to concentration, therein there is presented a dilemma, for its reduction by the employment of an acidic phosphate destroys the necessary alkalinity in the feed system. An answer lies in direct introduction of the acidic chemical into the boiler water.

The direct introduction of phosphate into the boilers has heretofore presented very serious difficulties, particularly as to proper proportioning and this the author has solved beautifully. The combination of a small-orifice chemical-solution meter, calibrated in terms of steam flow from boiler together with an

[2] Hall Laboratories, Inc.

adjusting needle valve so that the operator can keep the chemical-meter reading coincident with that of the boiler steam meter, is a smooth solution of the problem.

The proportioning of chemical to boiler feed imposes far less rigorous exactitude than, let us say, the proportioning of air flow to powdered-coal feed, for the momentary errors of the latter cause actual efficiency losses whereas the boiler water gives a chemical storage which can be momentarily drawn upon or temporarily increased within certain bounds without imposing the slightest detriment to the maintenance of the desired chemical equilibria in the boiler water. A complicated mechanical or electrical hookup of the boiler steam and chemical-flow meters to adjust automatically the control valve would be therefore entirely unnecessary.

It is perhaps not generally appreciated how really difficult it is accurately to control flows of a fraction of a gallon to one or two gallons per minute, and particularly so when the liquid whose flow it is desired to control is under pressure corresponding to those of modern boilers. The description of this pressure-feeding system and particularly the data on differential pressures through small orifices as shown by the curves should be of the utmost value to others who wish to adopt this method.

In regard to concentration of the various dissolved salts in reducing the size of steam bubbles in boiling water and in lengthening their time of rupture and hence the cause of foaming and wet steam, it is the writer's experience that the various sodium salts such as the sulphate, chloride, carbonate, and hydroxide have an effect in this regard all in the same order of magnitude, with sodium hydroxide heading the list, but not to such an extent that its concentration alone should be regarded to the exclusion of the others. The effect of suspended matter is also of the same order of magnitude and is not the predominating influence that it was formerly regarded.

With considerable dissolved material in the boiler water, the greatest change in boiling conditions is experienced in changing from a pH value of less than about 5 to one greater than 8 or 9. Above this value, the effect of increased causticity is not as great though definite, unless saponifiable matter is present in the boiler water.

The difference in foaming qualities between a boiler water having a definite caustic alkalinity and one having none is vast if there be saponifiable organic matter present. The higher caustic concentration accelerates saponification, hence supplies soap more rapidly, and likewise accentuates foaming tendencies greatly.

The author draws the conclusion that deposits similar to those formed in economizers would also be formed in stage heaters. This conclusion is correct, for that has been the writer's experience in a number of cases.

Calcium-phosphate deposits occur, however, not only in economizers and closed heaters, but also in check- and water-regulating valves and in the feed lines themselves. The author's theory of a calcium basic phosphate to account for their occurrence is very interesting.

It has been the writer's experience, however, from the results of a large number of analyses of such deposits, that the calcium found lines up with the phosphate of 2 Ca to 3 PO_4 and not in a variable relation. For the precipitation of a basic calcium phosphate, considerable hydroxide radical would necessarily be present in the water.

Even at relatively low pH values (7 for instance) the solid phase is tricalcic phosphate, but the solution phase under that condition is largely calcium hydrogen phosphate, since the tri-basic phosphate radical readily combines with the hydrogen of water to form the di-basic HPO_4 radical. As the pH value rises above 7, the tendency for formation o the di-basic radical decreases and therewith the apparent solubility of tricalcic phosphate also decreases. Thus the hydroxide alkalinity in the boiler water essential for clean surfaces may be under very pure boiler-water conditions, as low as that corresponding to a pH value between 10 and 11. If however, the boiler water results from 100 per cent make-up, and therefore contains considerable dissolved solids, and in particular if it contains silica, the hydroxide concentration must be high, corresponding perhaps to a pH value of 11.5. With the certain control that the author has developed for maintenance of phosphate in the boiler water, and if the hydroxide concentration is uniform throughout the boiler, the writer does not believe that maintenance of 100 p.p.m. hydroxide is essential for obtaining clean surfaces.

Now, the very property of tricalcium phosphate which makes it the most desirable form in which to precipitate entering calcium, namely its extremely low solubility and its precipitation as a sludge in a vessel in which its saturated solution is boiled, makes it an undesirable component to have in a feed system. That it precipitates as a sludge in the boiler is due to the fact that its solubility must decrease with increase in temperature and hence its saturated solution tends to form adherent scale on surfaces that are cooler than the contacting solution. This explains the deposits in feed lines, but not, however, those in heated portions such as economizers.

Its solubility is so slight that the addition of a phosphate solution to water containing more than a mere trace of calcium causes supersaturation to occur unless complete formation of the requisite amount of solid phase be instantaneous and this is not the case. Speed of formation of the solid phase of tri-calcium phosphate is greatly accelerated by elevation of temperature as may be easily observed by the simultaneous addition of sodium phosphate to dilute alkaline calcium solutions, one at ordinary and the other at boiling temperatures. Therefore the formation of economizer deposits is none other than the rapid increase in rate of desupersaturation by the sudden rise in temperature.

P. C. Fritz.[3] It is very evident that the adherent deposit occurring in the economizers, feed lines, and surfaces below the feed discharges in the boilers forms in an environment of comparatively low alkalinity, while the less adherent deposits and sludge occurring in the boilers forms in an environment of relatively higher alkalinity. Therefore, there is reason to believe that the material depositing in the economizers may be in the form of the calcium acid phosphate, while that depositing in the boilers is in the form of tri-calcium phosphate.

This is what may be expected when the equilibria is considered which is present in the solution of a phosphate salt.

$$PO_4^{\equiv} + H^+ \rightleftharpoons HPO_4^{=} + H^+ \rightleftharpoons H_2PO_4^-$$

An increase in the concentration of H ions shifts the equilibria toward the H_2PO_4 ions since an increase in H ions allows more PO_4 ions to combine to form HPO_4 ions and H_2PO_4 ions. An increase in OH ions means a corresponding decrease in H ions, since the product of the concentrations of H ions and OH ions equals a constant, the ionization constant of water. Consequently, a decrease in H ions causes the equilibria to shift toward the PO_4 ions, since the removal of H ions allows more H_2PO_4 ions and HPO_4 ions to dissociate, with a final result of more PO_4 ions. Therefore, it appears that the concentration of H_2PO_4 ions, HPO_4 ions, and PO_4 ions in the solution is somewhat dependent upon the concentration of the H ions, or inversely upon the concentration of the OH ions. As the solution is always above a pH of 7.0 it is probably better to speak of what happens in

[3] Assistant Chemist, New York Steam Corporation.

terms of OH ions. Therefore, we may conclude that a region of low alkalinity has more H_2PO_4 ions and less PO_4 ions than a region of high alkalinity.

Now when the calcium ions from the feedwater come in contact with these phosphate ions, it is likely that at places of low alkalinity more $Ca(H_2PO_4)_2$ and less $Ca_3(PO_4)_2$ will form than at places of high alkalinity. This is verified to a certain extent by examination of the analyses made on numerous samples of boiler and economizer deposits. These analyses show that the P_2O_5 content in the economizer and feed-line deposits is higher than that in the boiler deposits. However, the silica, carbonate, and sulphate contents in the economizer and boiler deposits are different, but even when corrections are made for these materials, the economizer deposits contain a higher P_2O_5 content. The P_2O_5 content of $Ca_3(PO_4)_2$ is 45.8 per cent, of $CaHPO_4$ is 52.2 per cent, and of $Ca(H_2PO_4)_2$ is 60.6 per cent. Therefore there is reason to believe that the deposit in the economizers, feed lines, etc., is in the direction of $Ca(H_2PO_4)_2$ and that in the boilers is in the direction of $Ca_3(PO_4)_2$.

This same line of reasoning can be applied to the problem of boiler water changing in OH concentration and PO_4 concentration upon standing. This seems to be entirely a problem of carbon-dioxide absorption. A series of tests was run on a sample exposed to the laboratory air. Another series of tests was run on a sample sealed tightly from the air. In order to guard completely against any CO_2 absorption between tests, each test was run on a new or separate sample, and the vessels were filled with the sample up to the cork so that there was no air above the water. A sample containing 220 p.p.m. of OH, 96 p.p.m. of CO_3, and less than 10 p.p.m. of free PO_4 was tested after standing unfiltered in a well-stoppered vessel for 120 hr. There was no change in the concentration of OH and CO_3. The phosphate increased slightly, but did not reach 10 p.p.m. A similar sample exposed to the air was tested after 24 hr. The OH concentration decreased to 45 p.p.m. and the CO_3 concentration increased to 410 p.p.m. Another test was made after 72 hr. standing. The OH concentration was found to be O and the CO_3 concentration increased slightly to 416 p.p.m. The phosphate increased, but still there was not 10 p.p.m. present.

There may be an explanation to this result in the fact that alkaline water is a good absorber of CO_2 which is present in considerable quantity in laboratory air. Therefore, OH ions are consumed with the production of CO_3 ions

$$2\ NaOH + CO_2 \rightleftharpoons Na_2CO_3 + H_2O$$

The concentration of OH ions is thus reduced and coincident with the decrease in OH ions is an increase in H_2PO_4 ions and a corresponding decrease in PO_4 ions as discussed previously. This means more $Ca_3(PO_4)_2$ solid must dissolve and dissociate until there are as many PO_4 ions present as required by the solubility product constant of $Ca_3(PO_4)_2$. Therefore, there is the same amount of PO_4 ions in solution and an increase in H_2PO_4 ions at the expense of solid material. The indicator tests all of the phosphate ions and calls them PO_4 ions. This may account for the slight increase in PO_4 on standing exposed to the air.

E. F. Walsh.[4] A system similar to that described was installed at the South Street Station of the Narragansett Electric Company in Providence, R. I., about six months ago and has proved very successful. The plant referred to consists of 400-lb. cross-drum boilers of 1800 hp. each. These boilers supply steam to a 35,000-kw. turbine and desuperheated steam to a lower-pressure and temperature plant. The water-heating cycle consists of a softener and stage bleeding from eighth, twelfth, and fourteenth stages. This plant employs jet condensers and requires 85 per cent make-up as raw water.

The original chemical treatment consisted of a hot-process system which was unsatisfactory and finally abandoned for the Hall system. Phosphate feed was first introduced into the softener and allowed to circulate through the entire water system to the boilers. It was found impossible to keep the high-pressure stage heaters clean. The maximum operating period was about three weeks and at the end of this period the deposits had increased to a point where it was impossible to maintain sufficient boiler-feed pressure. Feed-pump runners were found to contain heavy deposits and check valves did not function.

It was then decided to install high-pressure pumps and feed chemical directly to feed lines beyond the high-pressure heaters, thus bypassing all feedwater heaters. It was thought that the injection of chemical at that point would insure thorough distribution of chemical to all boilers and at the same time eliminate any major deposition in the lines. This, however, did not prove to be the case. In a short time it was impossible to open or close the feed valves, regulating valves failed to function, and the internal feed pipes plugged up, which required frequent cleaning.

The problem was finally solved by feeding chemical directly to each boiler with a system similar to that described in the present paper. Absolutely no trouble has been experienced since.

The writer agrees with the author in the statement that a critical value of the concentration of boiler caustic alkalinity exists. Much trouble with carry-over was experienced until it was discovered that there was a definite maximum point at which the caustic alkalinity could be carried for the production of clean steam. A slight increase above that point gave unlimited superheater trouble.

Much could be said about the control of boiler feedwater to produce clean boilers and clean steam. Every engineer contemplating such control should take advantage of the research work done in the past few years by those who have been forced to solve the issue. The writer wishes to compliment the author in bringing this important development of feedwater condition before the engineering profession. Until a chemical is produced containing the necessary available P_2O_5 and whose sodium salts are soluble, it will be necessary to use the high-pressure system if success is desired.

Author's Closure

Messrs. Jackson and Fritz are probably quite correct in their theories of economizer deposition. When Mr. Jackson states that sodium hydroxide should not be regarded as the primary variable in the foaming of boilers, he evidently refers to a body of data obtained in small-scale experiments on foaming properties.

Mr. Walsh's discussion is in confirmation of the author's statement with regard to hydroxide being the determinant in boiler foaming. Since the presentation of this paper, the author has received additional confirmation of the critical-value theory from sources of reliability. Therefore, he feels justified in strengthening his statement as to the critical function of hydroxide in boiler foaming.

Since the original presentation of this paper, the author has had additional experience with the type of system described. Beyond the completely satisfactory solution of the pump problem, there are few additional remarks to make. The flexibility of this method of feeding chemical has made available cheaper sources of treating chemical, since there is no longer need to purchase on anything but an active-ingredient basis. In addition, two considerable boiler installations have been tied into the systems described, at approximately the incremental cost figures quoted, thus materially reducing the investment per thousand pounds of steam.

Furnace-Gas Compositions and Temperatures in Underfeed-Stoker-Fired Boilers, and Their Effect on Boiler Settings

By ALBERT C. PASINI[1] and EDWARD M. SARRAF[2]

This paper is a study of conditions encountered in boiler furnaces using underfeed stokers. It includes the development of methods of test procedure and their application in investigating furnace-gas compositions, and of determining the temperatures to which the refractories of the setting are subjected. It contains a discussion of the effects of variation of the fuel-bed thickness on the brick in the settings, the efficiency of combustion, and the resultant superheated-steam temperatures. The paper further shows the widely divergent furnace-gas compositions which may be obtained directly over the fire along the wall in underfeed-stoker-fired installations.

COMPARATIVE service tests were instituted at Connors Creek Power House, The Detroit Edison Company, Detroit, Mich., to investigate the reasons for a noticeable difference in refractories service in two boilers (presumably similar in design and operation), and to determine to what degree the variable rate of deterioration of the refractories might be due to conditions of design and operation.

ALBERT C. PASINI

EDWARD M. SARRAF

DESCRIPTION OF BOILERS AND SETTINGS

The boilers under test (known at the station as Nos. 5 and 9) are of the Stirling "W" type, having 23,653 sq. ft. of effective heating surface, and operating at 225 lb. per sq. in. gage pressure and 600 deg. fahr. total steam temperature at the superheater outlet. They are identical in design and construction, as shown in Fig. 1, except that in No. 9 boiler the "B" type baffle[3] in the first pass is behind the third row of tubes, whereas the baffle in No. 5 boiler is behind the second row of tubes. Further, air backs were added to the tuyère stacks along the east front wall of No. 5 boiler within the last two years, while its west front wall and both front walls of No. 9 boiler are without such air backs.

Each furnace is fired on two sides by underfeed stokers of thirteen retorts each, placed in service about twelve years ago. Sectional extension grates and separate rotary clinker grinders are employed.

The furnace settings are solid refractory walls throughout, built of a standard brand of first-quality fireclay brick, laid with thin dipped fireclay joints, and backed with second-quality firebrick. The front walls are 22½ in. thick, and the side walls 28 in. thick. The outside face of the walls is coated with an oil compound containing asbestos to reduce air infiltration.

PROCEDURE FOLLOWED IN TESTS

The test methods employed in this investigation were based on earlier preliminary work. Temperature gradients through the refractory walls were measured by the method[4] devised by the U. S. Bureau of Mines in its five-year study of boiler-furnace refractories, in conjunction with the special research committee of The American Society of Mechanical Engineers.

The first attempts to collect samples of the furnace gases were made with a water-cooled sampling tube 12 ft. in length, but this method was found to be unsatisfactory in several respects. It was impossible to collect a large number of samples simultaneously from different parts of the furnace. The sampling positions could not be located with sufficient accuracy, nor could successive samples be taken from identical positions during the same or different tests. It was not feasible to collect composite gas samples over long periods of time. Instantaneous and composite samples could not easily be taken simultaneously at the same sampling point. The water-cooled sampling tube was heavy and unwieldy, and its manipulation involved considerable labor. Its length was limited to the space between boilers, which prevented a complete traverse of the furnace walls.

As a result of these limitations, it was found necessary to devise other methods for taking samples of the gases within the furnace. The method which was finally developed involved a minimum of effort and labor, was positive and easily controlled, and permitted the taking of composite and instantaneous samples simultaneously over any desired period of time. The sampling positions were definite and remained the same for all tests.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[4] Ralph A. Sherman and W. E. Rice, "Refractories Service Conditions in Furnaces Burning Pittsburgh Coal on Chain Grates," MECHANICAL ENGINEERING, vol. 48 (1926), p. 1115.

The locations of the test equipment are detailed in Figs. 2 and 3, and the various test methods are described in detail below.

Refractories Test Panels. The test panels (marked *A* in Figs. 2 and 3) of unused firebrick of the same brand as the settings, were approximately 36 in. × 24 in. in size and were built into the west front wall of each furnace, about 40 in. above the top of the tuyères, and 2 ft. on either side of the center of the wall.

Temperature Gradients Through the Walls. One 9-in. straight, used as a header (marked *X* in Figs. 2, 3, 7, and 8) in the center of each test panel, was equipped with five thermocouples in accordance with the method of the U. S. Bureau of Mines. The first two couples, spaced accurately 1/2 in. and 1 1/2 in. from the hot face, were platinum, platinum-rhodium couples, as the temperatures at these points were found to be above the safe limits for base-metal couples. Chromel-alumel couples were satisfactorily used at positions 3 in., 4 1/2 in., and 6 in. from the hot face. All thermocouple readings were corrected for cold-junction temperature.

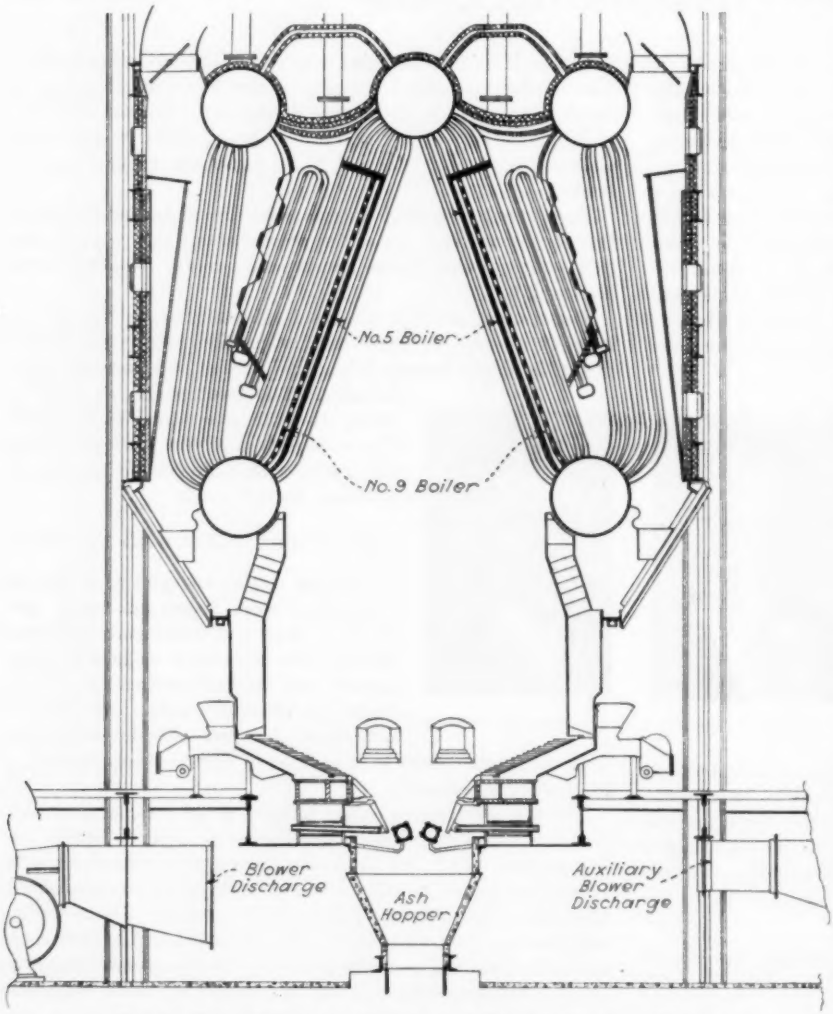

FIG. 1 CROSS-SECTION OF NOS. 5 AND 9 BOILERS (LOOKING NORTH)

Thermocouple readings were taken at hourly intervals during the 14-day period of the tests, and at 15-min. intervals while the individual tests were in progress. Extrapolation of curves drawn from these data gave the temperatures of the hot face of the wall.

Furnace-Gas Compositions. Gas samples were drawn from the furnace at eight sampling points (marked *B* in Figs. 2 and 3) located across the west front wall of the setting at significant positions with respect to tuyères and stoker rams, and at approximately the same elevation as the thermocouple brick in the test panels. Sillimanite tubes were inserted through 2-in. holes punched through the furnace wall, and projected 4 in. into the furnace. The spaces around the tubes were filled with mineral wool to within 5 in. of the hot face (to prevent breakage of the tubes as the walls shifted during the heating-up period), and the spaces at the hot face were filled with fireclay patching mixture.

The sampling-tube connections are shown in detail in Fig. 4. The sillimanite tubes were connected on the outside of the furnace wall to 1/2-in. steel piping leading to the sampling bench, through special copper-tubing connections which served also as stuffing boxes. Each sampling line was fitted with a separate laboratory-type aspirator operated by compressed air. All lines were adjusted to a negative pressure of approximately one inch of mercury.

Furnace gas was drawn continuously through the system and exhausted through the aspirator. Gas samples were taken by siphon action from the sampling offtakes. The rubber-tubing connections were made as short as possible. Before collecting each set of samples, the lines were carefully scavenged, and all connections were checked to eliminate air leakage.

Gas samples were collected in 2 1/2-gal. sampling bottles over saturated sodium chloride solution to reduce the solubility of CO_2 in the collecting medium. The samples were of two types: composite samples, drawn at a uniform rate over a period of one hour, and snap samples, drawn as rapidly as possible in order to determine the conditions at that particular time, and representing a sampling time of 30 to 45 sec. Three sets of composite samples were taken during each test, with a half-hour interval between sets. During all but the first three tests, a set of snap samples was taken at 5-min. intervals simultaneously with the composite sample at No. 5 sampling position, thus affording a cross-section of the composite sample. These snap samples were usually taken during the second set of composite samples.

All composite gas samples were analyzed for CO_2, O_2, H_2, and CO, using a standard combustion-type apparatus; and N_2 was determined by difference. Most of the snap samples were analyzed on the combustion-type apparatus, and when it proved necessary to use the Orsat apparatus for this purpose, care was exercised to insure complete removal of CO before reading the apparatus.

Composite Gas Samples at Entrances to Superheater Pass and Damper. During each test, gas samples were drawn at 15-min. intervals on both sides of the boiler at the entrance to the superheater pass and at the top of the last pass, just below the dampers, and were analyzed with Orsat apparatus for CO_2, O_2, and CO. The samples were composites taken from a 3-in. manifold, having six sampling pipes 3/8 in. in diameter extending into the pass. The gases were mixed in the manifold and drawn continuously

from its midpoint by means of a blower. The sampling connection to the Orsat apparatus was located in the system just ahead of the blower. Special high-temperature tubing was used for the sampling tubes in the superheater pass, and extra heavy steel piping at the damper.

Furnace-Gas Temperatures. An approximation of furnace-gas temperatures was secured during the tests by readings at 15-min. intervals with an optical pyrometer, focused on the closed ends of silicon carbide tubes (marked *C* in Figs. 2 and 3) located in the center of the west front wall of each furnace about 11 in. above No. 4 sampling position (see Figs. 7 and 8), and at a position in the side walls opposite the apex of the combustion chamber. The tubes in the west front walls projected 10 in. into the furnace; and at the apex of the combustion chamber, the tube projected 10 in. into the furnace in No. 5 boiler, and 4 in. in No. 9 boiler, the latter tube being smaller.

Operating-Instrument Readings. Readings were taken at 15-min. intervals during the tests of the following operating instruments:

1 Steamflow-airflow meter
2 Steam pressures: saturated, superheat
3 Total steam temperatures
4 Draft readings: under fire, over fire, damper
5 Gas temperatures at damper.

Hourly readings of the steam output were also taken during the 14-day test period.

Coal and Ash Determinations. Coal samples were taken at half-hour intervals during the test runs, at three positions in each coal spreader, for proximate analysis and determination of fusion point of the ash.

Fires were started in the two boilers under test at 7:30 p.m. on Sunday, March 10. The load cycle on both boilers was kept practically the same during the entire test period, as was shown by the records of the steam-flow meters.

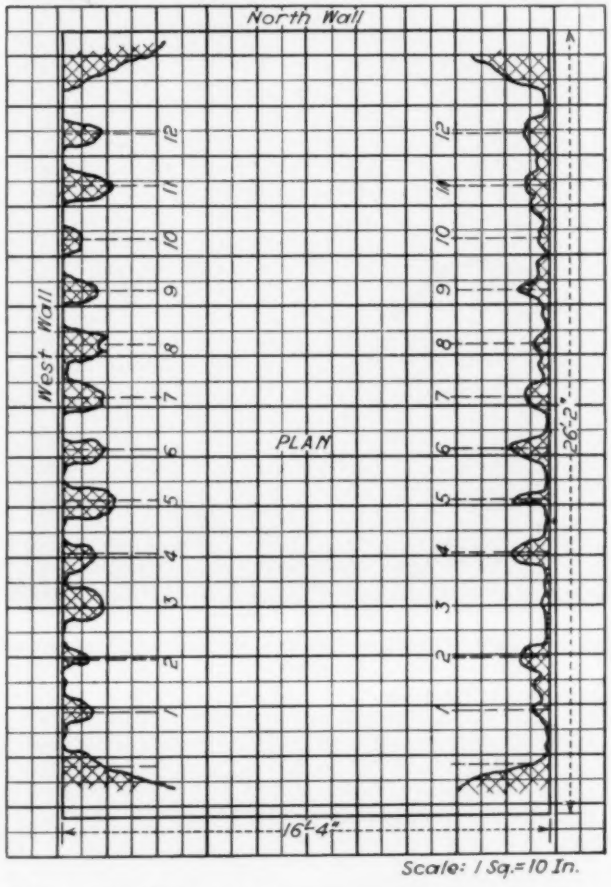

FIG. 11 PLAN VIEW, SLAG ACCUMULATIONS ABOVE TUYÈRES IN NO. 5 FURNACE, AFTER TESTS

The schedule of tests was as follows:

Test	Date	Boiler No.	Boiler output, per cent of rating	Fuel-bed thickness
A	3-13-30	5	145	Normal
B	3-14-30	9	145	Normal
C	3-15-30	9	102	Normal
D	3-17-30	9	187	Normal
E	3-18-30	5	186	Normal
F	3-19-30	5	100	Normal
G	3-20-30	5	230	Normal
H	3-21-30	9	230	Normal
J	3-22-30	5	145	Light
K	3-23-30	5	143	Heavy

Four days were allowed to elapse between starting the fires and the first test, in order to secure equilibrium conditions of heat flow through the walls. For the same reason, the load at which each test was to be run was applied to the boiler at least 6 to 7 hours before starting to take readings. While readings were being taken, the clinker grinders were not in operation, so as not to disturb the fuel bed; however, during the latter part of tests G and H, it proved necessary to run the grinders in order to maintain the desired load.

Immediately following the last test, the boilers were shut down for inspection. Photographs were taken of the settings (see Figs. 5 to 10, inclusive) and the brick in the test panels were removed from the walls and carefully inspected.

RESULTS

The various test data are listed in Tables 1 to 14, inclusive.

Tables 1 and 2 give summarized boiler operating-instrument readings on Nos. 5 and 9 boilers, respectively, and Table 3 contains data on the temperatures obtained during the tests. In Tables 4 to 13 are tabulated the analyses of the composite and snap furnace-gas samples. Table 14 describes the coal used in the investigation, and lists the proximate analyses, calorific values, and ash-fusion points of the samples of coal taken during each test.

During the entire series of tests, every effort was made to hold the two boilers under the same operating conditions at all times. As a general rule, the fuel bed in No. 5 furnace was somewhat lighter than in No. 9 furnace, which is the usual experience with this particular boiler.

The following detailed comments as to the character of the fuel bed and firing conditions in general, during the various tests, may be of interest:

Fuel-Bed Thickness. In the tests at 100 per cent of rating

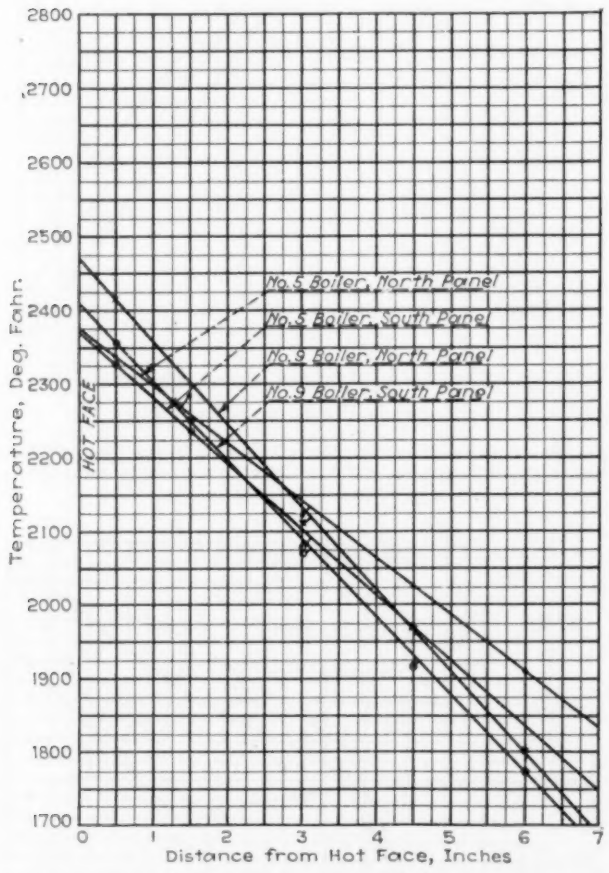

FIG. 13 TEMPERATURE GRADIENTS THROUGH WEST FRONT WALL, NOS. 5 AND 9 FURNACES, 100 PER CENT OF RATING, NORMAL FUEL-BED THICKNESS

(tests F and C), the fires on the east side in No. 5 furnace appeared to be thinner than in No. 9 furnace, while on the west side of each furnace the fires were of normal thickness. This is verified by inspection of the under-fire pressures (Tables 1 and 2).

The fires in No. 5 boiler at 145 per cent of rating (test A) appeared to be thinner on both the east and west sides than in No. 9 boiler at the same rating (test B).

At 185 per cent of rating (tests E and D), the fuel-bed thickness was the same in both furnaces except that the grinder pit carried a higher ash level in No. 5 boiler than in No. 9 boiler. During the first part of the test on No. 9 boiler, the accumulated slag on the south wall started to run.

The fuel-bed thickness in Nos. 5 and 9 boilers was about normal during the runs at 230 per cent of rating (tests G and H), with No. 9 boiler having a slightly heavier fire, as shown by an inspection of the under-fire pressures (Tables 1 and 2). It proved necessary to shorten the tests at this rating, because of the high overloads imposed on the blower motors. In order to maintain the rating during the test on No. 9 boiler, it was necessary to resort to clinker grinding and the consequent agitation of the fuel bed caused a disturbance of the furnace-gas conditions (excessive CO). Because of these abnormal conditions, the data

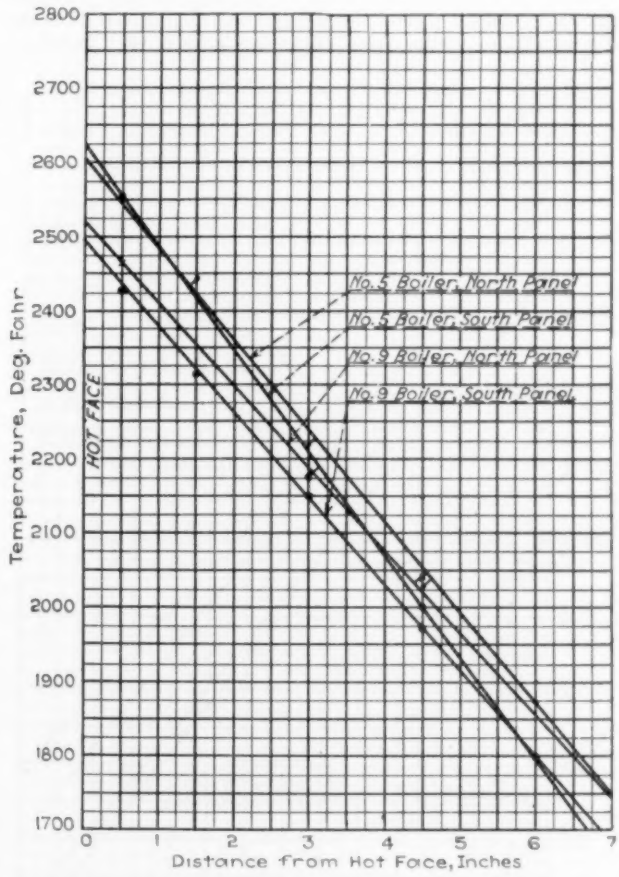

FIG. 14 TEMPERATURE GRADIENTS THROUGH WEST FRONT WALL, NOS. 5 AND 9 FURNACES, 145 PER CENT OF RATING, NORMAL FUEL-BED THICKNESS

on the last set of composite gas samples taken during test H should be discounted.

During the test on No. 5 boiler at 145 per cent of rating with abnormal excess air (test J), the fuel bed was very thin and, in fact, bare iron was showing at the base of the tuyère stacks.

The fuel bed was purposely made very thick in No. 5 furnace at 145 per cent of rating (test K), to establish excess air below the normal for that rating. This is evidenced by a comparison of the under-fire pressures with Test A (see Table I). The slag on the furnace walls was running noticeably throughout this test, and slag accumulations were heavy at the observation doors.

Condition of the Settings. Some idea of the condition of the settings following the completion of the tests may be obtained from Figs. 5 to 10, inclusive. The differences in the character of the slag formations, in the extent of shrinkage and vitrifica-

tion of the brick, and in the tightness of the joints are quite marked.

In No. 5 furnace, serious shrinkage took place in the front walls, with some cracks as wide as $^1/_2$ in. Many of the $13^1/_2 \times 9 \times 2^1/_2$-in. straights used in alternate courses had broken in two. The slag coating (originally 1 in. or more thick) had run from the walls, cleaning large areas of the front walls and lower end walls. The slag on the walls was glassy and vitreous, and stalactites of slag were frequent. Severe spalling had taken place in the leaning walls.

In No. 9 furnace, the setting was much more sound. Less of the original fly-ash and slag coating (somewhat heavier than in No. 5 furnace before the tests) had run from the walls. Shrinkage cracks did not appear through the slag coating, but when the slag was cleaned from the walls, it was evident that shrinkage

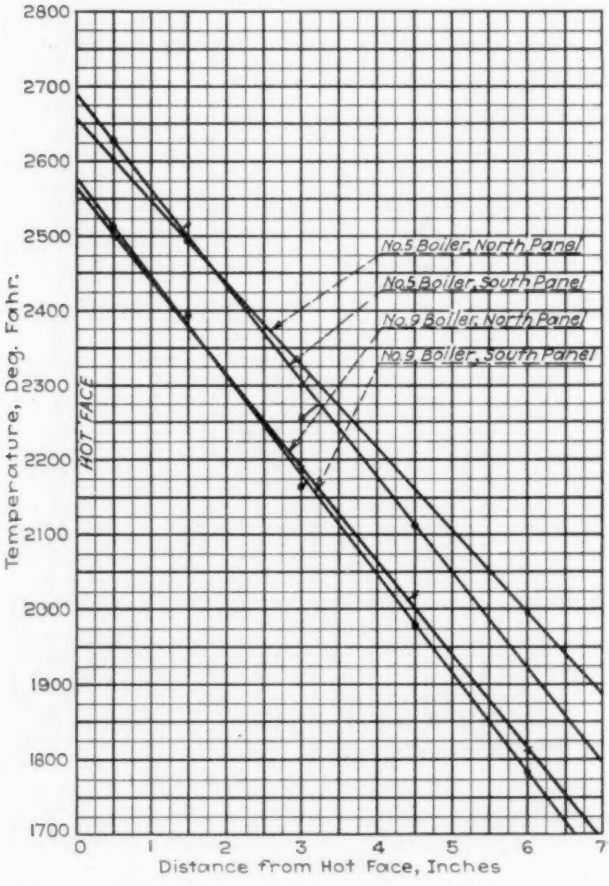

FIG. 15 TEMPERATURE GRADIENTS THROUGH WEST FRONT WALL, NOS. 5 AND 9 FURNACES, 185 PER CENT OF RATING, NORMAL FUEL-BED THICKNESS

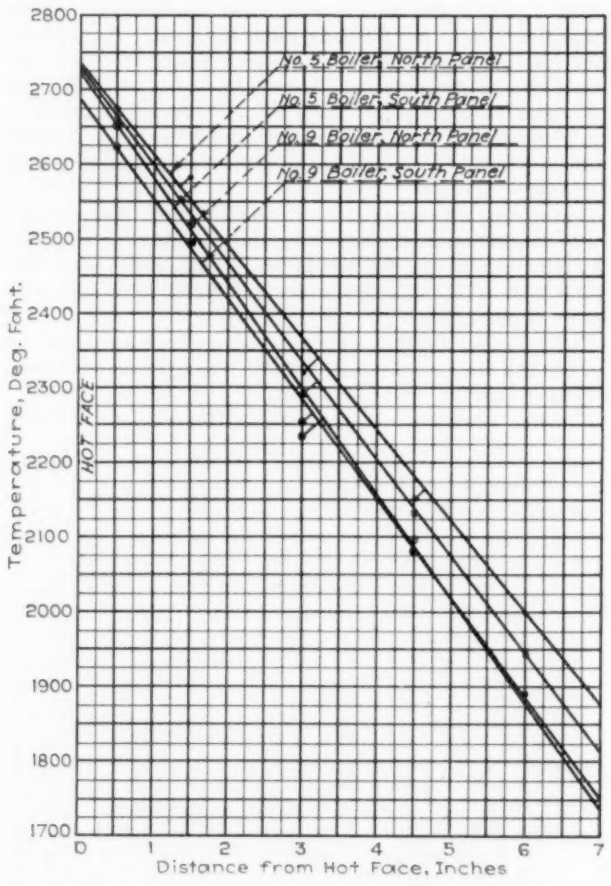
and vitrification of the brick had occurred, although to a considerably lesser extent than in No. 5 boiler. The slag coating on the walls was not as glassy as in No. 5 boiler. Considerable spalling had taken place in the leaning walls.

The brick in the test panels in each boiler had been eroded by the slag, and in fact, as is evident from Figs. 5, 7, and 9, ridges were worn in the brick in No. 5 furnace. The brick in No. 9 furnace had wasted away $^3/_{16}$ in. to $^1/_4$ in., and in No. 5 furnace as much as $^3/_8$ in., as a result of slag erosion. Vitrifica-

FIG. 17 (AT RIGHT) VARIATION OF INSIDE WALL-FACE TEMPERATURES (EXTRAPOLATED) WITH RATING, NOS. 5 AND 9 FURNACES, NORMAL FUEL-BED THICKNESS



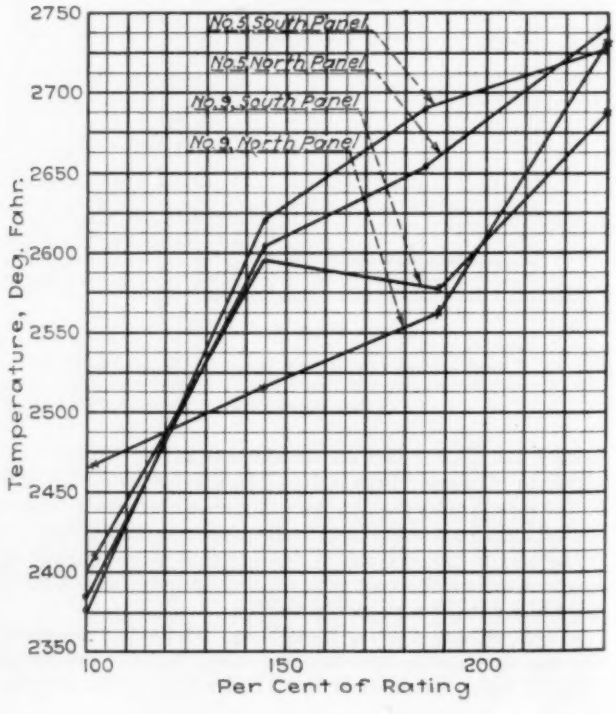


FIG. 16 TEMPERATURE GRADIENTS THROUGH WEST FRONT WALL, NOS. 5 AND 9 FURNACES, 230 PER CENT OF RATING, NORMAL FUEL-BED THICKNESS

tion was evident in the brick to a greater extent in No. 5 than in No. 9 furnace. Apparently the brick had commenced to shrink slightly at the hot face, but to such a small extent that it could not be measured.

Slag Accumulations. Slag accumulations on the walls along the clinker line were lighter than are ordinarily encountered in regular plant operation. The accumulations over the tuyères have been plotted in Figs. 11 and 12. It will be noted that the slag deposits are lighter above the air backs along the east front

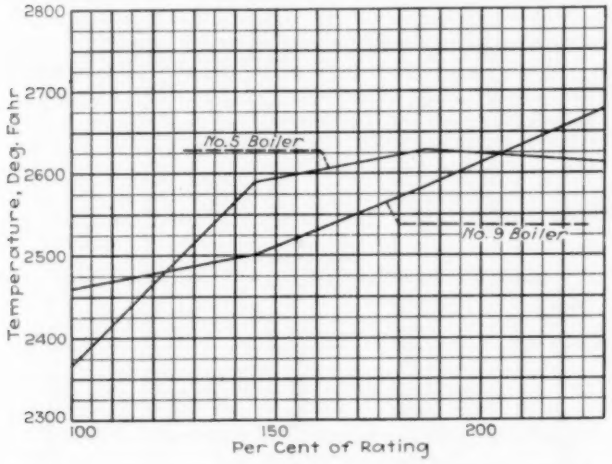

FIG. 18 APPROXIMATE FURNACE-GAS TEMPERATURES, CENTER OF WEST FRONT WALL DIRECTLY OVER FIRES, NOS. 5 AND 9 FURNACES, NORMAL FUEL-BED THICKNESS

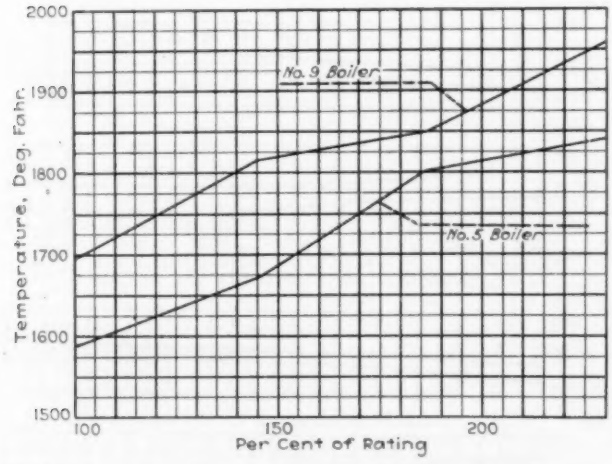

FIG. 19 APPROXIMATE GAS TEMPERATURES AT APEX OF COMBUSTION CHAMBER, NOS. 5 AND 9 FURNACES, NORMAL FUEL-BED THICKNESS

wall of No. 5 boiler than on the west front wall which has no air backs. Figs. 5 to 10, inclusive, show the walls of both furnaces to be fairly free from slag, resulting from the fact that the last tests, conducted at the higher ratings, involved high temperatures which caused the slag deposits to run from the walls.

Stoker Behavior. The tuyère stacks in both boilers were inspected following the tests. In No. 5 furnace, repairs were necessary to Nos. 2, 3, 4, 5, 6, 7, 8, 9, and 12 tuyère stacks on the west side. Nos. 5 and 12 tuyère stacks on the west side of No. 9 furnace were of the old single-piece type, and these were completely burned out, and in addition, repairs were also necessary to Nos. 3, 6, 7, and 8 tuyère stacks. The plenum chambers

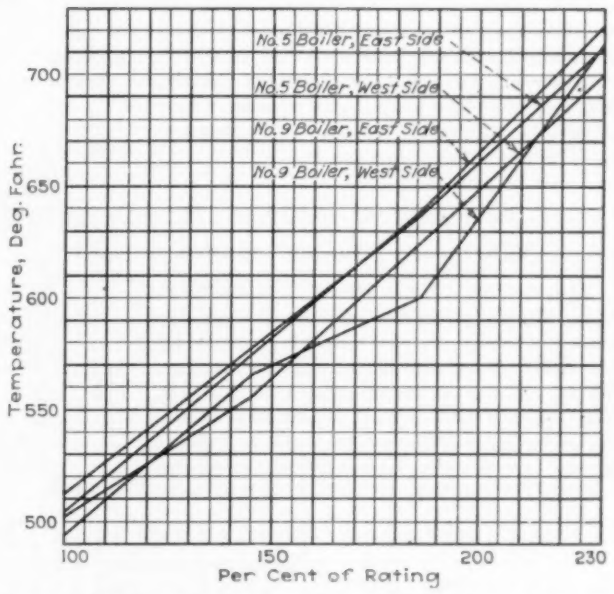

FIG. 20 GAS TEMPERATURES AT DAMPER, NOS. 5 AND 9 BOILERS, NORMAL FUEL-BED THICKNESS

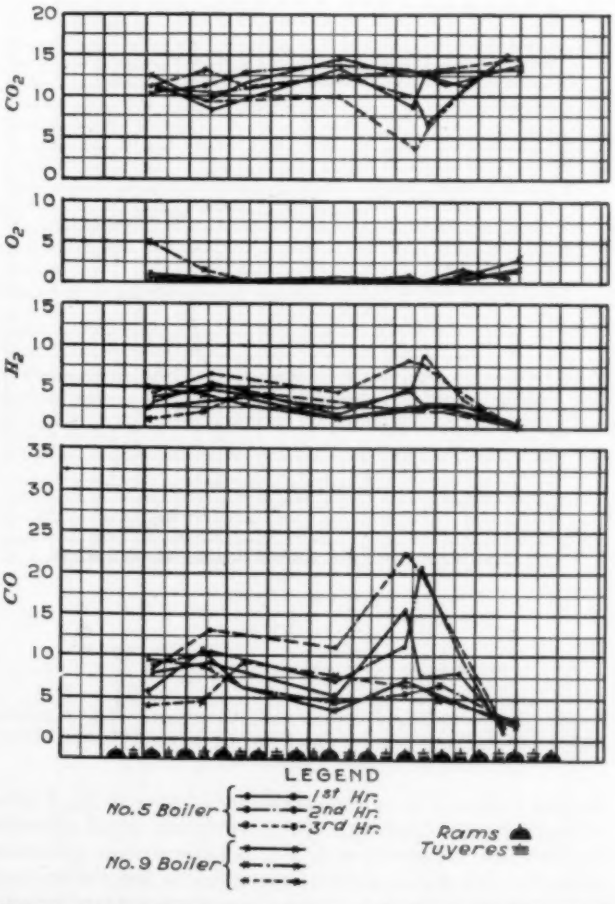

FIG. 21 FURNACE-GAS COMPOSITIONS, COMPOSITE GAS SAMPLES, NOS. 5 AND 9 FURNACES, 185 PER CENT OF RATING, NORMAL FUEL-BED THICKNESS

of both furnaces were also inspected to discover any difference affecting air distribution, and no such differences were found.

These remarks on slag accumulations, tuyères, and wind chambers are included because of their possible bearing on the admission of the air and its deflection into the furnace.

DISCUSSION OF RESULTS

Tests With Normal Fuel-Bed Thickness

Temperatures. For purposes of comparison, the temperature-gradient curves through the west front walls of Nos. 5 and 9 furnaces, for the same rating, are plotted together as Figs. 13, 14, 15, and 16, representing ratings of 100, 145, 185, and 230 per cent, respectively. Careful examination of these figures and of Table 3 shows that the temperatures of the hot face of

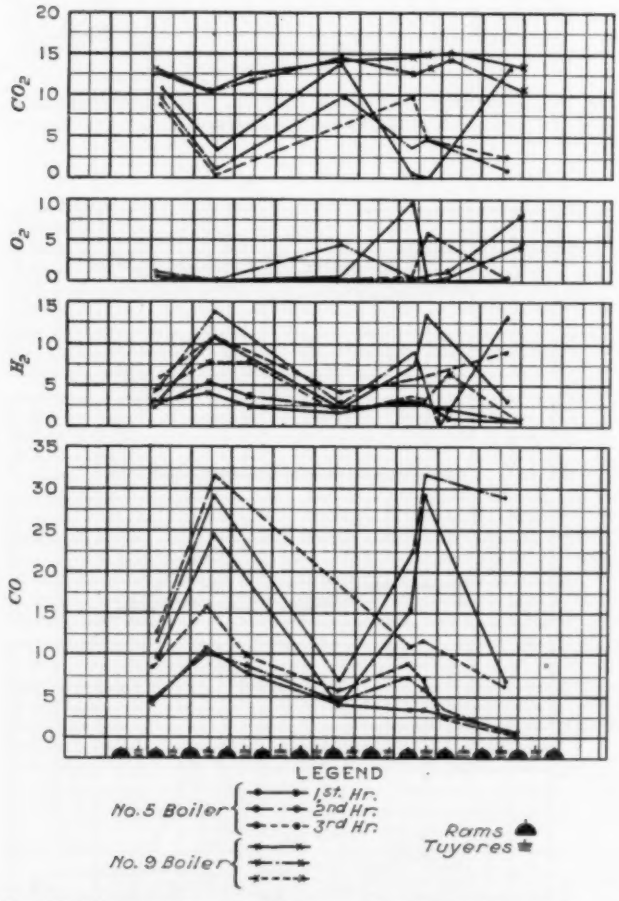

Fig. 22 Furnace-Gas Compositions, Composite Gas Samples, Nos. 5 and 9 Furnaces, 230 Per Cent of Rating, Normal Fuel-Bed Thickness

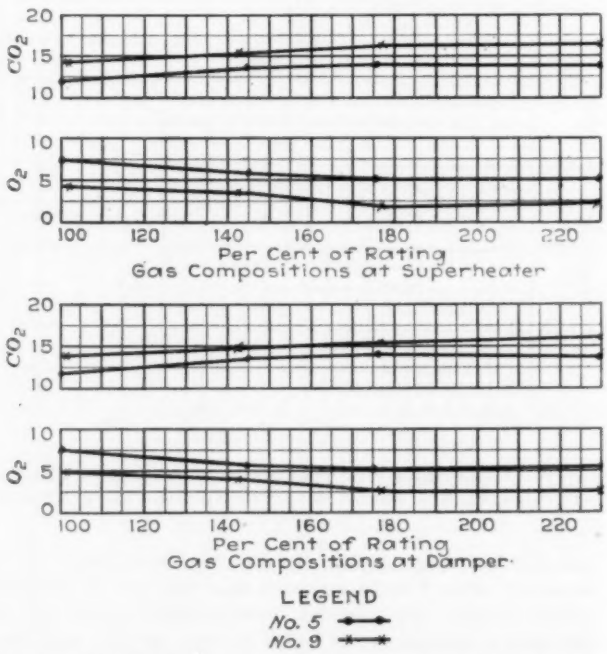

Fig. 23 Gas Compositions at Superheater and Damper, Nos. 5 and 9 Boilers, Normal Fuel-Bed Thickness

the wall (obtained by extrapolation) were higher in No. 5 than in No. 9 furnace, except at 100 per cent of rating, where, although the wall face temperatures in No. 5 furnace were somewhat lower, the temperature-gradient curves had a lesser slope than No. 9 furnace, indicating a higher average temperature through the wall. Temperatures well above 2700 deg. fahr. were obtained in both furnaces at 230 per cent of rating. The relationship between boiler rating and wall-face temperature is shown in Fig. 17.

The evidence of higher furnace temperatures in No. 5 furnace than in No. 9 was confirmed by the optical-pyrometer readings at the center of the west front wall, directly above the fuel bed.

However, the optical-pyrometer readings at the apex of the combustion chamber, and the damper gas temperatures were higher in No. 9 than in No. 5 furnace. At the same time, the steam temperatures were higher in No. 9 than in No. 5 boiler.

The explanation of this condition is apparently dependent on the fact that, since the fuel-bed temperatures were higher in No. 5 furnace, a greater proportion of the energy liberated was in the form of radiant heat. At the apex of the combustion chamber, that portion of the heat energy available by convection was less in No. 5 boiler than in No. 9 boiler, and consequently the temperatures at this point in the furnace were higher in No. 9 boiler. This also accounts for the higher steam temperatures obtained in No. 9 boiler than in No. 5 boiler.

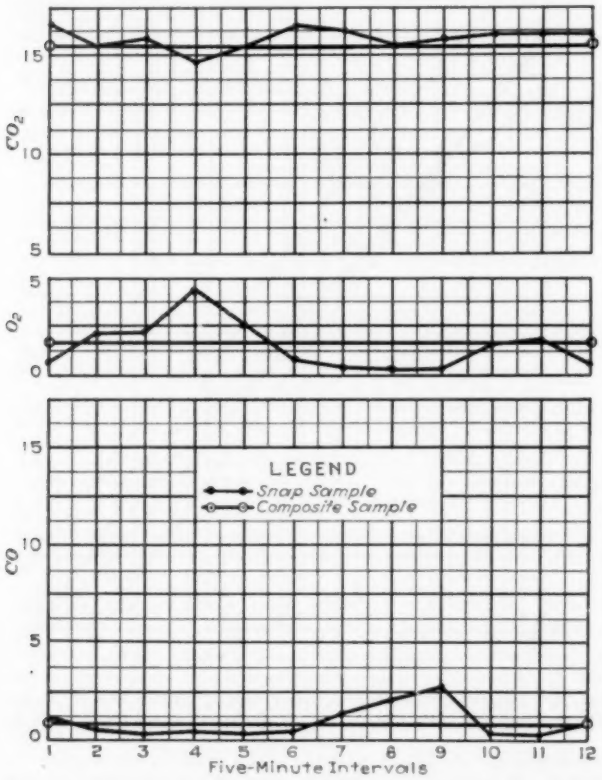

FIG. 24 FURNACE-GAS COMPOSITIONS, SNAP SAMPLES, NO. 5 FURNACE, 100 PER CENT OF RATING, NORMAL FUEL-BED THICKNESS

The optical-pyrometer readings are of little value as absolute data on furnace-gas temperatures, but are probably reasonably accurate as a measure of comparative temperature conditions in the furnaces.

The optical-pyrometer data and stack-gas temperatures given in Table 3 are plotted against boiler rating in Figs. 18, 19, and 20.

Furnace-Gas Compositions. To enable ready comparison, typical analyses of the composite furnace gas samples drawn from both boilers at the same rating (as given in Tables 4 to 11 inclusive) are plotted together, and the locations of stokers and tuyères relative to the sampling positions are also indicated. These data are shown in Figs. 21 and 22 representing ratings of 185 and 230 per cent, respectively.

It is evident that the furnace conditions immediately above the fuel bed were much more strongly reducing in No. 5 than in No. 9 boiler, particularly at the higher ratings. For some unaccountable reason, this situation existed in spite of the fact that the fuel bed in No. 5 boiler was usually somewhat thinner, offering less resistance to the

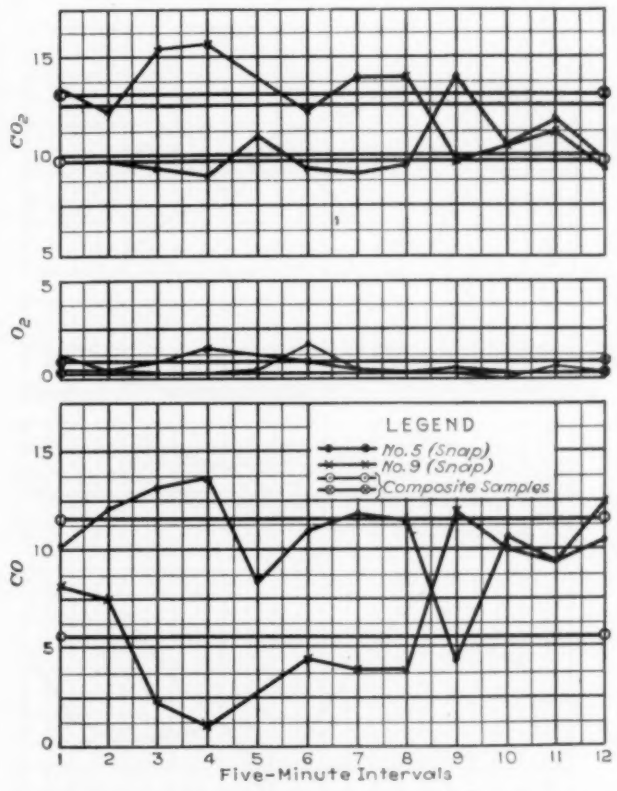

FIG. 25 FURNACE-GAS COMPOSITIONS, SNAP SAMPLES, NOS. 5 AND 9 FURNACES, 185 PER CENT OF RATING, NORMAL FUEL-BED THICKNESS

draft, and also that the gas analyses at the superheater and damper showed lower CO_2 and higher O_2 content for No. 5 furnace at all ratings (see Fig. 23).

The curves in Figs. 21 and 22 cannot be regarded as true curves representing any very definite variation of gas composition across the boiler front wall but, rather, are merely used for purposes of convenience in indicating the furnace-gas com-

positions at certain significant sampling points at which gas samples were drawn simultaneously.

The uniformity in composition of the several sets of composite (hourly) gas samples taken as checks during each test, is evident, and indicates uniform operation of the boilers during the test. However, it would be expected that the furnace-gas conditions would vary considerably for short intervals from time to time, and this is confirmed by the snap samples taken simultaneously with a composite sample at No. 5 sampling position. The variation of these instantaneous samples is plotted against time in Figs. 24, 25, and 26, with the composite samples indicated by straight lines. As will be noted from Tables 4 to 13, the averages of the snap samples usually checked fairly closely with the composite sample drawn at the same time.

(Broken line a–a indicates extent of erosion of wall at end of tests.)

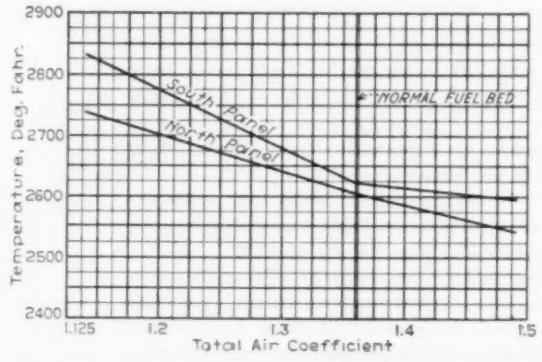

FIG. 29 EFFECT OF FUEL-BED THICKNESS ON INSIDE WALL-FACE TEMPERATURES (EXTRAPOLATED), NO. 5 FURNACE

Frequently carbon particles of colloidal dimensions were drawn over with the gas samples, and these were usually precipitated upon standing for a short time, forming a scum of soot over the saturated salt solution used as the collecting medium. The

collecting solution was at times discolored by certain substances, presumably tarry compounds distilled from the coal, which were collected during the sampling process. In certain instances, sufficient volatile compounds were carried over with the gases to form a film of oil over the salt solution.

Excess Air. It has already been mentioned that the superheater and damper gas compositions showed lower CO_2 and higher O_2 content in No. 5 than in No. 9 boiler at all ratings. These data are given in Tables 1 and 2, and plotted against boiler rating in Fig. 23. This condition was verified by the fact that the fuel bed in No. 5 tended to be somewhat lighter than in No. 9 furnace.

On checking those factors which might affect the distribution of air to the tuyères, as already noted, no differences were found in the plenum chambers, and although more tuyère stacks required renewal and repair following the tests in No. 5 than in No. 9 furnace, this factor would hardly seem to account for the difference. Of course, No. 9 boiler is baffled somewhat differently than No. 5, but other boilers at the station have the same baffling as No. 9, and behave somewhat like No. 5 boiler.

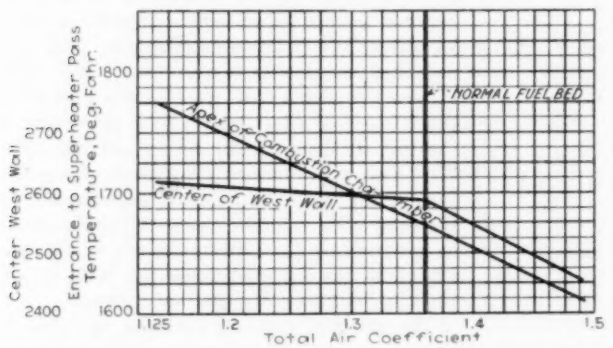

FIG. 30 EFFECT OF FUEL-BED THICKNESS ON APPROXIMATE FURNACE-GAS TEMPERATURES DIRECTLY OVER FIRES, NO. 5 FURNACE

Total Steam Temperatures. The total steam temperatures were higher in No. 9 than in No. 5 boiler, as indicated in Tables 1 and 2, and shown in Fig. 27.

Effect on Refractories. The effect of these tests on the boiler settings has already been described, and is evident from a careful inspection of Figs. 5 to 10, inclusive. Slag attack, shrinkage, and vitrification of the brick in the settings were obviously worse in No. 5 than in No. 9 furnace. Careful analysis of the steamflow-airflow meter charts since the furnace walls were last repaired showed that past load conditions averaged about the same for both boilers.

The severity of the furnace conditions during the tests may be deduced from the condition of the sillimanite sampling tubes. Several had been broken, either from having been struck by pieces of ash or slag, or from having been so weakened by slag attack as to be unable to support their own weight. As is evident from Fig. 8, the sampling tube at position No. 4 in No. 9 boiler had softened and sagged, and was eaten through by slag. Those tubes that had not broken during the tests were slagged about halfway through, with pinhole openings where the slag had completely penetrated, and were so fragile that they broke at a touch. The sillimanite tubes in No. 5 boiler were practically all broken off at the hot face of the wall during the tests, whereas most of those in No. 9 boiler were unbroken.

These factors are all the more striking when it is remembered that the sillimanite tubes are composed of super-refractory

material of approximately 70 per cent alumina content, with a fusion point about 200 deg. fahr. higher than a first-quality clay firebrick. Moreover, the porosity of the tubes is very low, which should increase their resistance to chemical action and slag penetration.

One thermocouple brick from each boiler, and one adjoining brick from the same test panel, together with composite samples of the coal burned during the tests, were sent to the U. S. Bureau of Standards, Columbus, Ohio, for petrographic study of the effect of slag. Their observations will presumably be reported at a later date.

Tests With Abnormal Fuel-Bed Thicknesses

Temperatures. The temperature-gradient data (as given in Table 3) through the west front wall of No. 5 furnace at 145 per cent of rating with varying fuel-bed thicknesses are plotted in Figs. 28 and 29 and indicate exceptionally high furnace-wall temperatures with heavy fuel bed. It seems probable that much of the erosion of the brick in the test panels took place during the test with abnormally heavy fuel bed (test K). This would naturally influence extrapolation of the wall-face temperature, because the thermocouples would be nearer to the wall face, as indicated by the broken line *a–a* in Fig. 28. Of course, the slag coating on the brick would tend to counteract the effect of erosion.

The effect of fuel-bed thickness on furnace-gas temperatures at the center of the west front wall and at the apex of the combustion chamber as evidenced by optical-pyrometer readings at these points (given in Table 3) is plotted in Fig. 30, and the effect on steam and stack-gas temperatures is shown in Fig. 31.

Furnace-Gas Compositions. The gas-composition data on composite and snap samples drawn from No. 5 furnace at 145 per cent of rating with normal, light, and heavy fuel beds are given in Tables 6, 12, and 13, respectively, and are plotted in Fig. 32. As would be expected, the proportion of combustibles and reducing character of the furnace gases were greatly increased with heavy fuel beds.

Excess Air. Obviously, the proportion of excess air was increased by lighter fuel-bed thickness, and vice versa.

Steam Temperatures. As will be noted from Fig. 31, a higher total air coefficient (lower CO_2 in stack gases) resulted in higher total steam temperatures, while the stack-gas temperatures were also higher. Apparently, there is a balance point where the greater plant efficiency resulting from higher steam temperatures more than equalizes the heat losses due to greater volume of hotter stack gases. It is evident, also, that a higher total air coefficient will result in lower boiler operating temperatures and less strongly reducing furnace conditions, thus prolonging the life of the refractory settings.

Effect on Refractories. Tests J and K show conclusively that the thickness of the fuel bed

has considerable effect on the life of the brick settings. However, it should be understood that the abnormal furnace conditions during tests J and K should never prevail for any appreciable length of time during regular operation.

The detrimental effect of abnormally heavy fuel bed on the refractories is very evident, in that the boiler temperatures were higher, the furnace atmosphere was severely reducing, and the slag[5] was far more fluid, greatly accelerating mechanical penetration and chemical attack. It seems probable that much of the erosion of the brick in the test panels took place during test K, since the slag on the walls was running throughout this test, the temperatures were very high, and the furnace gases were severely reducing. This is confirmed by the fact that the average temperatures at Nos. 1 and 6 thermocouples ($^1/_2$ in. from original hot face of brick in north and south panels) were considerably higher during the latter stages of the test, whereas the steam flow was lower.

[5] It is a generally accepted theory that the chemical attack of a coal-ash slag is more severe under reducing furnace conditions, because the iron present tends to be converted to the ferrous state, forming ferrous silicates which melt at lower temperatures than the corresponding ferric silicates obtained under oxidizing conditions.

CONCLUSIONS

At corresponding ratings, the operating conditions affecting refractories service are more severe in No. 5 than in No. 9 furnace; and particularly, the temperatures of the furnace gases and of the hot face of the wall in the lower part of the combustion chamber are higher in No. 5 than No. 9 furnace, the furnace gases are more strongly reducing, and the slagging action of the ash is greater. The evidences of these more severe conditions in No. 5 than No. 9 furnace are the greater shrinkage, vitrification, and erosion of the refractories.

Variation of the fuel-bed thickness has great bearing upon the life of the refractory brick. A heavy fuel bed produces a more strongly reducing atmosphere and higher furnace temperatures, which impose more severe conditions on the brick.

It is usually possible by increasing the proportion of excess air to reduce the severity of the conditions affecting the refractory settings. The extent to which this may be done at the expense of boiler efficiency, without decreasing plant efficiency, depends on the balance between heat losses up the stack and the increased plant efficiency resulting from higher superheated steam temperatures with convection-type superheaters.

ACKNOWLEDGMENT

Grateful acknowledgment for their many helpful suggestions is made to Messrs. W. A. Carter, Technical Engineer of Power Plants, The Detroit Edison Company, and J. Spotts McDowell, Director of Research, Harbison-Walker Refractories Company.

Discussion

DR. D. S. JACOBUS.[6] The Society is indebted to the authors of this paper for presenting the results of a series of tests made in the thorough and careful way that characterizes researches of the sort conducted by the Detroit Edison Company. The results are consistent in showing that placing the baffles which come nearest the furnace back of the third row of tubes in boiler No. 9 instead of back of the second row of tubes, as in boiler No. 5, led to lower furnace and wall temperatures and to lesser deterioration of the brickwork. This has been borne out in some of our own tests.

The falling off of the temperature as the distance from the faces of the walls increased shows how a firebrick wall may have enough strength in its cooler portions to allow it to be operated at near the fusing point of the brickwork at its inner face.

The difference in the degree of erosion of the walls in the two boilers demonstrates the importance of the temperature factor on the life of brickwork where corrosive slags are present. Even though there was apparently only about 50 to 100 deg. lower temperature on the wall faces in boiler No. 9 than in No. 5, the amount of slag erosion in the former was materially less, indicating that the rate of reaction increases out of all proportion to the increase in temperature.

The amount of excess air given in Tables 1 and 2 averages 17 per cent less for the normal fuel-bed thickness for the tests with the No. 9 furnace than for the No. 5 furnace. Where the

[6] Advisory Engineer, Babcock & Wilcox Co., New York, N. Y. Mem. A.S.M.E.

percentages of CO_2 are as high as were carried in the tests, lessening the amount of excess air may cause the flames to travel a greater distance. This may have been an additional element to that described in the paper in producing a higher gas temperature at the apex of No. 9 furnace than in No. 5 furnace.

The amount of CO in the gases drawn from the furnace and the very small amount of CO in the gases at the superheater and at the damper shows that the CO was burned in the upper part of the furnace. In tests that the writer made a long time ago at the Delray plant of the Detroit Edison Company on the same type of boilers it was found that there was a mingling action of the gases in the furnace which, combined with the large size and form of the furnace, led to an effective burning out of the combustible elements.

RALPH A. SHERMAN.[7] In the introductory chapter of the forthcoming bulletin of the Bureau of Mines, "A Study of Refractories Service Conditions in Boiler Furnaces," the following statement is made:

> Study of the data presented will show that conditions in a boiler furnace are extremely variable. It would be impossible, even if experimental investigations such as these were extended to a great number of furnaces of each type, to plot or tabulate more than an average of any service conditions, such as the temperature, gas composition, or velocity to be expected at any given rate of firing. Each furnace, even in the same plant, has its distinctive characteristics so that an individual analysis of special conditions will often be necessary.

The results of the investigation which the authors present in this paper fully confirm this statement. Although the work has been done in the thoroughgoing manner that characterizes all investigations conducted by the Detroit Edison Company, and although the existence of the different furnace conditions in two furnaces, apparently exactly alike, was clearly shown, yet the fundamental causes of these differences were not discovered.

An unusual stratification occurred in boiler No. 5, for although the gases at the front wall were more strongly reducing than in boiler No. 9, yet enough air entered elsewhere to complete the combustion before the superheater and, as the authors have pointed out, to give a lower content of CO_2 in boiler No. 5 than in No. 9. This stratification, with consequently delayed combustion, and the lower content of CO_2, are not in accord with the lower steam temperatures and gas temperatures at the damper in boiler No. 5 than in No. 9 and are to the writer the most puzzling features of the results.

The elaborate system for simultaneous sampling of the gases along the front wall was very good, but the writer wishes to call attention to the danger of using a refractory tube for the withdrawal of gas samples which may contain combustion gases. If free oxygen is present, the intimate mixing in the high-temperature tube will result in further combustion in the tube, and it is the writer's experience that even with a short distance of travel the gas collected in the sample holder may contain several per cent more CO_2, and less O_2, CO, H_2, and CH_4, than actually present at the point of sampling. In the absence of free oxygen, as in many of the samples of the investigation reported, there is opportunity in the hot refractory tube for the cracking of hydrocarbons, the deposition of soot, and the reduction of CO_2 by the incandescent carbon resulting in the collection of a gas with lower CO_2 and CH_4, and more CO and H, than at the point of sampling. By the use of a water-cooled sampling tube, the gas is quickly cooled to a temperature at which no reactions can occur, and the collection of a sample with the composition of that at the point of sampling is insured.

Many boiler plants have conditions similar to this where the refractories service is more severe in one furnace than in another apparently exactly the same. Similar investigations of this type, though not necessarily as elaborate, could not fail to lead to valuable information on the furnace conditions and, usually, to the determination and ultimate removal of the cause of the unusual conditions.

P. NICHOLS.[8] A reading of the paper is rather disappointing in that it stops short at the most interesting point. Like good detectives, the authors determined how the crime was committed, but apparently failed to arrest the criminal; perhaps they have left it open to the discussors to suggest solutions and will explain in their closure how the difficulties which were the cause of the investigation were overcome. They state that furnaces 5 and 9 were similar in all respects except that No. 9 had some advantage because three rows of tubes were exposed against two in No. 5; also, No. 5 had air backs on the east front wall. Apparently the latter difference can be eliminated as a factor because all measurements were made on the west wall, which was similar to that of No. 9. It would not be expected that the third row of tubes would make any material difference in the cooling of the front wall or on the fuel bed since, as shown by Professor Hottel, the radiation absorbed by the third row of tubes is very small, nor could the extra row of tubes appreciably affect the flow of gases near the fuel bed.

It is suggested that one more item of evidence would have been obtained by measuring the velocity of the gases at the west walls, but as it is, the authors proved that during the tests the average temperatures of the gases and walls were higher near the west face in No. 5 than in No. 9, and also that the CO in the gases was appreciably greater, but because the excess air in the flue gas was higher in No. 5, more air must have entered through the lower part of its bed. They conclude, therefore, that the fuel bed of No. 5 tended to be thicker, and presumedly they also conclude that this was the reason that its refractories showed more deterioration in regular operation previous to the tests.

They do not, however, give any explanation for this tendency to have greater thickness; presumedly the blame is not placed on differences in the human operating factor, but was caused by some peculiarity in the stoker. By a thicker fuel bed, do they mean for its whole length or was it only in the upper part? That would seem more probable as an average chance occurrence than that it should be thicker all the way down. The first explanations that one would offer for such a relative condition in No. 5 are that either the flow of air through the upper part was less for some unexplained reason or that the motion of the fuel was not the same because of some small difference in the mechanism—or it might be because No. 5 tended to get different size fuel on the average.

There is a large lack of, at least, published knowledge of the flow of the stream lines of coal in underfeed stokers. Some imagination of what this is and some ability to depict where combustion of the carbonized coal occurs are necessary to fix where the ash is released; this was of interest to us in our investigation on clinkering, but we could get very little help from operators or others.

It would be interesting to know whether, having settled that the main trouble was the thicker fuel bed, it has been possible to operate No. 5 since the tests in such a manner that the refractories give no more trouble than occurs in No. 9.

AUTHORS' CLOSURE

The authors would like to point out that this investigation was begun originally as the study of an operating problem;

[7] Fuel Engineer, Battelle Memorial Institute, Columbus, Ohio.

[8] Supervising Fuel Engineer, Pittsburgh Experiment Station, U. S. Bureau of Mines.

namely, a noticeable difference in performance between two boilers which should behave alike. The first step was to discover the character and magnitude of these differences in operation, as reported in the paper; and the second step would be to remove such differences. In the meantime, however, other conditions arose which made it impractical to carry the tests to a logical conclusion.

Although, as Mr. Nichols points out, the criminal was not apprehended, some of the methods followed in pursuing him may be of interest to other central-station operators. All data have been reported in very complete form, with the hope that others who have observed similar differences in operation between units which should behave alike may be able to offer helpful comments.

Mr. Sherman mentions the possibility of change in the composition of the gas sample during its passage through the hot end of the refractory tube, due to catalysis or to more intimate contact between combustibles and unconsumed oxygen. On the other hand, it has been claimed that the introduction of a water-cooled sampling tube into a furnace may so chill the gases in its vicinity, or otherwise alter the combustion conditions, that the gas sample collected through it may not be strictly typical. In order to compare the two methods of sampling, composite gas samples were drawn for a 45-minute period, directly over the fire in No. 12 boiler, through sillimanite and water-cooled sampling tubes whose ends were within $^1/_2$ in. of each other. The analyses of these samples, in percentages, are shown in the table.

These analyses may be considered to be "checks" within the normal experimental variations of sampling and analysis.

This paper will have served its purpose if it describes a method of studying boiler-furnace operating conditions, and shows the differences which may exist between units which should normally function similarly.

FSP-53-25

South Amboy Plant of the Jersey Central Power and Light Company

By R. C. ROE[1] and J. P. MAILLER,[2] NEW YORK, N. Y.

The Jersey Central Power & Light Company, an operating unit in the Middle West Utility System, has just put into operation a new plant on the Raritan River at South Amboy, N. J., designed and constructed by the Electric Management & Engineering Corporation of New York City. This plant at present consists of two 25,000-kw. vertical-compound turbines with condensers and all auxiliaries and three 280,000 lb. of steam per hr. boilers, furnaces, and accessories, operating at 1400 lb. pressure. Space has been provided for the installation of a third turbine within the station which is approximately 168 ft. square and 110 ft. high to the boiler-room roof and is constructed along modern architectural lines.

The plant is located at the geographical center as well as the load center of the system and will, when the transmission lines are completed, serve as a base-load plant for both the Northern and Southern divisions, which at the present time are operated as independent divisions.

THE UNUSUAL features of the South Amboy station of the Jersey Central Power and Light Company are:

1 The use of outside concrete cylindrical-type bunkers which allows extremely light and airy boiler room and firing aisle.

2 The use of unit boiler-turbine construction, one boiler per turbine with a spare boiler applicable to either turbine, which eventually will be used for the third turbine.

3 The use of double-deck, compound turbines as a single unit without provision for separate operation.

4 The use of condensers designed for higher vacuum than has been customary.

5 The use of a five-point regenerative cycle with direct-contact heaters on all stages, eliminating drip pumps or condensate cascading and bringing terminal differences practically to zero, with expected improvement in overall thermal efficiency.

6 The use of premeasuring devices for coal and air, and individual mills per burner with multiple burners per boiler, permitting great flexibility and accurate predetermination of combustion conditions prior to the actual combustion.

A complete description of the plant appeared in the July 15, 1930, issue of *Power Plant Engineering*. A brief description of the station and its preliminary operation is as follows:

Coal and Ash Handling and Pulverization

Coal may be procured in the station by rail or water, being handled by rail by a balanced skip hoist through a Bradford breaker and a belt conveyor to the station bunkers and by water through a Mead-Morrison barge unloading equipment to the same Bradford breaker and belt conveyor. Arrangements are also made for the storage and reclamation by drag scrapers.

The station is unique in the fact that it has no inside bunkers nor inside storage of coal, all active coal storage being in six outside concrete bunkers or silos, two per boiler, each of 125 tons. From each of these concrete bunkers, three spouts are taken, two spouts leading to individual pulverizers and the third spout to the corresponding spout from the adjacent bunker to feed a common pulverizer. By this arrangement the two bunkers serve five pulverizers, all of the ball-mill type. Each pulverizer is equipped with its own primary fan and burner, there being five burners for each furnace.

Coal is ground to a fineness of 88 per cent through 200 mesh, according to the manufacturer's guarantees. Ash is removed from the furnace in a molten state by the usual slag-tapping method into an Allen-Sherman-Hoff conveying system.

Air and Gaseous Products of Combustion

Air is taken from the top of the boiler room through a pair of forced-draft fans, a tubular air preheater and metering devices

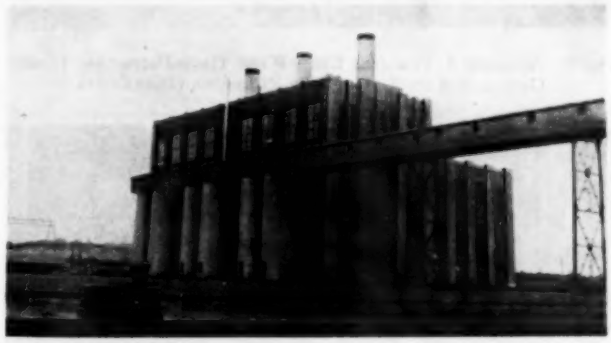

Fig. 1 Exterior of South Amboy Plant of the Jersey Central Power and Light Company

to the pulverizers and burners. The burners on two of the boilers are of the Calumet type and on the other boiler are of the Roe type. The products of combustion pass through an eight-tube boiler section, the initial superheater, the gas section of the steam resuperheater, economizer, and air preheater, and hence through connecting ducts to twin induced-draft fans which are mounted in the base of a venturi stack. Provision is made for the removal of soot by compressed-air soot blowers and removal of accumulated soot in the hopper between the economizer and air heater by the Allen-Sherman-Hoff conveying method.

Steam and Water Cycle

Steam leaves the boiler drum through the distributing tubes to the superheater which is built as an integral part of the boiler and immediately above the boiler-tube sections. It then goes through the desuperheater and main steam piping to the high-pressure turbine throttle, thence through the high-pressure turbine and intermediate piping to the steam to steam reheater, thence to the gas-steam reheater and then to the low-pressure turbine, after passing which it goes to the condenser, which is of the divided water-box, single-pass type with tubes rolled at both ends and arranged for extremely high vacuum.

[2] Chief Engineer, Electric Management and Engineering Corporation. Mem. A.S.M.E.

Presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Steam for the regenerative cycle is extracted as follows: From the fifth stage of the high-pressure unit for No. 5 heater, from the exhaust of the high-pressure unit for No. 4 heater, from the first stage of the low-pressure unit for No. 4 heater, from the seventh stage of the low-pressure unit for No. 2 heater and from the twelfth stage of the low-pressure unit for No. 1 heater. The evaporator operates in parallel with No. 3 heater and discharges condensate into No. 3 heater. The heater system, it is believed, is different from any other now installed, in that all bleeder heaters are of the direct-contact type arranged for coordinated

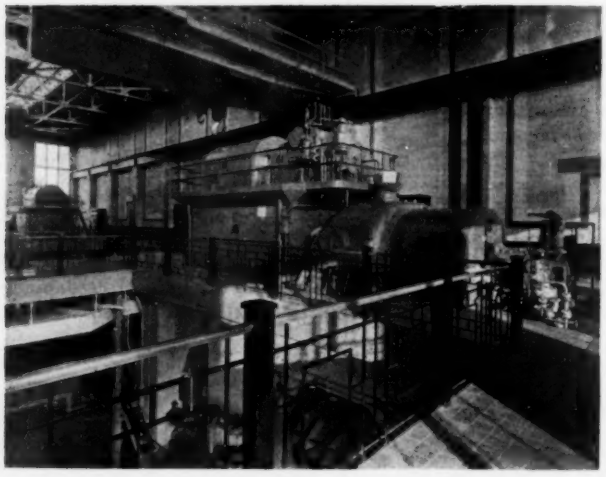

FIG. 2 NUMBER 3 TURBINE UNIT WITH HIGH-PRESSURE TURBO-GENERATOR ON TOP OF LOW-PRESSURE GENERATOR

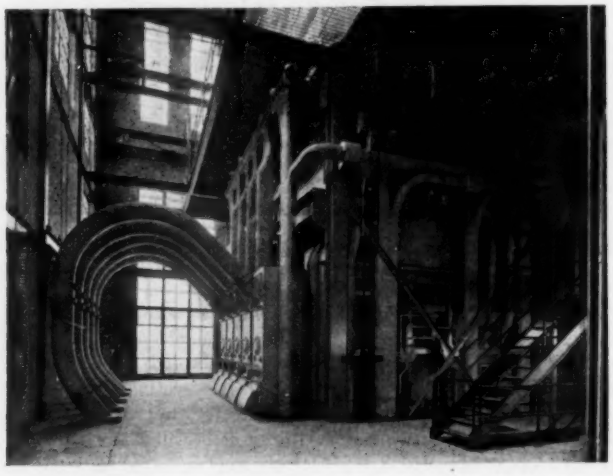

FIG. 3 NUMBER 3 BOILER—NOTE ABSENCE OF BUNKER AND LIGHT-FIRING AISLE

water and steam flow with specially designed pumps which will be described later. Provision is made for the proper air removal and deaeration by the venting of each heater through a vent condenser to the next preceding heater and finally from No. 1 heater to the main condenser at a point suitable for air removal. The condensate is taken from a storage-type hotwell at the bottom of the condenser, supplemented by an outside condensate storage for overflow and renewal purposes, by means of the first section of a three-section, variable-speed condensate pump, thence from the first- and second-stage condensers for the steam-jet air pumps, generator air cooler, oil cooler, and to No. 1 heater. From No. 1 heater, the condensate flows to the second section of the condensate pumps, then through the third-stage condenser to the steam-jet air pumps to No. 2 heater; from No. 2 heater the condensate flows to the third section of the condensate pumps, through the evaporator condenser and thence to No. 3 heater. From the storage tank of No. 3 heater, the condensate flows to the first section of a variable-speed two-section booster pump and thence to No. 4 heater. The condensate then flows to the second section of the booster pump and to No. 5 heater, and from the storage tank of this heater the condensate is taken by a constant-speed boiler feed pump through the economizer to the boiler.

The condensate and booster pumps are designed for and are controlled to give the required head and capacity between their respective heaters to accommodate varying loads on the turbine and in accordance with the bleed-point pressures, which pressures are the highest on No. 5 heater and taper down to the lowest on No. 1 heater and also vary in accordance with the load on the turbine. The boiler-feed pumps take condensate from the tank of No. 5 heater, and because of the change in heater pressure due to change in load, this pump is designed with special head-capacity characteristics for constant-speed operation, giving practically constant boiler-feed pressure throughout the load range without the use of regulating valves or other devices to accomplish this purpose.

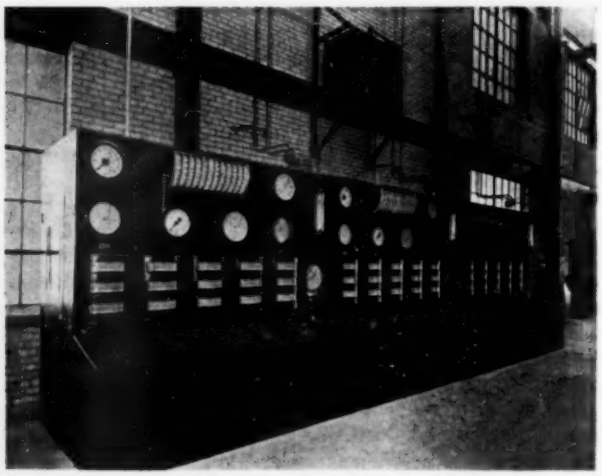

FIG. 4 BOILER-ROOM CONTROL BOARD, WITH THREE-DIAL COAL AND AIR METERS

STEAM TEMPERATURE CONTROLS

The initial steam temperature is controlled by the automatic operation of the desuperheater compensated to maintain 750 deg. at the turbine throttle by means of a butterfly bypass valve operated by thermostatic temperature control. The desuperheater takes its water from and returns the steam evaporated to the corresponding boiler drum. The steam for the low-pressure unit is maintained at 750 deg. at the throttle somewhat similarly by the regulation of the amount of high-pressure steam to the steam to steam reheater.

METERS

All the boiler-room meters, indicators, and controls are grouped on a centralized control board located in the center of the boiler room where the operator can see all the boilers.

An interesting feature of this board is the coal and air meters. The coal fed to each burner is weighed individually and indicated in pounds per hour and per cent of burner rating for varying fuel-heat contents on these meters. Likewise, in the same meter

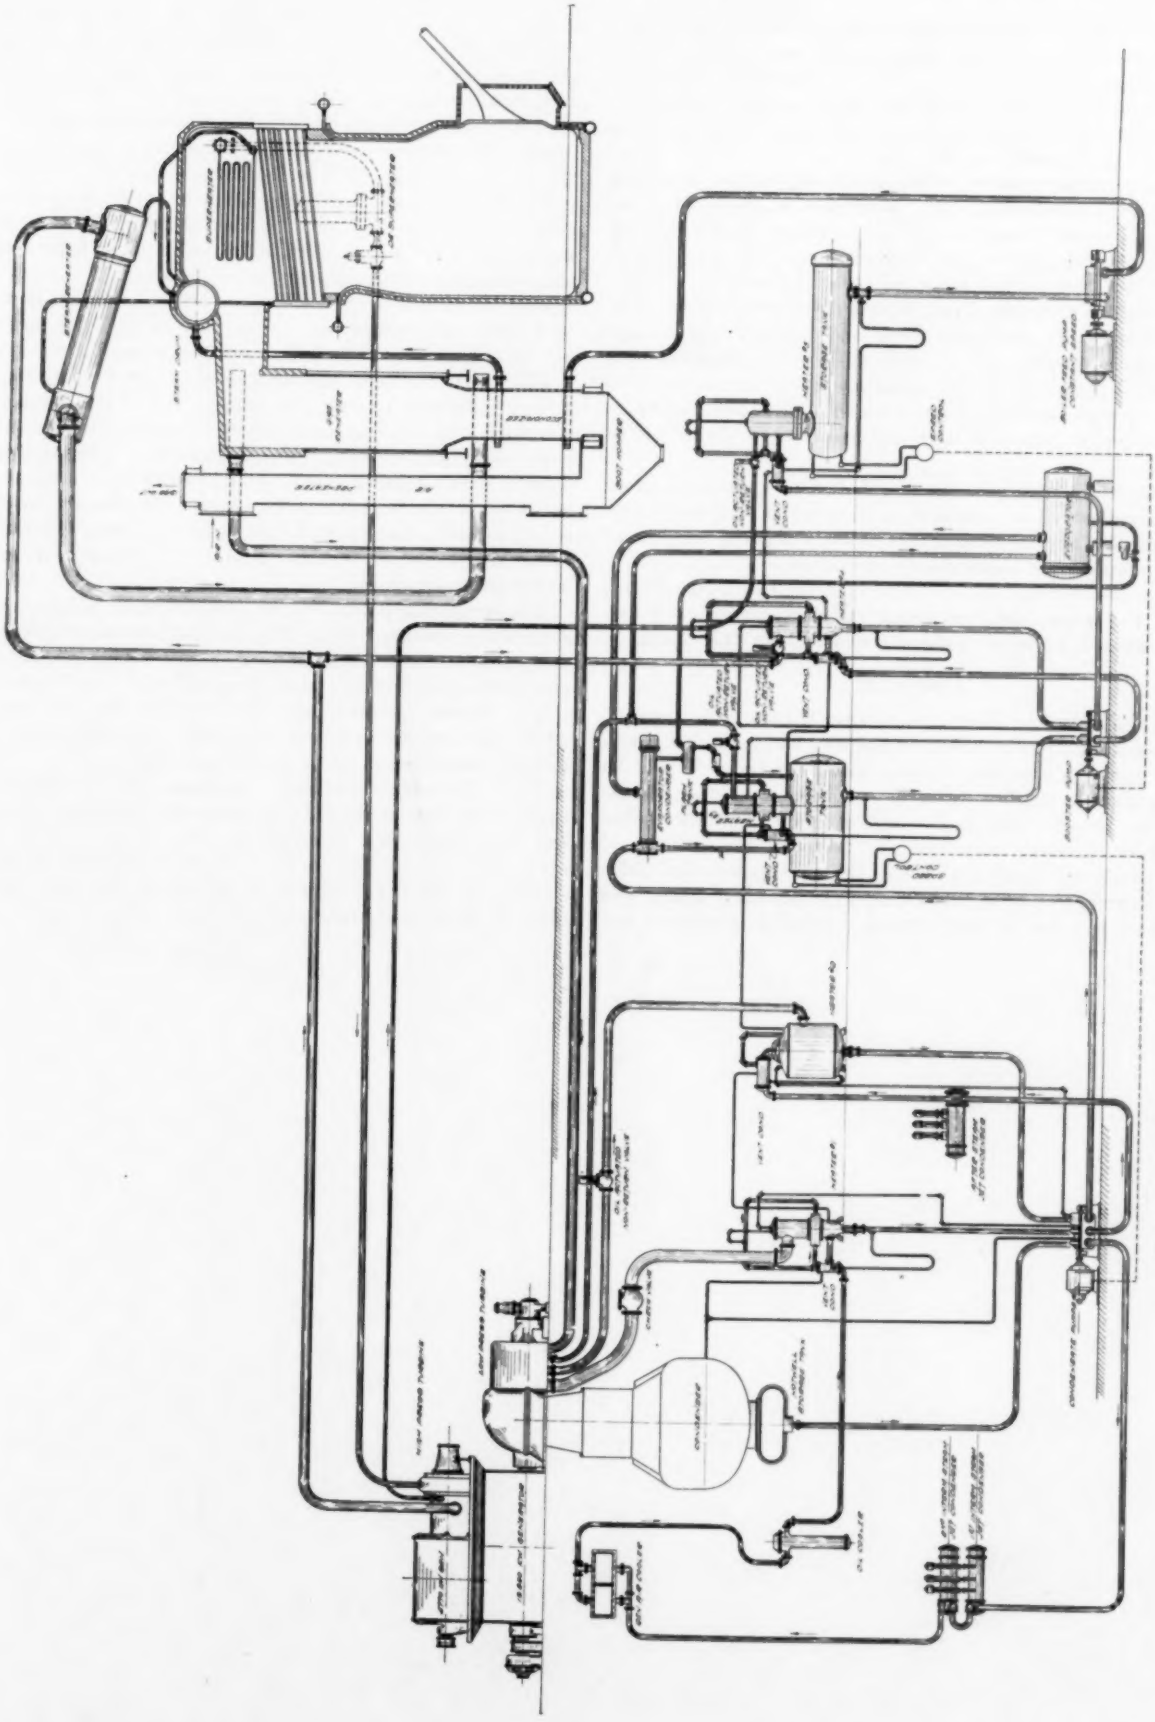

FIG. 5 SCHEMATIC DIAGRAM OF STEAM AND WATER CYCLE AT SOUTH AMBOY STATION

sections are incorporated the primary and secondary air quantities in per cent of burner rating and in pounds per hour, regardless of the temperature of the air. This arrangement permits an accurate preproportioning of the ingredients necessary for correct combustion prior to entering the furnace which many engineers believe to be a logical method.

For a permanent record of the entire combustion, recording CO_2 meters are also installed. Feedwater is measured in an orifice-type meter compensated to give accurate results with the varying temperatures of the feedwater. For the guidance of the operator, the water level of the boiler is shown on the control board by a remote liquid level indicator. In addition to these instruments, the usual draft and pressure gages, also temperature recorders, are mounted on this board, together with the control push buttons and indicating lights for properly controlling combustion. Also on this board is located the manually actuated remote control of the boiler feedwater to the individual boilers.

In the turbine room is provided a turbine control board on which are mounted the usual instruments, and in addition thereto the recording and controlling meters for the initial and reheat steam temperatures as previously mentioned.

The main electrical control board is of the bench-board type, one of the unusual features being the development of a new flush-mounted, indirectly lighted instrument for this board.

Operation

The South Amboy Plant is, as of Dec. 1, 1930, in its preliminary operating stage in a commercial way and has not had sufficient operating experience so that much can be said about its operating characteristics, except as covered by experience to date.

At the present time, both turbines and two of the boilers have been operated under load, and the plant has carried load continuously for about a month. The starting troubles which have occurred to date in this station have been very minor, and have been less than is usually to be expected in starting a new station. A total of two small gaskets were lost in the entire starting operation and one valve-bonnet gasket. There was no joint failure of any of the main steam or reheat lines or any trouble with these steam lines. Two cases of tube leakage occurred in the boilers in their seats, one of which has been repeated several times. One of these cases was due to improper rolling on erection and the other case was due to failure to provide properly for expansion stresses in the design. These were two cases of minor nature, which is a very small percentage considering the large number of rolled joints involved in one of these boilers. No major troubles are anticipated from this source.

Ignition burners were provided for each coal burner and these have operated satisfactorily. They have been a very material help in eliminating the difficulties of the starting period.

There was no serious trouble with the boiler-feed pumps, although experience to date does indicate that slight changes are necessary, and steps are being taken to modify one set of these boiler-feed pumps to make it slightly less sensitive and to provide a better packing arrangement. It is probable that similar steps may need to be taken in the other pumps. This matter, however, is well in hand, the pumps having operated satisfactorily to the extent that there has been no difficulty in putting water in the boilers whenever desired.

The circulating pumps on the condensers are equipped with synchronous motors. Some difficulty has been experienced with the pull-in torque of these motors. This is being corrected now, and in the meantime the station is not suffering from this feature.

The turbine operation has been excellent, the only trouble which has occurred being one case where too much or too little lubrication was put on the valve mechanism and it had a tendency to bind. No trouble has been experienced from the growing of parts in this mechanism and the operation of the turbine governor has been very good. The freedom from this difficulty is probably due to changes made, based on the experiences of others. Beyond the usual adjustment of apparatus, this has been the total of the plant-starting troubles.

Combined Heat and Power Supply in Industrial Plants

By W. F. RYAN,[1] BOSTON, MASS.

The ever-increasing demand for cheap power—the foundation of American industry—has been ably met by the public utilities in the past, and the industrial power engineer is now taking his part in promoting the productiveness of human labor.

The use of high steam pressures has been the most noteworthy development in the industrial power field during the past few years. There are now about 200 industrial plants in the United States operating at pressures above 300 lb. gage, almost all of which have been built since 1925. The industrial plant which has a large demand for process steam has a natural advantage over the condensing central station, in that the latent heat in the exhaust is utilized, and the cycle efficiency of the prime movers is 100 per cent. The quantity of power which can be generated so economically is limited by the demand for exhaust steam, but can be materially increased by raising the throttle pressure.

There are few industries which can generate their entire power requirements, at all times, in all seasons, as a by-product of their process steam. There are still many such plants which generate power in condensing prime movers, but the vast majority purchase their requirements from public utilities. There is rarely any economic justification for the private generation of steam power in condensing units, although under certain conditions internal-combustion engines may be used advantageously. There is a growing tendency in this country to use the Diesel engine as an adjunct to an industrial steam-power plant; when the electric-power demand exceeds the relative demand for exhaust steam, the deficiency is supplied by the Diesel engine.

There are many plants which have large demands for process steam, but relatively little demand for electric power. The most significant trend in the industrial power field today is the cooperation of public utilities with manufacturing plants to develop "by-product" power to its economical limit. An example of such cooperation is cited in which the power output of an industrial plant is increased from 5500 kw. to 25,500 kw., the surplus power being distributed to other consumers, over the transmission lines of the public utility. The fuel cost of the additional 20,000 kw. is less than 4500 B.t.u. per kw-hr. The combination results in a decrease of 10 per cent in capital cost and a decrease of 20 per cent in fuel consumption, as compared with the separate generation of electricity by the public utility and of power and heat by the industrial plant.

Gratifying progress has been made in the conservation of fuel by developing the high-temperature end of the industrial power and heat cycle. An enormous quantity of potential energy is still being dissipated in the relatively low-temperature wastes from our manufacturing plants. For the present, the high-temperature field offers more attractive return on investment, but the future will undoubtedly see much progress in the recovery of heat at low temperatures. This source of energy will become economical long before such projects as the generation of power from the tides, which have greater appeal to the imagination, but which inherently involve enormously greater capital outlay.

THE development of industrial heat and power supply in the United States is an outstanding illustration of Henry Adams' dynamic theory of history; that is, progress has been proportional to the square of the time.

From the early New England water wheels to the advent of the Corliss engine, progress was continuous, but at so slow a rate that it was almost imperceptible to contemporary engineers. The economical prime mover which George Corliss developed gave the industrial power plant its first notable impetus, and by the end of the nineteenth century the use of steam power was almost universal in American industry.

At the beginning of this century the typical large manufacturing plant had a number of small hand-fired boilers, frequently distributed among several isolated boiler plants, in order to produce steam as near as possible to the point of consumption. Reciprocating engines, driving lineshafts by means of belts and rope drives, were also widely distributed throughout the works. Frequently these engines were run condensing, and live steam was used for heating and processing. In other words, heat and power supply were not effectively combined, but were essentially separate services.

Electrification of mills began a little later, together with centralization of boiler plants and the substitution of purchased power or turbine generators for the old engine drives. The use of exhaust steam for heating and processing became widespread, and condensing prime movers began to disappear. By 1925 most of our larger industries possessed efficient boiler plants, and great improvement had been made in the economy of steam use.

[1] Mechanical Engineer, Stone & Webster Engineering Corporation, Mem. A.S.M.E. Mr. Ryan was born in Woodbury, Conn., in 1889, and was educated in the public schools of Everett, Mass., and at Harvard University. His professional experience has been almost exclusively in steam-power engineering, as prior to assuming his present duties he has been employed in work of this kind by the Interborough Rapid Transit Company, the Wright-Martin Aircraft Corporation, the Harry M. Hope Engineering Company, and by subsidiaries of the Allied Chemical & Dye Corporation.

Contributed by the Power Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Communicated to the Second World Power Conference, Berlin, Germany, June, 1930.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Since 1925, the development of the industrial power plant has been truly remarkable. Higher pressures, higher temperatures, and higher rates of heat transfer have brought about even greater changes in the industrial steam-power plant than they have in the central station. Higher pressures and temperatures have materially increased the yield of "by-product power" from process steam, while higher rates of heat transfer have more than offset the increases in capital cost of plant which higher pressures and temperatures would otherwise have produced.

High-Pressure Steam in the Industrial Plant

In 1925, the author discussed the advantages of higher steam pressures in the industrial plant.[2] It was pointed out that

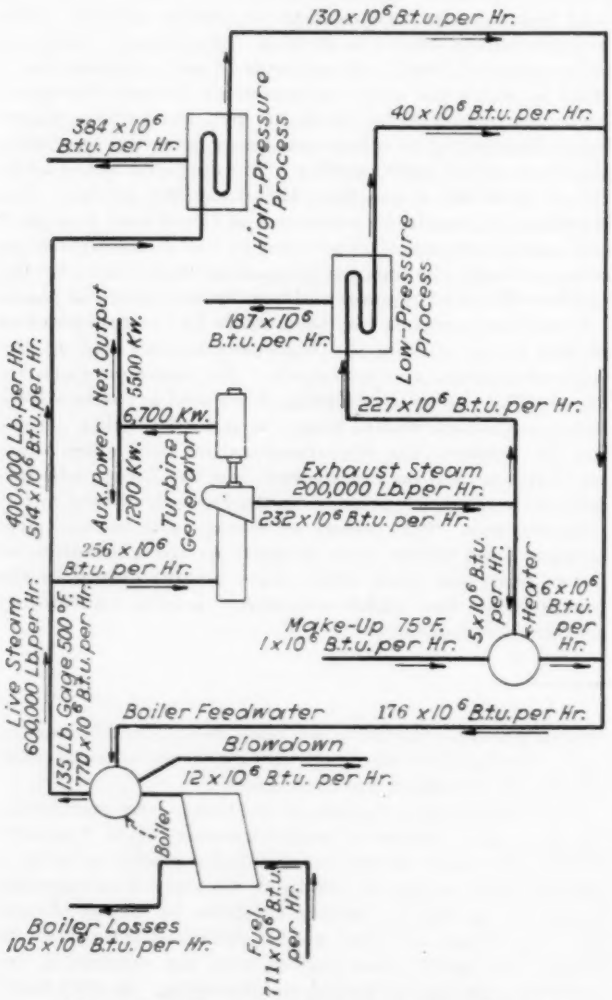

Fig. 1 Heat Balance, Isolated Industrial Plant

whereas the efficiency of a central station was increased only 10 per cent by increasing boiler pressure from 400 lb. gage to 1200 lb. gage a similar increase in pressure would more than double the effectiveness of non-condensing prime movers supplying high-back-pressure steam to a manufacturing process. The mechanical difficulties of generating and using very high steam pressures had been solved by the public utilities, and our industries were not slow to appreciate the value of this new development in their own plants. Early in 1929 an American technical magazine[3] was able to list 141 industrial plants using steam pressures above 300 lb. gage. Only two of these high-pressure plants had been installed prior to 1924.

The majority of high-pressure non-condensing plants have proved thoroughly reliable in operation. The turbine wheels are small in diameter and the blades are short, so that in spite of high speed, usually 3600 r.p.m., the stresses are low and the availability factor high. Many of these prime movers have never been taken out of service except for routine inspection and repairs.

Thanks to the pioneer work of central-station designers and operators, no unusual difficulties have been experienced with steam-generating equipment except when feedwater conditions have been unfavorable. In many industries the process steam cannot be returned as condensate, and the use of treated water has proved very troublesome, if not impracticable, in the higher-pressure plants. This condition may compel the use of an intervening evaporator condenser between the prime mover and the process-steam supply, or it may compel the use of very extensive evaporators for make-up water. The former increases the capital cost of the plant and reduces the yield of by-product power; the latter increases capital cost and operating expense. Even under these unfavorable conditions, however, a high-back-pressure non-condensing power plant will ordinarily produce electric power at a cost that is gratifying to the owner.

Where the amount of power required is large in proportion to the demand for exhaust steam, the reciprocating engine is advantageous. In capacities up to 5000 kw., a non-condensing engine will consume less steam per unit of output than a non-condensing turbine. The thermal efficiency of the engine is less, because radiation and external friction are greater. All of the other losses in both types of prime mover result in higher heat content of the exhaust, and no heat is actually lost thereby. These losses degrade the energy, however, and from this point of view the engine is superior.

The steam engine is in common use for driving low-speed pumps, compressors, and other variable-speed machines in industrial plants. In these applications, better efficiency of the driven unit, as well as lower water rate of the prime mover, favor the use of the reciprocating machine.

The cost of electric power in a high-back-pressure industrial plant is largely a matter of bookkeeping, because of the lack of uniformity in dividing fixed charges and operating expense between the two items of electric power and process steam. In the larger plants, the cost should not exceed 5 mills per kw-hr. Much lower costs have been reported, one as low as 1.5 mills per kw-hr., but it is probable that these very low costs are the result of some arbitrary method of accounting in which the process steam carries more than its proper share of operating expense, or they may be due to a neglect of capital charges. The latter are rarely included in published power costs, either by industrial plants or central stations.

Cooperation of Public Utilities With Industries for Combined Production of Steam and Power

While the advantages of private power generation in high-pressure prime movers are obvious, and are being convincingly demonstrated, very few industries are capable of developing this idea to its economic limit. The big power-consuming industries—for example, automobile manufacture—are not great consumers of process steam; frequently a seasonal heating load is the only steam demand. On the other hand, the big consumers of exhaust steam—oil refineries, salt works, alkali plants, etc.—are relatively small consumers of electric power. Moreover,

[2] "The Value of Higher Steam Pressures in the Industrial Plant," W. F. Ryan. Trans. A.S.M.E., vol. 47 (1925), p. 779.

[3] See *Power*, May 28, 1929.

there is frequently a regrettable lack of synchronism between the demands for these two forms of energy. For example, in many industries the greatest single item of power consumption is for pumping cooling water; this load is greatest in the summer months. An important item of steam consumption is usually the heating of buildings; this demand occurs only in the winter. There are other variations between summer and winter, between day and night, and between Sundays and week days that make private generation of power unduly expensive in most industries, and impracticable in many.

The full economic value of the high-back-pressure prime mover can be developed only by cooperation between industries and public utilities for the combined production of process steam and electric power. Cooperation of this type has been discussed academically for some time, but it is only now beginning to find practical application. This step is the outstanding development in the field of industrial power and heat supply today.

As an example of the possibilities of cooperative steam and power production, consider a relatively large industrial plant, having an average steam demand of 600,000 lb. per hour. Two-thirds of this steam is used at boiler pressure, and the remainder at a lower pressure, after passing through non-condensing turbine-generators. The power demand of the mill, which is only 5500 kw., is easily and economically supplied in this way. Fig. 1 shows the essential features of the plant heat balance, with heat flows given to the nearest million of heat units, above 32 deg. fahr. Steam is generated in an efficient boiler plant; the entire electric-power requirements are generated in non-condensing prime movers with a cycle efficiency of 100 per cent and a thermal efficiency of about 95 per cent. The whole installation approaches the limit of economical heat and power supply for this particular industry.

The territory in which this plant is situated is served by a central station, which is also highly efficient. The essential features of its heat balance are outlined in Fig. 2. Steam is supplied to the turbine throttles at 625 lb. gage and 750 deg. fahr. The turbines exhaust at a vacuum of 29 in. hg. There are four stages of regenerative feedwater heating, and the boilers are as efficient as those of the lower pressure industrial plant. The overall fuel consumption is at the rate of less than 13,000 B.t.u. per kw-hr. generated, and less than 1 lb. of good steam coal per kw-hr. of net output. This also approaches the economic limit for a station of this type.

Fig. 3 shows the economies that can be effected by combining the functions of these two power stations in a single plant, producing the same quantities of steam for process and the same net output of electric energy. Instead of the total heat consumption of 990 million B.t.u. per hour required for the two individual plants, we have a heat consumption in the combined plant of only 800 million B.t.u. per hour, a saving of 19 per cent. Had we assumed a more efficient central station, with higher initial pressure, reheat, and additional stages of feedwater heating, the fuel saving would have been proportionately greater.

The above fuel saving is based on the ideal condition illustrated in Fig. 1, where the demand for exhaust steam is precisely equal to the supply. This never occurs in practice. Either there is an excess of exhaust steam which is blown to the atmosphere or concealed by wasteful application in process, or there is a deficiency of exhaust steam, and live steam is supplied through a reducing valve. In one case there is a total loss of valuable heat, in the other a degradation of energy and loss of potential power. Under any practical conditions, therefore, the saving should be greater than that indicated by these heat-balance diagrams.

Many industrial boiler plants are operated in whole or in part on waste fuel. If 50 per cent of the heat supplied to the boilers in Fig. 1 is waste fuel, and this waste is utilized in the combined plant of Fig. 3, then the saving in purchased fuel is 30 per cent.

Analysis of the more important wastes in these heat balances shows that the fuel saving in the combined plant is effected by a 22 per cent decrease in auxiliary power consumption (largely due to elimination of condenser auxiliaries), 13 per cent reduction in blowdown losses, 28 per cent reduction in other boiler losses, and 100 per cent elimination of condenser losses. Reduction of radiation, leakage, friction, generator losses, etc., not taken into account on these diagrams, should offset, in large part, the transmission losses incident to the combination.

Under favorable circumstances, the cost of a combined steam and power plant of this kind will cost less than two separate plants for the two functions. If the combination involves transmission of power or steam over great distances, or if the loss of steam in process necessitates the installation of expensive evaporators, the case may be reversed, but there are obvious savings in the elimination of condensers and circulating-water supply, and the reduction in the number of boilers and other items of equipment. These savings are not offset by the greater amount of high-pressure piping and equipment. For the particular case under discussion, the capital cost is estimated as follows:

Cost of complete industrial power plant, in accordance with Fig. 1, including land, auxiliary structures, etc...	$2,168,000
Increment cost, for capacity assumed in Fig. 2, for large central station, including land, auxiliary structures, etc.....	2,220,000
Total cost, separate plants.....	$4,388,000
Complete cost, combined plant, in accordance with Fig. 3, including land, auxiliary structures, etc.....	3,928,000
Saving effected by combination.....	$460,000

If the combination plant is so situated that it can supply steam and power to several contiguous industries, then the cost of such a plant might be taken on an increment basis, as well as the central station. The same applies if an existing central station is so situated that it can supply one or more industrial plants without duplicating existing coal-handling facilities and the like. Both of these cases result not only in a greater reduction of initial cost, but also in material savings in operating labor and maintenance.

Now, to discover the potential savings from the cooperative effort of industries and public utilities, and to illustrate these savings by diagrams, is a very simple engineering problem. To put the idea into practice, and to convert these potential savings into cash, is a business problem which is not simple at all. There is a deep-seated and well-founded reluctance on both sides to invade what, up till now, they have each considered the domain of the other. However, our electric-power companies have neglected few opportunities to extend their service or to reduce their costs. Our manufacturers have been equally diligent in reducing production costs. These heat units, and the dollars they represent, will not be allowed to roll into the atmosphere and into the ocean forever.

The first requirement for the success of such a cooperative enterprise is that the advantages must be equitably divided between the two parties. If the plant is owned and operated by the manufacturer, the utility must be assured of the continuity of the power supply. If, on the other hand, the utility owns and operates the plant, the manufacturer must be assured of the reliability of his steam supply. If a plant is built under joint ownership, there must be a just division of costs between the two services. All three of these plans are in use in this country today. All require mutual confidence, good engineering,

and intelligent management, and each party must have a sympathetic understanding of the problems of the other.

Another field in which public utilities and the industries may profitably cooperate is in the better utilization of waste fuel. There are some industrial plants which can supply their entire heat and power requirements with combustible waste from their manufacturing operations. To improve the efficiency of power generation or heat utilization in such plants would only create an unmarketable surplus of waste fuel. If surplus power could be sold at a figure advantageous to both producer and purchaser, then it would pay to use efficient apparatus and prevent unnecessary waste.

The pioneering is now being done by the more enterprising managements, and we may look for a rapid and widespread development of cooperation between public utilities and the large steam-using industries.

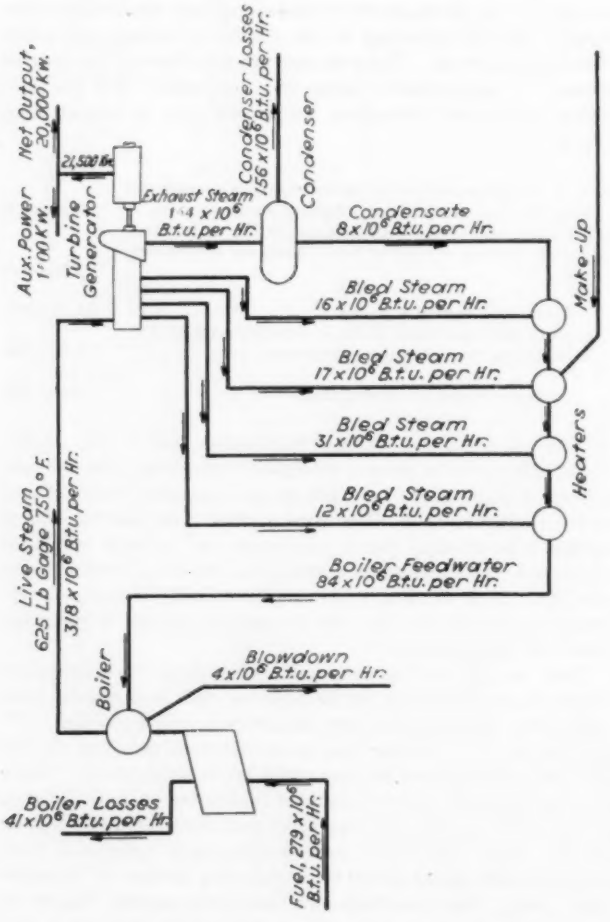

FIG. 2 HEAT BALANCE, CONDENSING CENTRAL STATION

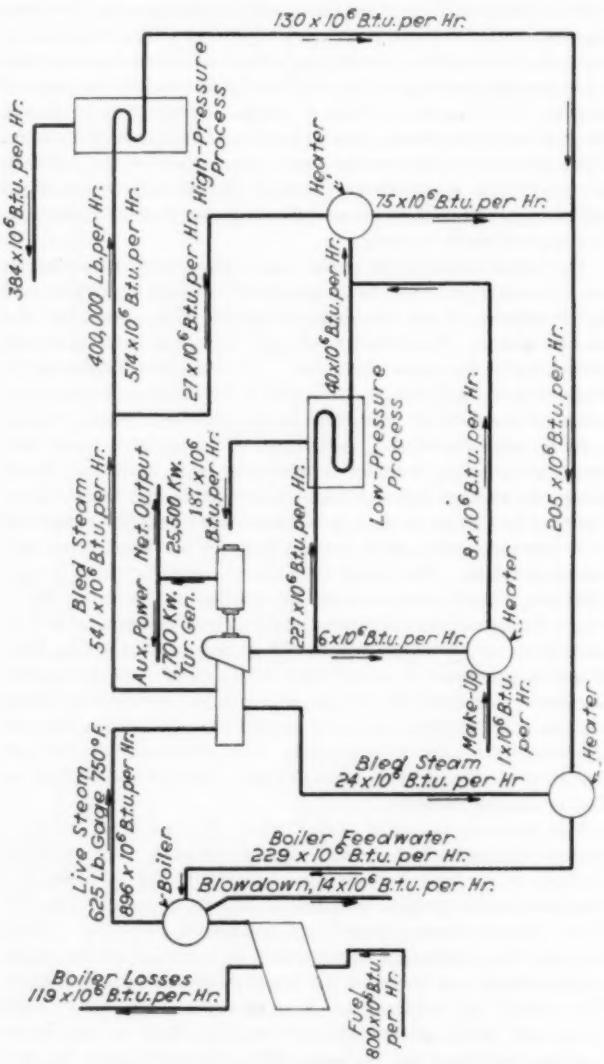

FIG. 3 HEAT BALANCE, COMBINED CENTRAL STATION AND INDUSTRIAL PLANT

INTERNAL-COMBUSTION ENGINE IN THE INDUSTRIAL PLANT

The Diesel engine has been used for many years as a prime mover in industrial plants, where the cost of oil fuel and other conditions have made its use economical. Industries which require process steam have generally found it cheaper to use steam-driven prime movers, but even in this case, oil and gas engines have been effectively used in conjunction with steam boilers. Boiler feedwater has been used as a cooling medium in the cylinder jackets, and in some cases the heat in the exhaust gas has also been utilized for preheating feedwater.

TABLE 1 SUMMARY OF SAVINGS EFFECTED BY COMBINED PLANT, FIG. 3

	Industrial plant, Fig. 1	Central station, Fig. 2	Total separate plants, Figs. 1 and 2	Combined plant, Fig. 3	Saving effected by combined plant, per cent
Gross output, kw	6,700	21,500	28,200	27,200	3
Auxiliary power, kw	*1,200*	*1,500*	*2,700*	*2,100*	22
Net output, kw	5,500	20,000	25,500	25,500	
Fuel input, B.t.u. per hr	711,000,000	279,000,000	990,000,000	800,000,000	19
Blowdown losses, B.t.u. per hr	12,000,000	4,000,000	16,000,000	14,000,000	13
Other boiler losses, B.t.u. per hr	105,000,000	41,000,000	146,000,000	105,000,000	28
Condenser losses, B.t.u. per hr	0	156,000,000	156,000,000	0	100
Capital cost of plant	$ 2,168,000	$ 2,220,000	$ 4,388,000	$ 3,928,000	10
Reduction in capital cost effected by combination					$460,000
Annual saving in fuel cost based on coal at $3.50 per ton of 2000 lb					$210,000

Very recently, a number of Diesel engines have been installed to perfect the heat balance of industrial plants. Attention has been called to the lack of synchronism between steam and power demand in the average industrial plant. In the past it has been common practice to design the electric-power plant to meet average conditions, and to blow exhaust steam to the atmosphere whenever the demand for power was out of proportion to the demand for exhaust steam. Condensing units to take care of this condition are impracticable in plants which lack an abundant supply of cold water. A purchased-power connection is also frequently undesirable, on account of the high cost of furnishing current for intermittent use; also the hazards of interconnection make it difficult to secure an exact balance by this method. In this situation the Diesel-engine generator becomes a very effective method of perfecting the balance.

All of the power that can be generated non-condensing, and without waste of exhaust steam, is obtained from steam prime movers; the deficiency is supplied by the Diesel. The heat saving is obvious; a non-condensing steam engine may reject 20,000 to 40,000 B.t.u. for every kilowatt-hour generated, whereas the heat loss from a Diesel need not exceed 4500 B.t.u. per kw-hr.

Internal-combustion engines are also commonly used for starting up service in isolated plants. Where all auxiliaries are motor driven, as is now common practice, and where electric current is required for fuel supply, which is usually the case in pulverized-coal plants, the boiler cannot be put into operation after a complete shutdown without some auxiliary source of power. A small gasoline-engine-driven generator is usually sufficient for this purpose.

Recovery of Heat From Low-Temperature Waste

As noted in the foregoing pages, much progress has been made toward developing the full possibilities of the high-temperature end of the industrial heat-power cycle. If we continue to progress in proportion to the square of the time, the possibilities in that field will soon be exhausted. Fortunately, there will remain almost unlimited room for improvement in the low-temperature ranges.

There are industrial plants in the United States which use as much as 100,000,000 gallons of cooling water per day. In some cases this water is heated as much as 40 deg. fahr. This represents a potential energy source, at Carnot efficiency, of more than 30,000 kw. continuously. It would be costly, but nevertheless entirely feasible from an engineering point of view, to install apparatus which would extract more than 10,000 kw. continuously from this warm water, without any expenditure for fuel.

Other plants discharge smaller quantities of water at much higher temperatures. Some chemical plants in Europe are actually extracting electric power from hot waste liquors. Vapor flashed from the hot liquor is drawn through a turbine into a condenser. The operating pressure may be as low as 5 lb. absolute.

Except in exceptional cases, the development of power from this source is not yet commercially practicable in the United States, but it would appear to offer a much more economical source of power than exists in the differential temperature between the surface and the depths of the sea. The work of Messrs. Claude and Boucherot on the latter project is of exceptional interest, and the author does not wish to disparage their experiments in any way. The ultimate value of this research, however, may be found in the recovery of energy from the higher heat head of industrial wastes.

For many years the boiler-feedwater economizer was in disfavor among American central-station designers. It was considered to give more trouble than its heat recovery was worth. When we began to force our boilers to higher outputs, and the temperature of gas from the boiler increased accordingly, the economizer came back into fashion, not only as a desirable feature, but almost as a necessity for an efficient boiler plant. We may look for a renaissance of the waste-heat boiler in the industrial plant for much the same reason. We are pushing all production apparatus to higher and higher rates of output. As the waste gases get higher in temperature and greater in quantity, the possibilities of heat recovery become correspondingly more attractive. Waste-heat boilers have been developed for high steam pressures, several have been installed for pressures above 350-lb. gage, and this further increases the recoverable energy.

Hot gases are also being used directly, or through the medium of an air heater, for drying and for other manufacturing requirements. At the Iron Mountain plant of the Ford Motor Company stack gas from the power plant is used for drying wood. This plant, which utilizes not only the latent heat of the exhaust steam but also the sensible heat of the stack gases, eliminates the two major losses in the central station. This is the goal for which we should strive in low-temperature ranges. If operated at the highest economical steam pressure, distributing cheap surplus power to less fortunately situated neighbors, such a plant would represent the ideal industrial heat-power cycle.

Forecast

Not many years ago the industrial-power engineer spoke contemptuously of his central-station brother as a "B.t.u. chaser." The implication was that the central-station designer pursued ideals of thermal efficiency without regard for sound economics. In spite of this alleged extravagance, the public utilities have waxed great and prospered. Industry has seen the light. It is chasing a few heat units on its own account, and finding that dollars may be caught in the same net.

The charge was also made that public utilities could be extravagant with impunity, because monopoly assured them of an adequate return on any investment they chose to make. This, of course, was nonsense. In the industrial field the central station is in competition with private generation of power. In the domestic field it is in very keen competition for the consumer's dollar. Electric light may now be regarded as a necessity in the American home, but one does not have to have four base plugs in every room, an electric washing machine, an electric ironer, an electric radio, or an electric refrigerator. Still less does any one need an electric range. Yet all of these luxuries are in quantity production solely because the electric-light industry is successfully meeting competition. Here again industrial management has caught the idea; it has learned to distinguish between extravagance and financial courage. Industrial executives are now willing to make sound investments in power equipment, and they are finding them gilt-edged investments.

Therefore we may look for an undiminished acceleration of progress in the industrial-power field. More high-pressure plants and higher pressure plants will be built. Public utilities and industries will cooperate to obtain the maximum power yield from process steam; the day may come when we shall reverse our present nomenclature, and call the single-purpose central station an "isolated plant." Industrial-power engineers will attack their present low-temperature wastes with more success; they will contribute their share to retard the ever-increasing entropy of the universe. It is difficult to believe that the first differential of the progress curve can always be positive, but Henry Adams assures us that it can, and that it will.

Discussion

EDGAR J. KATES.[4] Mr. Ryan alludes to the fact that very recently a number of Diesel engines have been installed to perfect the heat balance of industrial plants; the principle is that all of the power that can be generated non-condensing and without waste of exhaust steam be obtained from steam prime movers and that the deficiency be supplied by the Diesel.

Why not carry the idea further, and rather than merely add a Diesel engine as an auxiliary to a complete full-size steam plant, design instead a combination power plant with steam and Diesel capacity carefully proportioned so that the load will be shared according to an analysis of capital investment as well of operating cost? In other words, do not install a Diesel engine just for the purpose of occasionally improving plant efficiency by preventing the waste of exhaust steam. Greater savings can be effected by planning a well-balanced combined plant in which both types of prime movers will be used more hours per year than a thermal analysis alone would call for. It is evident that that part of the steam power plant whose exhaust can be utilized only a short time per year will not justify its capital investment if Diesel capacity is available to carry that part of the load. The principles involved in the joint use of Diesel and steam engines are given in a recent paper presented to the Oil and Gas Power Division, A.S.M.E.[5]

Complete analyses of actual installations frequently show that the most profitable design of plant is a combination of steam and Diesel power units in which neither the steam nor the Diesel capacity by itself is sufficient to carry the full load. Such combinations will result in a considerably lower capital expense than if Diesel power is added to a full-size steam power plant, and despite some loss in thermal economy the decreased investment will result in lower overall costs.

A further saving can sometimes be made in such plants through the use of steam power equipment of lower cost and somewhat lower efficiency than would be desirable if the plant were all-steam. Inasmuch as the power required beyond that obtainable from the non-condensing steam equipment can be generated at slightly additional cost by Diesel engines, it does not pay to increase the capital investment in the steam plant too much in order to obtain the utmost thermal economy from the steam equipment. For instance, in a combination plant a four-valve steam engine may be better than a uniflow engine because its lower initial cost may offset the slightly increased fuel consumption under conditions of moderate steam pressure and atmospheric exhaust.

There seems to be an error in the author's statement that "the heat loss from a Diesel need not exceed 4500 B.t.u. per kw-hr. even if no attempt is made to recover heat from jacket water or exhaust." The heat loss of a modern Diesel engine is about 7500 B.t.u. per kw-hr.; of this loss about 4500 B.t.u. per kw-hr. is recoverable from the jacket water and exhaust.

Mr. Wood refers mainly to large industrial power plants that are able at times to deliver considerable amounts of power to the public-utility lines to which they are connected. The protection of service to the industrial plant is cited by the author as one of the advantages of the interconnection.

There are hundreds of small industrial plants whose capacity is not enough to justify the complication and expense of delivering surplus power to the public utility, but which, like the larger plants, would benefit greatly by a connection with the public utility that would protect their power service.

However, judging by the almost prohibitive rates which many public utilities charge for such a connection, which they generally designate as "breakdown service," the utilities seem to oppose rather than to welcome this type of service. For instance, a utility in a large Eastern city makes a service charge of $24 per year for each kilowatt of maximum demand contracted for under the breakdown agreement, even if no power is actually supplied. At the usual rate of return of 8 per cent on the investment, this service charge pays, for each kilowatt of maximum demand contracted for, the full rate of return on an investment of $300. Since this is approximately equal to the utility's whole investment per kilowatt installed, the implication is that the utility is setting aside solely for the use of each breakdown service customer the full amount of capacity called for by that customer's *possible* demand. That, of course, is not the case, as the diversity factor of the breakdown service supplied to a group of customers is quite large. In fact, if the business were cultivated, it is likely that its diversity factor would be much larger than that of any other class of service. Consequently only a small fraction of the maximum breakdown demand of any one customer needs to be actually reserved for his use, and this justifies a large reduction in the service charge.

If breakdown service were less costly, the owner of a private power plant would be justified in depending entirely upon the utility for reserve power and in reducing his own plant capacity and investment. The gain would be mutual, as not only would the plant owner save capital investment and space, but the utility would earn a reasonable return on its own additional investment. On the other hand, under existing conditions, the plant owner is put to an unnecessary capital expense because he cannot afford to pay the present utility rates for breakdown service, and the utility is deprived of additional profitable business.

JOHN H. LAWRENCE.[6] The subject of power and heat supply in industrial plants is one which was long neglected by industrial executives. Although the industrial power plant was the first power plant, its existence was practically ignored, and it was almost left to shift for itself.

The advent of the central station brought new ideas into the power field, and, as the author says, "the public utilities have waxed great and prospered" because they have studied their problems.

Granted that power is not the salable product of an industrial company and is only one step in the manufacture, still it is regrettable that executives have not had their organizations keep pace with developments in a subject which is absolutely essential to their companies. Power is essential, and if this is so, why not procure it at the lowest cost consistent with good business judgment? The writer adds the last phrase because sometimes a company cannot afford to tie up too much of its capital in plant other than what is necessary to produce its product.

However, we can find today plants making an investment to cut down manufacturing cost of products, where the same investment made in the power plant could net a larger return. This is done because the executive has ignored the power plant and has been satisfied as long as steam and power have been available. In the meantime, the heat, for which he has paid good money to the coal man, is going up the stack or into the condensing water. Heat units are elusive things, and if they get an opportunity to escape, they do not wait to ask permission.

Fortunately, industry has seen the light, and there are many excellent examples of efficient power plants in industry today. However, the writer is not so optimistic concerning the extent of improvement in industrial power plants. The average plant today looks as if it were handed down from the Ark.

There is an enormous field for improvement in industrial power. The surface has hardly been scratched. It is up to the engineering profession to educate the industrial executive in the economics of steam and power development.

The central station has been developed to such a point that very little improvement can be made unless some new cycle or process is developed, and the only hope at the present time for materially reducing the cost of power in central stations is to reduce fixed charges.

Many industrial plants are in an enviable position. Due to their processes, they are in a position to manufacture power at a rate lower than it can be purchased from any utility company, for the investment cost in excess of that required for process steam and the heat required to develop the power are less than in a central station.

On the other hand, one may find industries making their own power when they should be purchasing from the central stations.

Economics should govern, but unfortunately some people are not as familiar with that term as they are with slices or hooks on the golf course. We should endeavor to get the plant owner to look at his power plant from the standpoint of economical production of power and not of the necessary expense of providing something with which to drive machinery.

The author and all of the others who write papers on this subject are spreading the cause of good engineering and also of conservation of the fuel resources. As a nation, we are wasteful, and this is particularly true of the manner in which we have been using fuel in our industrial plants.

In tackling the problem of improving the industrial power plant, we should not blindly follow central-station design. What may be good for the central station may be very costly for the industrial plant. Unfortunately in the past designers patterned too closely after the central stations, and as a result progress in industrial power-plant design was held back. Today, the problem is attacked from the standpoint of building a plant which will be coordinated with manufacturing processes, so far as use of heat is concerned, instead of giving out power and steam promiscuously in a haphazard fashion.

The author's suggestion of interconnection of public utilities and industries is well worthy of serious thought, as under certain conditions large savings can be made in this way. Until recently public utilities were loath to interconnect with industrial plants owing to possible disturbances on the systems due to plants over which they had no control. The central station had to meet this problem, and today there are many such interconnections. However, the industrial operator should not be content merely because he has an interconnection; he should know that he is using heat in the most economical manner, and this is true whether or not he has an interconnection.

E. D. Dickinson.[7] For several years the writer has given this subject much study, and it has been interesting to note that this question of the desirability of generating by-product power is being answered as all engineering questions are ultimately answered, on its economic merits. In other words, in any instance where it can be shown that it is a sound economic policy to generate electric power from process steam, it is then the problem of the engineer to see to it that the installation be entirely reliable and proportioned so as to satisfy all the requirements on which the decision has been based.

The author has very clearly illustrated the savings to be made by cooperation of public utilities with manufacturing plants to develop by-product power to its economical limit.

At a meeting of the Affiliated Technical Societies of Boston in December, 1925, the writer predicted that there would be many cases in the future where there would be cooperation between the industries and the public utilities to their mutual advantage.

It is gratifying to observe that each year there is increasing interest shown in this phase of heat and power supply. This statement regarding the present trend is based on a continuous survey of all requests for quotations on steam turbines.

That the manufacturers have anticipated the use of by-product power to its economical limit is manifest by the many recent installations of highly efficient back-pressure and extraction turbines for by-product power application. These by-product power turbines are essentially special. It is not unusual to find such a turbine of 5000 kw. rating taking as much steam as a 20,000-kw. condensing turbine and exhausting no more than a 1000-kw. non-condensing turbine, the balance of steam being extracted at one or more openings.

The question of reliability is of paramount importance. Manufacturers of steam turbines recognize this, with the result that they are prepared to furnish so-called industrial turbines; that is, turbines arranged for extraction and back pressure that are as conservatively designed and in every way as reliable as the large turbines operated by the public utilities.

The writer would stress the necessity for most careful study of all operating conditions before drawing specifications for the turbine. The greatest gain can be secured only when the turbine is properly proportioned to meet the operating conditions.

The many problems of governing and control are not generally appreciated by many, but are well understood by those who have given the subject much study. It will be appreciated that when there are several variables and that when fine control in pressure is to be maintained at several extraction points, in addition to close speed regulation, the governing mechanism must be powerful, strongly built, and at the same time sensitive. Adequate provision must be made to properly safeguard the turbine at all times.

The matter of bookkeeping that the author mentions is no doubt one of the most important and yet most unreasonable elements tending to retard the by-product power situation. Figures always have been and always will be convincing, but if they are based on unsound presumptions they will lead to false conclusions. Without doubt there will be found many desirable applications for interchanging power between the public utilities and the industrials.

Charles W. Conrad.[8] The excellent papers of Messrs. Ryan and Wood appeal to all utility and industrial power engineers because we are interested in the most economical utilization of heat. It is hoped that these papers will be one more step in the education of managements of both the utility and the industrial plant.

In a paper presented by the writer at the October 26, 1927, meeting of the Boston Section of A.S.M.E., it was stated, "The future will find our large utilities deeply interested in the development of a number of medium-size combination power and steam supply plants suitably located to furnish manufacturers, or in establishing manufacturing districts around their base plants to obtain a market."

Therefore the writer would like to supplement Mr. Wood's means of securing advantages of massed resources of power production with the proposal that the utility should plan for a manufacturing district around its large generating station. Land or buildings could be leased or sold to manufacturers planning new factories or branch factories. This opens a field for the future

[7] Designing Engineer, Turbine Engineering Department, River Works, General Electric Company, Lynn, Mass. Mem. A.S.M.E.

[8] Plant Engineer, Bird & Son, Inc., East Walpole, Mass. Mem. A.S.M.E.

for which the medium-size as well as the large utility can plan.

JAMES M. TAGGART.[9] Power is becoming a fluid commodity, due to interconnection of generating systems and facilities for power storage inherent in a combined steam and hydraulic system. Improvements in design of generating plants and increases in size have resulted in a production cost largely dependent on fuel burned and fixed charges for steam plants and fixed charges alone for hydraulic plants. On this account cooperation between industrial companies, having both steam and power requirements or waste heat, and power supply concerns has become of extended importance economically. In the past there have been many cases where the conditions were such that cooperation would have been just as beneficial, but it has been extremely difficult for the interested parties to comprehend the facts. Papers like those of Mr. Wood and Mr. Ryan should help clear up the situation.

On account of the many varying factors each case involves special engineering and economic features that require special study to solve effectively. The success of such special installations depends inclusively on suitable arrangements, correctly selected equipment, and designing of the essential details to fit the conditions.

While in some cases, as suggested by Mr. Wood, the power supply company will be best fitted to build and operate the combination plant, on the other hand often it will work out better for the industrial company to provide the plant. The latter would be especially true where the plant is relatively small, where its location is isolated, and where its arrangement and operation naturally tie up with the industrial plant.

Just as the arrangement of each cooperative plant is special, so also is the value of the heat or power interchanged. As a rule, in addition to the reduction in total B.t.u. required, there should be a reduction in total investment required and an increase in reliability of operation. Mr. Wood mentions 5000 and 12,000 B.t.u. as a proper ratio of the heat per kilowatt for power produced with exhaust utilization compared to power produced in a high-pressure central station. While this is comparatively correct for power at the generator outlets, it is normally different for the usual conditions. Thus for power delivered to an industrial plant there will be transmission and transformation losses often over 20 per cent in amount. When power is to be delivered to the power supply company, the points of supply and the location of the load need to be considered.

Mr. Ryan speaks of a cost of 1.5 mills per kw-hr. as probably in error for plants utilizing their exhaust steam. In such plants there is always a question as to just what should be charged for power. Where the load factor is high, as is true for certain types of plants, and the coal cost is low, with fixed charges at 15 per cent, 1.5 mills per kw-hr. is possible. With direct steam drive, where the conditions are favorable, an equivalent power effect can be obtained at less than 1.5 mills. It is true, however, that in most industrial plants careless design, skinning down of investment, and unintelligent operation produce an actual power cost exceeding 5 mills per kw. even where all the exhaust is utilized.

Power-supply companies tend to underestimate the value of a possible power supply from industrial works and to totally disregard the value of an increase in capacity. Industrial concerns producing their own power on the other hand normally overestimate their loads. Unprejudiced and accurate engineering is required to achieve a mutally profitable and efficient cooperation.

GUY B. RANDALL.[10] Mutuality of interest in more and cheaper electric power by the public utilities on the one hand and all the other types of industries, as well as the public at large, on the other is readily apparent, at least in the abstract. The papers of Mr. Wood and Mr. Ryan are successful attempts to give this mutual interest a practical and concrete form through the medium of high steam pressures. The great possibilities appear to lie in:

1 Joint ownership as quite clearly described in the two papers
2 Simple interconnection of electric circuits.

Joint ownership may develop a fair field of action in some of the larger projects. A start has been made. But there are serious objections to it in the case of the majority of industrial companies unless the utilities use the new medium to insure the equivalent of far more favorable rates relatively than their present rate structures provide. The writer's observation indicates they may be disposed to do this to some extent, but the savings to be derived by the industrial plant are heavily reduced by the higher cost of public utility construction and the profit the utility must earn. In both papers construction costs are given which for this discussion represent large power developments and the cost ranges from $100 to $114 per kw. In the writer's recent experience a first-class 650-lb. industrial plant station ranging in capacity from 15,000 to 20,000 kw. can be built completely new for $70 to $85 per kw. including all legitimate charges and profits. (A general description of the 650-lb. plant of the Champion Coated Paper Company, on which this statement is based, is given in the December, 1929, issue of *Power Plant Engineering*.) This price does not include the effect of substantial price reductions in the last six months. Nor is the average industrial plant likely to look with favor on the contractual relations required for joint ownership which, as Mr. Wood points out, may be complex. It would appear that joint ownership and so-called mass production have yet to demonstrate that they may offer the public utility a suitable profit without serious infringement on the industrial plant potential profit.

Industrial plants do not suffer, in general, from lack of funds. In the writer's experience with several companies he has yet to find one which could not obtain money for a development program provided it was worked out in clear and concise fashion and where the profits therefrom met the required minimum. In competitive industries profits cannot be standardized. But the high thermal efficiencies obtainable today in up-to-date plants of moderate cost open the door to attractive savings. Almost any plant is a good prospect. If it is a large buyer of power, it may prove to be a better prospect. While many industries vaguely feel the urge to action, they also know from previous painful experience that it is quite possible to get a brand new, up-to-date set of equipment or its equivalent in the form of a contract while others absorb the lion's share of the profit to be derived therefrom. Even with highly detailed specifications in connection with construction work, it may be found that one bid for high-pressure equipment is double another. This simply means that both engineering and purchasing must be done with circumspection and with the widest possible canvass of the market until practice and prices get on a more uniform basis.

Simple interconnection of electric circuits would seem to offer the really great and essential opportunity for development. Under this scheme, if the isolated plant has surplus power, it dumps it into the general pool of power. If it needs some, it draws from the pool. There are no financial complications. But it must get paid reasonably for what it delivers, and it must pay reasonably for what it gets. This relationship is simple and direct, with points of resemblance to both modern

[9] Consulting Engineer, New York, N. Y. Assoc-Mem. A.S.M.E.
[10] Superintendent of Power, Champion Coated Paper Company, Hamilton, Ohio. Mem. A.S.M.E.

railroading and modern banking. A power pool would take power on consignment somewhat like a railroad takes freight. For a moderate tariff it would take it at one point and deliver it at another. It would be able to consolidate these varying and variable deliveries into such a large fund of power that the greatly reduced discrepancy between supply and demand could be smoothed out by its own firm power resources which, like a bank's own financial resources, would be small in size compared to the total deposits. You will notice that the emphasis is placed on the electrical transmission and distribution network (which today probably compares as to reliability with railroad lines of thirty or forty years ago), while the utility power station shrinks in relative size and becomes a balance wheel or equalizer to take care of unusual conditions. If every plant which has use for process steam or process heat were working on 1400-lb. pressure and the best heat cycles of today, the utility steam stations would probably be nearer their no-load point than their normal load point so far as a national pool is concerned. Almost regardless of where you live, just check up on this carefully with a radius of twenty-five or fifty miles and you will appreciate the full force of this statement. This does not mean that properly managed public-utility stations are going to permanently lose load. It is, rather, a striking way of indicating where it would seem the future additions to capacity should come from.

As matters now stand the public utility does not in general seem disposed to buy firm power from an industrial plant, and it is "willing" to purchase dump power only at a price close to the utility's fuel cost of a kilowatt-hour. It is easy to demonstrate that at this price there is little or no incentive to design to get the maximum of this, the world's cheapest power. It is also easy to demonstrate that by the standard of present utility rates dump power is worth far more than this. But an attractive price for dump power gives the utility a double handicap. It increases the incentive to build modern industrial power plants, which in turn means loss of more revenue-bearing load for the utility—a vicious circle. No utility company can wisely ignore the plain implication of this trend. But looking at the problem from the standpoint of national economics and national welfare, it would appear that the sooner we develop a large power network with great freedom of pool action—that is, the sooner the public utility regards itself as something of a common carrier rather than an exclusive manufacturer—the sooner will the country enjoy an abundance of really cheap power. Our national power problem is not solved until the cheapest power has a reasonably good road to market. Meanwhile, it would appear advisable for the industrial plants not to make long-time dump power commitments, for the market may improve considerably within the next ten years.

Both Mr. Wood and Mr. Ryan regard evaporators as necessary for the high-pressure plant. For the average industrial plant, the writer's studies and experience indicate that evaporators offer little benefit while they add to the cost and complication and greatly lower the thermodynamic efficiency where the make-up is large. Let us not forget that the following pressure changes are thermodynamically of approximately equal order: a decrease of $^1/_2$ lb. at 1 lb. absolute, 12 lb. at 30 lb. absolute, 55 lb. at 190 lb. absolute, 110 lb. at 400 lb. absolute, 150 lb. at 600 lb. absolute, 325 lb. at 1200 lb. absolute. Regardless of whether evaporators are used, final reliance for trouble-free operation at the present time must be placed on boiler-water chemical control with secondary phosphate conditioning. From recent experience, for example, at 650 lb. a large boiler operating on 30 to 40 per cent make-up of bad water is as clean after six months of operation as it was after six days. As nearly as one can determine, the boiler can be kept clean forever with primary hot treatment of lime and soda ash and secondary phosphate conditioning. In this particular case, 650 lb. pressure without evaporators was thermodynamically equal to something like 800 lb. with evaporators. The increase in expense and complication caused by evaporators with large make-up is too great to ignore. This does not mean that there are not many legitimate evaporator applications. In dealing with sea-water impurities, for just one example, they are probably imperative. But the work of Dr. Hall and his associates in boiler-water conditioning has opened up a field which is not generally appreciated. People just do not believe it when one talks about running a boiler forever without the use of a tube cleaner.

Mr. Ryan also directs attention to the superior engine efficiency of the reciprocating unit up to 5000 kw. The writer would in general prefer to have a small high-pressure plant with turbines (in place of engines and oily condensate filters) and without evaporators. The cost is much less and the elimination of the evaporators offsets the higher engine efficiency of the reciprocating unit. It is believed that this condition will hold down to units as small as 1000 kw. Further, there is no serious objection to a small condenser with the turbines. In general, it is cheaper to have a little condensing capacity to care for fluctuations than to boost the steam pressure so high that a bypass valve is the only medium necessary to obtain balance. This particularly applies to plants which cannot get a reasonably profitable outlet for dump power through the public utilities or through local groups of industrial plants.

Mr. Ryan questions industrial power costs of 1.5 mills per kw-hr. including fixed charges. In Ohio that is possible if no reserve equipment is carried. With reserve equipment, a total cost of 2.0 to 3.0 mills including fixed charges is readily achieved provided only the load factor is good. It is interesting to note that at the beginning of this century a kilowatt-hour was priced in dimes, fifteen years ago it was priced in cents, while today it is priced in mills. In fact, we are now very much interested in small fractions of a mill. We are approaching the price range of one of Fred Low's old editorial dreams of "power cheap as tap water at the kitchen sink."

R. J. S. Pigott.[11] Mr. Ryan's excellent paper brings out again the fact that the power and heat supply for any industrial plant requires an individual solution. There is no such thing as a general solution. A further complication of the situation is that in many cases it is very difficult to determine the precise heat and power distribution in any industrial. Furthermore, any solution for a particular plant must be made flexible enough so that considerable changes in processes which materially alter the balance between heat and power might be made without destroying the ability of the system adopted to handle the change of balance to advantage. Without doubt the most useful information one could obtain would be a write-up of every individual solution that actually has been developed and in particular the operating results where these figures are available. These, as a general rule, are rather hard to get because the industrial is usually more interested in running the new plant after it has been obtained than in checking up how well it justifies the original computations.

Another factor which has recently reentered the field is the Diesel engine. When internal-combustion engines (and in particular the Diesel) were first commercially pushed, they were much too enthusiastically sold on the basis that they required little skill to run them. This was certainly not true, and is not true today. The result was that the internal-combustion engines and in particular the Diesel engine got a black eye which has taken 15 or 20 years to cure, but we have now available in-

[11] Chief Engineer, Research Department, Gulf Production and Pipe Line Company, Pittsburgh, Pa. Mem. A.S.M.E.

ternal-combustion engines whose reliability is certainly on a level basis with other forms of prime mover. In marine service and in the oil industry this condition has been obtained to a degree quite surprising to those interested in the electric-power industry. The Diesel engine very often offers a solution for industrial heat-balance situations that can be reached no other way.

With regard to low-head heat recovery as another avenue of improvement in thermal economy, it does seem as if something useful might be done in this direction. At Youngstown, for example, the whole of the Mahoning River is raised to a temperature of 120 deg. in July and August near some of the steel mills, and a few cases have been reported where the temperature rose to 136 deg. Of course much of this heat actually need not be wasted; the writer's experience indicating that in general the steel mills are extraordinarily lavish in their use of cooling water, and the process as a whole is relatively uneconomical in the use of heat. The main obstacle in the way of providing low-head heat recovery equipment will be the size and cost of apparatus developed.

Many of the industrial plants must lose much of the condensate from process steam and are therefore under the necessity of providing a large percentage of boiler feed as make-up. The solution generally adopted so far for high-pressure plants is to use high-pressure evaporators to deliver steam for industrial service. However, it is very probable that we shall be able to supply boilers operating at quite high pressures with treated make-up and have no more trouble than is now experienced with evaporated make-up and condensate.

Another discussor has mentioned the use of hot-process lime-soda treatment followed by phosphate secondary treatment in a 600-lb. plant. The writer can supplement this experience with another case where the plant operating at 450-lb., 70 per cent make-up is operated with the same treatment and producing no scale in the boilers that will not wash out. In this case, however, a very considerable deposit of scale is thrown down in the high-pressure heaters (140 lb., 360 deg.). This plant is operated with a continuous blowdown system to keep the boiler-drum concentration down to about 200 grains per gallon total solids.

Mr. Wood's interesting paper brings forward again, and forcibly, the necessity for serious consideration of more widespread combination of power and heat facilities between public utilities and industrials. The battle between the industrial plant and the public utility on the question of which is better equipped to furnish the cheapest power has in the past 15 years become more clearly defined as an economic question of how to furnish heat and power. It has been fairly obvious that where by-product heat at a lower heat level than the initial steam conditions is required by an industrial plant, two to three times the heat may be usefully obtained from fuel by means of a combination plant over that which a straight condensing plant can deliver. There have been a great many industrial plants built in which full advantage of this situation has been taken, but it is relatively recently that serious consideration has been given to the question of how much more can be saved by combining the facilities of a public utility with those of an industrial. Those cited by Mr. Wood are perfectly clear and determinable in each case, and it may be pointed out again that there is no general solution for the problem, but each industrial must be calculated individually, since the accident of location and the synchronization or lack of synchronization of heat and power loads have a most profound effect upon the solution.

The major obstacle to the more rapid development of interconnections by way of combination plants between public utilities and industrials is mainly lack of confidence of the two groups in each other. For example, as a general rule the public utility engineers look upon the power produced by an industrial plant as being less reliable than that which they produce themselves. On the other hand, the industrials, and especially the larger ones, feel that their own power service is more reliable than that of the public utility. Such a situation is somewhat absurd. It may be fairly said at this time that the production of power by a public utility is actually more reliable than that produced by industrials. The reasons are perfectly obvious. The business of the public utility is to make power, and almost any one will admit that a specialist is best at his own game. The making of power in an industrial establishment is certainly not the main issue, and neither receives the careful attention that the product of the industrial receives, nor is it usually of the size which justifies the employment of high-grade specialists. Nobody will deny that the large public utilities employ more highly trained technical men that any other single group. One can find case after case were an industrial management is afraid that the public utility cannot serve them with power as continuously as they themselves when the industrial boiler plants are showing efficiencies as low as 45 per cent and generating equipment is being operated without any spare capacity whatever.

Of course it is true that some of the very large industrials, such as the steel mills, have plants of their own of sufficient size to justify the services of power specialists and have reliability and operating facilities on a par with those of public utilities. In this situation public-utility service is slightly less reliable than that of the industrial plant, as the outage of the transmission line service is superposed on that of the public-utility station. However, these examples are few and far between, and so far as the writer's experience goes, the plants and operation in the steel mills and other large industrials are definitely inferior of those of public-utility operation.

Another obstacle arises which is equally serious. In many cases the power available from an industrial plant as a by-product for delivery to utility lines is of the nature of off-peak or dump power, and it is more or less the custom of public utilities to rate this power as only valuable to the extent of fuel increment cost. Therefore they are only willing to offer figures of 1 to $1^1/_2$ mills per kw-hr. delivered to their lines, whereas the current they furnish may be charged at 7 mills to 9 mills. It is true that if the power is purely off-peak it is really worth only this much to the public utility, but a great many of the plants which might be considered for interconnection or combination service will deliver large quantities of power which is not dump or off-peak power, and in this case is worth just as much to the public utility, provided it is reliable, as if they made it themselves. This is likely to be the case for certain industrials such as steel mills, paper, rubber, and chemical plants which operate largely on a basis of a 24-hour day, seven days a week. The writer feels that, in the interests of getting a safer consideration of the value of such power, the method of figuring comparisons of cost on the basis of incremental statistics is decidedly dangerous. It is felt it is much safer and clearer to figure complete costs of power for each set-up using graphic methods covering the whole range of loads. The writer has seen figures prepared by two different parties on the same situation which showed a complete reversal due to a slight variation in incremental cost. If total costs had been employed, there could not possibly be any difference between the two. When working with incremental statistics, it is only too easy to lose sight of the effect upon total costs when the variation is carried any distance from a single load point.

On the other hand, the industrial management usually recognizes only operating and maintenance cost as representing the cost of power and lumps its power-plant investment costs in with other plant investment. This results in making comparisons

which are totally useless. No comparison of cost between public-utility and industrial-power service can be worth much unless made on the basis of both fixed and operating charges fairly determined. This second obstacle, therefore, sums up as a failure of both parties to determine prices for incoming and outgoing power that divide the profits reasonably between the public utility and the industrial. There are a great many industrials in which a combination plant owned and operated in some joint manner between the public utility and the industrial would pay the best returns on the investment. There are likewise a great many plants in which no such solution will be profitable, but no real growth can be expected in combination service by industrial and public-utility joint operation until real costs are fully recognized and there is full willingness on both sides to divide the profits fairly. To this end we need standard methods of accounting for costs which will be accepted by both groups and some method of evaluating reliability which is based on other things than opinions.

JULIUS G. BERGER.[12] This important subject of combined heat and power supply in industrial plants is one to which the writer has devoted many years, and he would cite a typical case where a manufacturing plant was about to increase its size considerably owing to another interest coming in with more capital. One of the questions to be decided was as to how steam and electricity needed to be supplied under the new conditions.

Two arguments were set forth by parties having something to sell—one recommended entire purchase of current, the other advised adding several more engines like those installed and making all electric power on the premises.

After a test of the existing power plant and a set-up of the steam and the electric current required in the future, a careful analysis was made of the problem, which was about as follows:

1 Make all possible power in the old plant; buy the requirements beyond that
2 Add a turbo-alternator to the old plant for heat-balance purposes; buy the requirements beyond that
3 Buy all the power, discard the old generating equipment, and motorize some steam-driven compressors with synchronous motors
4 Make all power in an extraction turbo-alternator plant
5 Make all power in a uniflow-engine generator plant.

The comparative figures then became about as follows:

Method	1	2	3	4	5
Comparative investments	$78,000	$111,000	$71,000	$449,000	$497,000
Comparative operating costs	170,000	161,000	171,000	177,000	183,000
Lowest investment, zero; others are relative increase	7,000	40,000	0	378,000	426,000
Lowest operating cost, zero; others are relative increase	9,000	0	10,000	16,000	22,000

This plainly indicated that a heat balance was most desirable, but still to make use of the old equipment and to keep the investment down, a method between 1 and 2 was adopted with very satisfactory results.

The writer has touched on only one phase of the problem that Mr. Ryan has so ably presented, to indicate that such studies lead to the obtaining of economical operating conditions at the lowest investment consistent with good practice.

It is hoped that the Society will continue to keep this subject before its meetings as an aid to awaken industry to the fact that it can not only often reduce its production cost in the power plant, but help to conserve our natural resources.

[12] Consulting Mechanical and Electrical Engineer, Newark, N. J. Mem. A.S.M.E.

C. F. HIRSHFELD.[13] The writer is heartily in accord with the views presented by Mr. Wood and with the arguments which he uses to support those views. In fact, the writer has been working and studying along such lines himself for several years and has reached similar conclusions independently.

There is no question that industrial competition is becoming rapidly more keen, both nationally and internationally. Such competition necessitates the study of everything that can possibly reduce production costs, even though the possible reduction per unit of output be exceedingly small. This is the driving force which activates those engaged in productive industry. A very similar motive, quite differently expressed, activates those engaged in the public-utility business. Here there is the continuing desire to be able to reduce the price charged for services. This reduction can occur only as the cost of producing units of such services can be reduced.

These motives are driving toward a common solution—a solution along such lines as indicated by Mr. Wood. But it must not be thought that this solution is completely or basically new. It rests, in the end, on that old friend, diversity. The public utilities have utilized diversities of various sorts, first in restricted areas and later over large areas, until now we have networks interconnecting such vast areas as are indicated by the author in his paper. We have not yet utilized all the previously recognized diversities along such lines, but we are daily coming closer to the time when we shall have done so; even now the pickings are becoming very lean. Interconnection with industrials, as described by the author, brings in a new set of diversities which can be used to the advantage of both the industrials and the customers of the utilities. It appears, therefore, as the next logical step in the steady march of ever-decreasing cost based upon the utilization of diversity.

Stripped of all complicating considerations, it is this idea that leads the writer to believe in the inevitable progress of the art in the direction indicated by Mr. Wood. But this progress will not be made without great difficulty. There are many complicating factors, psychological, physical, and economic, and it must not be concluded that, now that we see the light, we can all effect such interconnections overnight. Much study and much education are required before much progress can be made.

The time allotted for individual discussion does not permit even a cursory enumeration of the more important difficulties. This is regrettable because a comprehensive statement of them is necessarily the first step toward their solutions. However, one very important one may be mentioned profitably at this time.

A public utility is, among other things, a sort of trustee for the public that it serves. That public profits directly as the utility handles its business wisely and properly. Now consider a situation in which it can be shown that the utility might construct a plant on or near the property of an industrial primarily for the service of that industrial, say with electric power, process steam, and hot water. Assume that it can be shown that such action would result in cheaper service to the industrial than it could itself supply and also in cheaper service to the public through the utilization of otherwise unusable diversities.

Obviously all such results rest upon the assumption that the industrial is going to remain in business long enough to retire the investment made specifically for its service by the utility. Probably they rest on the further assumption that the industrial will maintain at least a certain average percentage of productive activity during that period. It is obvious that the utility when contemplating such a course is faced with the question of how far it is justified in gambling the necessary investment on the assumed

[13] Chief of Research Department, Detroit Edison Company, Detroit, Mich. Mem. A.S.M.E.

continuing solvency and business activity of a single large industrial.

In these days of rapidly changing industrial conditions and industrial products this is no insignificant consideration. The writer does not mean that it is to be regarded necessarily as an argument against interconnection with industrials. He does insist that it is an item which must come up for very serious consideration in any case in which such interconnection involves a large and specialized investment on the part of the utility. And there are many other equally difficult problems involved in this movement.

Z. G. Deutsch.[14] The papers by Mr. Wood and Mr. Ryan have dealt with apparently the same problem. The authors of both papers have clearly and forcibly demonstrated that, if we have sand in one hand and a rathole in the other, our procedure becomes obvious. They have further indicated that in the past this procedure has not been so obvious because, if one may be permitted to continue with the metaphor, the sand has been in the possession of one group, whereas the rathole has been held by another.

It is gratifying to hear that in a few isolated instances these two groups have been able to get together satisfactorily. As pointed out, there is still an enormous field for further work of this nature. It is felt, however, that extension of this work does not alone wait for a financial understanding together with an equitable means of bookkeeping, but that more often the difficulty is the amortization of present invested capital in power-producing equipment, which even though obsolete from the standpoint of utmost thermal efficiency, is still in good physical condition.

As an example of this, the writer knows of one mill which burns approximately 50,000 tons of coal per month and is capable of producing on the order of 40,000 firm kw. as by-product power. In this particular case the local public utility is unable to, or at least is prohibited from arranging for the purchase of this power due to certain contractual relationships; and furthermore the mill is not particularly interested in investing an enormous sum to replace a boiler plant which was a model of efficiency and size about twenty years ago and which has, of necessity, been kept in reasonably good physical condition. The administrators of this mill, and one has heard this as a common expression of other mill administrators, merely say, "But we are not in the power business."

Mr. Ryan's paper refers frequently to 100 per cent elimination of condenser losses and to 100 per cent thermal efficiency as long as the "exhaust steam" can be utilized by process. From the standpoint of the central-station engineer the industrial plant with a large heating or process load certainly does have the appearance of eliminating the condenser loss. However, this is only true in a few cases where the heat in the process steam is actually put into the product and shipped away with the product. Most generally an overall heat balance of a mill which uses large quantities of process steam will show that the heat content of the raw material is about equal to, or if anything more than, the heat content of the finished product. This includes, of course, all chemical heats of combination. The thermal balance of the mill referred to, which burns about 50,000 tons of coal per month, shows that this 50,000 tons of coal has been added to the atmosphere and to the source of cooling water almost quantitatively.

In an almost innumerable number of cases evaporator installations are built to use very low-pressure steam, and in this respect they are entirely comparable to a central station which has a boiler plant operating at 25 or 50 lb. pressure and condensing at about 20 in. vacuum. An evaporator is directly comparable to a boiler and condensing generator cycle.

Almost invariably equipment can be installed which will permit the evaporator to operate on steam of any assignable pressure and temperature, and this installation would substantially decrease the consumption of fuel in the same way that high-pressure boilers for turbines do. This last analogy is an example of a general case where new capital will reduce the consumption of process steam. Industrial plants also suffer tremendously from a lack of analysis of the consumption of the process steam. The writer knew of one instance where a chemical solution was being prepared in one portion of a large plant. This solution was concentrated up to about 50 deg. Baumé and was pumped to various processes within one-quarter mile of the point of preparation. Each of these processes then diluted the solution down, sometimes as low as 34 deg. Baumé, because it was more convenient to use in that particular strength.

By many other examples it can be shown that the consumption of process steam can be enormously reduced, often to such an extent that a central-station analysis together with an acceptance of the industrial process steam requirement may lead to a misexpenditure of money.

Therefore, in making a study for the purpose of recommending a unification of power-generating facilities between an industrial plant and a public utility it is recommended that the heat balance of the industrial plant itself be carefully studied to make sure that the portion of the low-head heat required in process cannot be obtained through some means of recirculation. Mr. Ryan himself once said to the writer that when the average mill is in trouble as to its steam supply there are two general things that can be done. The first is to buy and install more boilers; the second, which can much more frequently be carried out, is to reduce the current steam consumption to fit the existing boiler plant.

In a few words, the writer's recommendation is that the engineer engaged in this type of study work should be careful not to pass the buck of the condenser loss too easily to his industrial power-plant brother.

Author's Closure by Mr. Wood

The author agrees with Mr. Conrad in his suggestion that utility companies should plan for the establishment of a manufacturing district adjacent to large generating stations. Such a plan would reduce to a great extent the cost of transmission and distribution. It is this element of cost of power service that has trended upward while generating costs have continuously been lowered. Such a plan of interconnection would meet Mr. Taggart's criticism as losses of transmission and transformation would be greatly reduced and process steam sent to manufacturing plants. However, it is the existing diversified industrial plants that may be reached by the utility system that offer the greatest potential possibilities of interchange of power.

One of the most gratifying results of the presentation of Mr. Ryan's and the author's papers is the interest aroused among engineers who are actively interested in power problems of industrial plants. The more fully these problems are discussed and mutually understood the better for all concerned. We are all prone to magnify the importance of our relationship to such matters, but it is well to occasionally get the other fellow's point of view.

As a result of these discussions there is one point on which some agreement obtains; viz., the wastefulness of duplication of investment.

Author's Closure by Mr. Ryan

The author is glad to accept Mr. Kates' correction in regard to the efficiency of Diesel engines. However, with Mr. Kates'

[14] Consulting Engineer, Syracuse, N. Y. Jun. A.S.M.E.

figure of 7500 B.t.u. per kw-hr. rejected by the Diesel, there is a marked saving in thermal efficiency over a non-condensing steam prime mover which exhausts to the atmosphere.

The facts brought out in the discussion in regard to the practicability of using treated water in high-pressure boilers are most encouraging to the industrial-power engineer.

The prospect of becoming common carriers instead of manufacturers of power, as predicted by Mr. Randall, may not be very gratifying to the public utilities at the present time. Nevertheless, if Mr. Randall's prediction should be fulfilled, it is possible that the utilities would make more money with less investment than they do now. The author has heard the statement made by a prominent financier that the most profitable electric-light property in New England never owned a power plant.

Mr. Deutsch's comment on the desirability of investigating the process-steam consumption of an industrial plant, before designing a new power plant to provide that steam, is sound advice. By changes in process equipment or in methods of operation, it is frequently possible to save more fuel and more money than can possibly be saved by any power development.

Most of the statements made in this discussion, and in other papers concerning the cost of industrial power, are based on the erroneous assumption that one B.t.u. is worth as much as any other B.t.u. in an industrial process. The power engineer knows that this is not true in his own business, and that a B.t.u. at 700 deg. fahr. is worth almost infinitely more to him than one at 70 deg. fahr. This is just as true in almost any industrial process. It is common practice to credit a non-condensing prime mover with the heat content of its exhaust in direct proportion to the heat content of the live steam at the throttle. This basis of cost accounting does not represent the production cost of exhaust steam, and it establishes a price for exhaust steam which exceeds its value to the user.

It is probably on some such unsound basis of cost accounting that some astoundingly low costs of industrial electric power are obtained.

The discussion of Mr. Wood's paper and the author's has been most gratifying in that it shows an awakening respect for the public utilities' problem on the part of the industrial-power engineers, and likewise it displays an appreciation of the opportunities for cooperation with industrial plants on the part of the public utilities' engineers. Much as the engineers in these two fields of power engineering would like to maintain separate and distinct functions, the laws of economics compel a merging of their problems to produce solutions which best serve the interests of our country and of mankind.

FSP-53-26b

Engineering Aspects of Interchange of Power With Industrial Plants

Establishment of Means and Facilities for Utilizing Massed Resources to Serve the Power Requirements of Individual Industries

By B. F. WOOD,[1] NEW YORK, N. Y.

Economical operation can be effected and overhead costs greatly reduced in a great many cases where public-utility or other steam-generating or hydro power plants find it possible to hook up with large industrial operations. The advent of high steam pressures has largely increased these possibilities and extended the engineering problems involved in their proper solution. The engineer must seek the maximum overall economy with minimum investment having regard for reliability of service, and then work out a plan for the undertaking that will be to the equal advantage of all parties at interest.

INTERCHANGE of power may be secured by means of some plan of interconnection. The term "interconnection" carries the thought of tying together the transmission or other electrical facilities of two or more power systems.

Let us, for a moment, review the accomplishments of interchange of power by interconnection between public-utility systems.

About 25 years ago, in the United States, isolated or independent plants for the supply of electrical service to a community began to give way to the grouping of adjacent systems by the tying together of the transmission systems. This was primarily done for protection of service in emergencies and could be successful only when each company had a mutual regard for the common interest. As the advantages of interchange of power became better understood and appreciated, independent operating companies were brought under a common financial control through holding companies. Interconnection, more intelligent load dispatching, the use and development of the most economical power sources, standardization and interchangeability of equipment, better system planning, and many other advantages logically followed the extension of holding-company control.

Progress in interconnection has reached a point where the principal electric power systems between the Mississippi River and the Atlantic Coast and from the Gulf of Mexico to and across the Canadian boundary line may now interchange power. This territory comprises an area of approximately 900,000 sq. mi., about twice the size of Germany, France, and England combined.

Within a relatively short time interconnecting links will be extended to include other power systems west of the Mississippi, making the area of the then connected systems in excess of 1,500,000 sq. mi., in which there is a population of approximately 98,000,000. Some 20 major power systems and many more of smaller size serve this territory, in which there is a total of about 20,000,000 kw. in power-generating capacity. Each of the major power systems comprises a transmission network within itself, interconnecting from 400,000 to 2,000,000 kw. in power-generating facilities with interconnecting ties having capacities ranging from 25,000 to 125,000 kw. This great spread of interconnection has resulted in benefits to the power systems in the following respects:

1 Greater leeway in the choice of plant sites
2 Decrease in generating capacity due to diversity
3 Decrease in spare generating capacity
4 Increase in size of generating units, resulting in lower unit cost
5 Staggering of new construction
6 Making hydro capacity firm capacity
7 Making possible the use of more economical units.

The choice of plant site for a new generating station is influenced by three major considerations, namely: center of load, availability of condensing water, and the delivery and cost of fuel.

Interconnection tends to eliminate the restrictions due to load. As illustrating this statement, one may cite cases of such stations as Stanton, Deepwater, Trinidad, Toronto, Philo, Gorgas, and many others. All of these stations supply power into a transmission network of considerable extent, thus permitting selection of plant site to secure minimum operating cost because of cheaper fuel and increased available capacity because of an adequate supply of condensing water.

One advantage secured by interconnecting is the decrease in capacity due to diversity. The magnitude of this diversity may perhaps best be illustrated by the following cases:

1 The Southeastern system interconnects the Alabama-Mississippi systems (325,000 kw.) with the Georgia-South Carolina systems (225,000 kw.) and the Tennessee system (136,000 kw.). Diversity in loads adds about 40,000 kw. effective capacity to the combined system, about 5 per cent of the total.

2 Niagara-Hudson system connects the Buffalo System (900,000 kw.) with three systems in the eastern part of the

[1] President, Allied Engineers, Inc. Mem. A.S.M.E. Graduated from University of Arkansas and entered the employ of the Complete Electrical Construction Co. as Chief Engineer. For 15 years he had charge of the construction of steam and electric power stations for the Pennsylvania Railroad. In 1913 he became Vice-President and Chief Engineer of the United Gas and Electric Corporation. Four years later he entered business for himself, first as B. F. Wood, Inc., and later as Wood, Hulse, Yates Co., Inc. This company combined with Republic Engineers to form Stevens and Wood, Inc., which combined with the Dixie Construction Co. and changed its name to Allied Engineers, Inc.

Presented at the Second Plenary World Power Conference, Berlin, Germany, June 16 to 25, 1930. Also contributed by the Power Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

State (375,000 kw.). Load diversity adds between 30,000 and 50,000 kw. to the combined systems, or about 3 to 5 per cent of the total.

3 Pennsylvania-New Jersey interconnection ties Philadelphia Electric Company (950,000 kw.), the Public Service Company of New Jersey (860,000 kw.), and the Pennsylvania Power & Light Company (831,000 kw.). Load diversity adds over 300,000 kw. to the combined system, or nearly 12 per cent of the total.

It becomes possible, therefore, to reduce the total plant investment by 5 to 10 per cent because of system diversity when adequate transmission facilities are provided to distribute to the entire system the necessary reserve or standby capacity.

A further saving results in the decrease in spare equipment necessary to maintain reliability of service. Spare generating equipment in capacity equal to the largest single unit on one system becomes adequate spare for the interconnected system.

Increase in the size of generating units, which becomes possible for plant installations on interconnected systems, makes a substantial lowering of unit costs. A station, either hydro or steam, containing large units may be developed on the system or portion of a system, and later a station developed at another location, thus alternating or staggering the construction program to bring in only the additional capacity properly to meet the growth in load.

The possible saving in capital investment may be illustrated by the Toronto Station. This station in its first construction stage consisted of two 35,000-kw. units, which were installed at an average cost of $128 per kilowatt of capacity. In the next stage two additional 35,000-kw. units were added, making the average cost for the 140,000 kw. of installed capacity $114 per kilowatt. Had this station been constructed as a complete unit, under an interchange agreement, the generating equipment, instead of four 35,000-kw. units, would probably have been two 70,000-kw. units, which could have been constructed at a cost not in excess of $100 per kilowatt. The total cost of the output, including fixed charges on capital investment, operation, and maintenance, would have been 15 to possibly 20 per cent less for the station of larger generating units.

It is perhaps necessary to make some explanation of the statement that interconnection makes hydro capacity firm capacity. The usefulness of a hydro plant is limited to the ability of the system to absorb the capacity and energy that the stream flow as regulated by the available storage may develop. During low stream-flow periods the available capacity of run of river hydro plants may be supplemented by either storage hydro or steam plants, and the capacity of run of river hydro plants then becomes firm or useful capacity.

Many of the larger systems in the interconnected systems referred to are served by hydro as well as steam-generating stations, and to the extent that the systems are not so served the tendency is to interconnect with systems having generating facilities of different characteristics. Steam and hydro stations on a system supplant each other because of different characteristics.

The economy of combining such generating facilities results from the fact that the available output of the hydro station may be more fully utilized. There is thus provided a larger system into which the hydro energy may be poured, making it possible, during the high-water periods, to run the hydro plant to full capacity on base load, and during low-flow conditions the full capacity may be used during the short peak period, placing the economical steam stations on base load.

Large blocks of hydro energy available during high-flow seasons may be utilized to replace steam-generated energy, while during low-flow seasons when but little hydro energy is available the full hydro-plant capacity may be used daily for short periods on the system peaks. In this manner, every drop of water up to the installed hydro capacity may be effectively utilized. Such complete utilization, however, is only possible when the hydro plants are connected into systems having a minimum night or week-end load requirement sufficient to absorb the flood-flow hydro capacity and energy. With large hydro projects such load is rarely available except by extension of the interconnected system over a considerable geographic area without reference to political lines of division.

There remains, however, another condition that must be satisfied to secure the full advantages of the physical possibilities. The administrative direction must be in harmony with the economical advantages of the interconnected systems, a condition fully satisfied through ownership or lease of the hydro plant. In those cases where the ownership of the hydro plant, particularly if on streams where complete seasonal or yearly regulation is not obtained, lies with other interests, a mutually clear understanding of the common interests must obtain. It is extremely difficult if not impossible to express in a contract all conditions to secure the full utilization of all available power. The utility companies transmitting and disposing of the energy must say how and when the hydro plant is to be operated. The operations of the hydro as well as other generating stations must be under the immediate direction of the system load dispatcher unhampered by other restrictions.

The Conowingo (Susquehanna River) development of the Philadelphia Electric Company illustrates this point. The stream flow varies yearly as well as seasonally between wide limits (minimum 3000 sec-ft. to a maximum of 750,000 sec-ft.) and the day-to-day variation is frequently of considerable magnitude. The installed capacity of 250,000 kw. is used during high water at nearly 100 per cent load factor to carry the base load of the Pennsylvania-New Jersey interconnected systems on which the minimum load is approximately 460,000 kw. During low stream-flow conditions this full capacity is used for short periods on peak. In this plan of operation the total annual available output of some 1,350,000,000 kw-hr. is poured into the interconnected systems and profitably utilized. Without this mutually cooperative arrangement a considerable portion of usable hydro energy would be lost to the disadvantage of large numbers of domestic and industrial customers, and, in fact, is actually so lost on large undertakings where the administrative operation is by different authorities.

Interchange of power by means of the physical interconnection of different systems is thus the employment of massed resources. The unification of financial and administrative control extends the advantages of massed resources to other features, such as resources of capital and organized personnel. Larger and better projects may be developed and more intensive and careful study by a skilled organization may be devoted to the improvement of service and betterment of operating results.

The great development of and economic advantages gained to the utility systems of the United States during the past two decades by interchange of power through massed resources have been discussed at some length because, for similar reasons, it is believed that a great opportunity is offered for cooperation between industrial plants and utility systems. The next two decades should witness even greater strides in extending the interchange of power between industrial plants and utility systems through massed resources.

Let us now consider interchange of power with industrial plant; and in this discussion it is the purpose to think of interconnection as the means employed to secure the advantages of massed resources of power production.

Within the area over which this network of interconnected

utility systems extends, nearly 200 industrial concerns have, during the past few years, established new plants, with boiler equipment designed to operate at a pressure of 300 lb. or higher. Nearly two-thirds of this number installed power-generating equipment aggregating approximately 500,000 kw. of capacity. The advent of high pressure has made it possible for the industrial plant to get some or all of its power requirements from the steam that is subsequently used for process or other heating operations. There is, beyond doubt, a very much larger number of industrial plants in operation at less than 300 lb. pressure supplying the multiplicity of power and heating requirements of industrial enterprises. An industrial plant often requires process steam as well as electric power, and frequently some form of waste heat is available. Steam and electric power requirements of an industrial plant do not usually coincide, either hourly, daily, or seasonally, and these requirements do not, except in a general way, synchronize with the liberation of waste heat or the possible production of surplus electric power. A great field of opportunity is here presented for cooperation between utility and industrial companies to bring about a massing of resources of power production.

To secure the maximum degree of reliability and economy of power service and the fullest utilization of any waste heat or usable surplus power some arrangement must be made to bring about a massing of the industrial and utility companies' resources of power production. This is hardly possible if the utility company limits its activity solely to the furnishing of electric service, particularly if the utility company adheres rigidly to an established schedule of rates. A discussion between utility and industrial people frequently starts with a mutual distrust of each other's cost statements, which leads to dickering and may end in the industrial company determining to be wholly independent in its entire power service. Recently, a broader and more liberal view has prevailed, and progress is being made in bringing about an agreement to the mutual advantage of both interests. To some extent, this change of attitude may be due to a better understanding of unity of interests.

Among the means that may be employed to secure the advantages of massed resources of power production, with respect to utility and industrial plants, there may be mentioned the following:

1 The interconnection of the electric circuits securing advantages of protection of service, diversity of load conditions, economy of operation, etc.

2 The establishment of jointly owned plants and facilities, supplying to the industrial plant electric, steam, or other power service, utilizing the utility system as the reservoir from which to draw or into which any and all surplus electric power may be poured.

3 The building and operation of plants and facilities by a utility company near the industrial plant, supplying such power service as required by the industrial plant, making up any deficiency from or taking any surplus electric power on the utility company's power system.

In the first case there are the possibilities of all the advantages of interchange of electric power presented by interconnection between different utility systems with the further advantage, usually, of a different character and greater degree of diversity of load.

It is, however, the last two cases that present the greatest possibility for mutually advantageous arrangement between industrial and utility plants and that make the engineering studies to secure maximum economic results most interesting.

In the establishment of jointly owned plants or the allocation of a portion of the plant facilities to the service of the industrial plant, the total investment may be minimized. Many plant facilities such as real estate, railroad sidings, coal- and ash-handling equipment, etc., need not be duplicated. Spare equipment may serve as spare for both the industrial and utility. The organization for operation and maintenance may be spread over both operations.

A good illustration of the second case is the Deepwater Station, located on the New Jersey side of the Delaware River, just opposite Wilmington, Del. This station is jointly owned by the American Gas & Electric Company and the United Gas Improvement Company, with a portion of the plant allocated to the services of the E. I. du Pont de Nemours & Co.

The first two companies are important utility companies, with a large and rapidly growing electric light and power business. The du Pont company is one of the largest industrial companies, manufacturing widely diversified products and having a substantial and increasing need for both process steam and electric power. The combined additional electric-power requirements of the two utility companies was in the order of some 100,000 kw. demand and 400,000,000 to 600,000,000 kw-hr., annually while the industrial company wanted 200,000 to 400,000 lb. per hour of process steam at 180 lb. pressure. Mutual discussion between the three companies led to the conclusion that they could combine their needs to the economic advantage of all concerned. The power companies organized a company to build and operate a power station for their joint interests and to enter into a contract to furnish steam and electric service to the du Pont company.

After a careful study of plant investment and operating costs the power companies adopted a station designed to operate with a boiler pressure of 1400 lb. The initial installation includes six boilers, each of a capacity of about 330,000 lb. of steam per hour. Two such boilers are allocated to the service of the du Pont company, leaving two boilers, one standard and one reheat boiler, for each of the utility companies. The station is laid out on the unit plan with one standard and one reheat boiler in each of the utility sections and two standard boilers in the center or du Pont section. The initial turbine installation consists of two cross-compound units, each of a capacity of 55,000 kw. The high-pressure elements of these compound units are identical in design with the 12,500-kw. unit in the du Pont section. The exhaust from the du Pont unit, however, which at maximum load amounts to 530,000 lb. per hour, goes directly to evaporators which furnish 400,000 lb. of steam per hour at 180 lb. pressure.

Steam from the evaporators passes through live-steam superheaters bringing the temperature up to 440 deg. fahr. before it is sent out on the du Pont lines. The condensate from the evaporators is returned as feed to the boilers, making a closed cycle. The du Pont company returns or makes up the condensate of its steam supply, and to the extent that the return is at high temperature less heat is required in the evaporators.

The essential features of the contract between the utility companies and the du Pont company are as follows:

1 The du Pont company pays in monthly instalments a sum representing a reasonable return on the investment in that portion of the plant facilities allocated to their service.

2 It pays the proportionate share of all direct operating and maintenance costs, including fuel.

The du Pont company is thus entitled to all electric power generated by the steam that passes through its high-pressure turbine unit, and should its need for process steam be in excess of that required to produce the necessary supply of electric power, the excess power flows into the utility system and is credited to the du Pont company. On the other hand, should its need for electric power at any time exceed the production of the generating unit, power will be drawn from the utility company's system.

The second element of the du Pont company's monthly charge is determined by the ratio that the total heat supplied to its generating unit bears to the total heat supplied to all generating units. As a result of this arrangement it is given full access to all station-operating records and may even purchase or designate other sources of fuel if it believes lower operating costs would result.

The combined full utility and industrial load will require the operation of five boilers, leaving the sixth as spare for all companies. Furthermore, either utility company may, at any time, take any unused capacity of the other, paying only the proportionate operating and maintenance costs. Thus, to the extent that their respective loads do not synchronize, each company has the privilege of fully loading the unused capacity of the other without increasing its share of capital expense. An incentive is thus created that should result in keeping the station as nearly fully loaded at all times as possible. Should this occur, the net effect will be to the benefit of all parties, as in this manner the unit station-heat costs will be less because the total cost will be spread over a larger output.

This is believed to be one of the largest instances, if not the first instance, in this country of utilizing the massed resources of utility and industrial companies for power production. The successful working out of this arrangement should open up many new opportunities for the engineer in the problem of interchange of power between utility and industrial plants.

As an example of the third class—that is, of the utility company owning and operating the plant and facilities—may be cited the case of a steel company wishing to change its rolling mills and other steam-engine-driven equipment to electric-motor drive. The steel company produces finished products in an amount of approximately 90,000 gross tons per month. It was found that, after making use of coke-oven and blast-furnace gas in heating furnaces and other metallurgical operations, sufficient gas was available to supply the steel company's electric-power requirements after complete mill electrification. The steel company's electric-power requirement will then be about 300,000,000 kw. annually, with a maximum demand of 54,000 kw. The available waste gas will produce, over and above the steel company's requirements, a surplus of some 40,000,000 kw-hr. annually. The steel company either would have to install complete spare equipment or relay its electric-power service from the utility company's power system, thus either materially increasing its annual capital charges or adding to its operating charges for reserve or standby service.

An industrial company such as the steel company is usually not prepared to make large capital investments, except under pressure of necessity, unless the annual return on capital investment is greatly in excess of that required in the diversified power service of a utility company. This situation led to the suggestion that the utility company build, own, and operate the power plant and facilities, purchasing the waste heat from the steel company at substantially the equivalent cost of other fuel, and furnish the steel company with its entire electric-power requirements on a cost basis to yield a proper return on the investment.

The utility company could build a station designed to operate at 1400 lb. pressure, instead of 400 lb. as contemplated by the steel company, providing no spare generating equipment. The utility company could relay the steel company's service with the spare equipment required for its other service. Such a plant, in addition to supplying the steel company's requirements, could generate some 100,000,000 kw-hr. annually at a cost that could advantageously be poured into the utility company's system. The net result will be to furnish the steel company's entire electric-power requirement at a cost comparable with any cost to itself and to save the steel company an investment of something over $6,000,000 in power-station facilities and to increase the annual return on the monies to be spent by the steel company on its electrification program from about 20 per cent to about 25 per cent. While as yet no actual contract has been consummated to carry out this program the general principles have been accepted pending the development of details. The resources will be massed, no usable product wasted, and capital investment conserved.

A case now under consideration is that of a large manufacturer using some 3,000,000,000 lb. of steam per year for process and heating and at the same time buying and generating electric power up to a maximum demand of 42,000 kw. The manufacturer is faced with the necessity of abandoning one of two large boiler plants, and being thus faced with rehabilitating his steam and power supply, can effect substantial gains by building a high-pressure boiler plant and generating by-product power. Here again even greater overall results can be obtained by the public-utility company building the new plant and serving both the steam and electric-power requirements, primarily because the utility company can make a materially greater use of the investment in plant facilities.

Another case recently under consideration was a group of stockyard and packing-house companies whose plants are located close together. Their combined maximum demand for steam is almost 2,000,000 lb. an hour, now served from eight relatively low-pressure boiler plants, while they generate or purchase about 130,000,000 kw-hr. a year. Estimates of a central high-pressure steam station producing by-product power, including, of course, fixed charges on the new investment, show very substantial economies over the present operating costs, but the point to emphasize is that the overall saving is a maximum when the public-utility company is associated with the new enterprise, as this permits minimizing investment in spare or reserve plant capacity; it permits maximum economical use of all by-product power; and it supplies, in the most economical manner, electric power which at times is required in quantities greater than is available from the steam then used.

The economic advantage of expanding high-pressure steam through engines or turbines to make by-product power before the steam is used in process work is being lessened by two factors, namely: the constantly improving thermal performance of modern large turbine installations and the higher cost of boilers, evaporators, and other equipment required for by-product power production with high steam pressures.

Only a few years ago, a station thermal performance of 20,000 B.t.u. per kw-hr. was regarded as excellent. Many large central-station plants are now being designed for approximately 12,000 B.t.u. By-product power may be obtained for about 5000 B.t.u. per kw-hr., but in high-pressure plants evaporators are usually necessary to insure scale-free water in the boilers, and as much as 6000 B.t.u. per kw-hr. may be required. The ratio has thus been changed from about 4 to 1 to 2 to 1. If to obtain by-product power it becomes necessary to make large capital investment or if the rate of annual fixed charge is high, the economy of an independent high-pressure plant to supply the service to an industrial company is thus greatly reduced. The economic results of a station supplying combined service to an industrial plant and a utility system may, however, be quite improved and in any event should be better than is possible if each develops independently.

The principles of contractual relations between the industrial and power company are simple, but their application may be complex.

In principle the industrial should pay the power company a reasonable rate of return on all investments made on its account and also pay its proper share of all operating costs. In

practice it is often desired to reduce the payments to unit rates for steam and electric power.

While it is relatively simple to ascertain the probable costs for any given set of operating conditions, it is difficult to determine unit rates which will be equitable at all probable ranges and conditions of electric load and steam flow.

For instance, if by-product power from steam be involved, then the combined unit cost of saving both steam and electric power is a minimum when the investment in steam capacity is fully utilized and when the electric-power requirement is just that of the by-product power available from this amount of steam. Any unbalanced conditions from this exact relation between the quantity of steam and of electric power will increase the combined unit cost. Hence, the unit rates for each should bear some relation to the quantity of the other, and in the limit be equitable on the one hand for furnishing steam only a portion of the time and on the other hand for furnishing electric power only a portion of the time. This requires a very careful survey of all probable operating conditions and a clear understanding between the engineers of both companies.

Many other examples of the interchange of power with industrial plants might be cited. There are undoubtedly thousands of opportunities for the establishment of means and facilities to utilize massed resources to serve the power requirements of industrial plants. The advent of high steam pressures has largely increased these possibilities and extended the engineering problems involved in the proper solution. The engineer must seek the maximum overall economy with minimum investment, having regard for reliability of service, and then work out a plan for the undertaking that will be to the equal advantage of all parties at interest. These problems are of special interest because of the many new and unusual factors involved.

[NOTE: Discussion of this paper jointly with that of W. F. Ryan by Edgar J. Kates, Charles W. Conrad, James M. Taggart, Guy B. Randall, R. J. S. Pigott, C. F. Hirshfeld, and Z. G. Deutsch will be found following the Ryan paper.]

FSP-53-27

Combined Burners for Firing Waste Fuels

By R. C. VROOM,[1] NEW YORK, N. Y.

Waste by-products of oil refining, formerly difficult of disposal, are now burned in special plants to furnish electric and steam power. This is made possible by the design of high-capacity burners, some liberating 100,000,000 B.t.u. per hour. The author describes a wide-range mechanical atomizer of the circulating type and the results of an installation at the Louisiana Station at Baton Rouge of the Louisiana Steam Products, Inc. The burners are successfully firing crude or lubricating (acid) sludge, soda bottoms, neutralized sludge, acid tar, wax tailings, and flux bottoms, in addition to fuel oil.

IN certain industrial processes, and in particular in oil refineries, there are obtained various combustible by-products or residues which can be used as fuel provided that suitable combustion equipment is employed. In the past this utilization has been confined largely to those plants in which such materials were produced. In some cases their combustion has proved so difficult that it has been impracticable to consume them in such a manner. As a result they sometimes have collected in considerable quantities, and their disposal has represented a serious problem. In an article by Dr. A. E. Dunstan, chief chemist of the Anglo-Persian Oil Company, he says when referring to petroleum coke: "In the majority of refineries no immediate use for the coke could be found, and there arose again the question of storage space, almost acreage, as was the case with acid sludge."

Within recent years waste fuels have become of increasing importance, and not only more effective efforts to burn them have been made in the plants where they are produced, but often they are given some treatment to minimize their undesirable characteristics, and in this treated form the better grades are being furnished to outside plants.

In some instances public-utility companies have found it economical to construct a steam station adjacent to an industrial plant in order to make use of waste fuels, in which case the steam station supplies to the industrial plant process steam and electric current which the latter previously had produced itself.

The combustion of residual or waste fuels requires special attention, as fuels which heretofore have not been considered commercial, now are occupying a position of increasing importance.

In oil refineries the use of such fuels has been coupled with the necessity for a great increase in heat liberation per furnace, per unit of furnace volume, and per burner, due to the fact that these fuels often must be used for firing larger units requiring a higher rate of heat absorption per unit of heating surface. Also, modern refining processes frequently are sensitive to furnace conditions and necessitate a greater use of radiant-heat transfer with a minimum of excess air. In such cases absolute control of flame shape and other furnace conditions is essential.

The use of a few flexible and economical high-capacity burners for fuel firing, in contrast to a great number of smaller units, is in accordance with the modern trend of design for fuel-firing and other plant equipment. Burners are available in sizes to liberate up to 100,000,000 B.t.u. per hour when burning practically any liquid, gaseous, or pulverized residual fuel, without any sacrifice in economy or flexibility, and with the ability to give absolute control over the furnace conditions.

Often such burners are used with highly preheated air. In oil-still installations, where there have been great advances in the methods employed, the use of preheated air has been developed beyond the range ordinarily found in power plants, temperatures approaching 1000 deg. fahr. sometimes being employed. Such temperatures of course require the use of insulated panel burner register fronts and special metals, not only for the register parts, but for air preheaters and other equipment in contact with unusually hot gases.

The higher air temperatures increase the forced-draft pressure necessary at any given fuel rate per burner, and while the use of highly preheated air speeds combustion, the most careful burner design is required. Not only must air pressures be maintained within reason, but at the same time the correct flame shape and the other desirable characteristics which the burner had when operating at lower temperatures must not be sacrificed. Maximum turbulence is essential, as each particle of fuel must come in intimate contact with the greater volume occupied by the air necessary to burn it.

Not only is it necessary to have individual burners which are capable of handling standard as well as waste fuels at high capacity, but it is essential to have flexible combined units for two or three fuels, these being capable of obtaining maximum capacity with any one of the fuels. Fig. 1 shows part of a boiler room having six 3400-hp. boilers, each equipped with 20 combined gas and oil burners similar to the design shown in Fig. 4. In another boiler room of this station are eleven 1500-hp. boilers, each equipped with 15 of these burners, the total number of burners of this type in the plant being 285.

The word "combined" as used in this connection must be taken in its proper sense, or else the full advantage of a combined burner will not be indicated. Until a few years ago combined burners generally meant a multiplicity of burners for liquid, gaseous, or pulverized fuels "combined" in the same furnace. What is meant in this paper by a "combined burner" is a burner in which any one of three forms of fuel, liquid, gaseous, or pulverized, may be fired through the same throat opening into the furnace, and in which use is made of a common passage for the combustion air.

Combined units are advantageous for various reasons. In certain plants they are needed due to the fact that prices of the different types of standard fuels may fluctuate widely from time to time, and the use of such equipment enables the plant to burn that fuel which is the most economical. In some industries there are obtained from the various processes numerous waste fuels which are of such a character as to have practically no market value, but the supply of such fuels is irregular or inadequate to carry the entire plant load continuously, with the result that provision also must be made for burning standard fuels.

The advantages of combined burners over independent burners for the various types of fuels may be summarized as follows:

---

[1] Chief Engineer, Peabody Engineering Corporation. Assoc-Mem. A.S.M.E. After graduation from Stevens Institute of Technology in 1922 with a degree of M.E., the author spent a short period of service in the Engineering Department of the Western Union Telegraph Company. He then entered the employ of the Peabody Engineering Corporation, being engaged in problems related to the combustion of liquid, gaseous, and pulverized fuels.

Presented before a meeting of the Metropolitan Section, New York, N. Y., Jan. 20, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

1 The ease of operation due to a smaller number of burners.

2 The simplicity of furnace and air-duct construction and air control, due to the location of all burners in a single group in a common windbox, so that all fuels are fired through one furnace wall and with one set of throat openings into the furnace. The latter is of particular importance when water walls are used.

3 The ability to keep in operation at all times all of the burners firing any one furnace, thus eliminating the necessity for protecting the burners not in service.

4 The ability to light one fuel quickly from the other, permitting a practically instantaneous change in fuel without

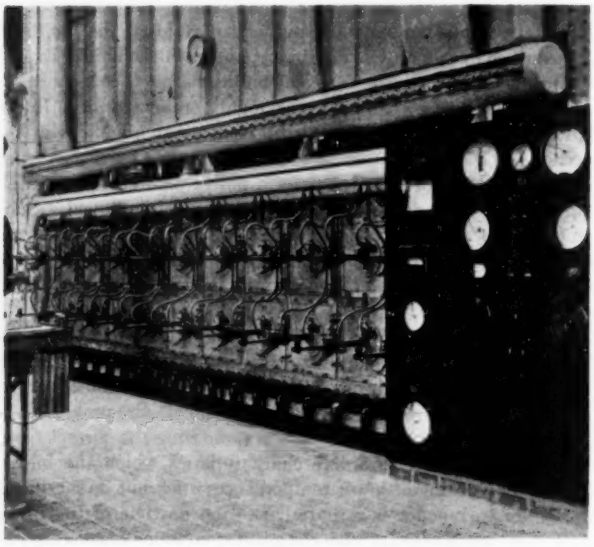

FIG. 1 PART OF BOILER ROOM EQUIPPED WITH COMBINED GAS AND OIL BURNERS

loss of output from the unit being fired. This feature makes a standby fuel instantly available.

5 The ability to burn pulverized fuels of very low volatile content or fuel containing considerable water, as ignition can be maintained, when not otherwise possible, by also burning simultaneously a small quantity of another fuel such as oil or gas.

Fig. 2 shows a convenient and reliable form of high-capacity combined burner for firing three fuels. It is a true combined burner in that all three fuels may be burned simultaneously. It is not necessary to remove a part of the burner for firing one fuel in order to insert a part of the burner for firing another fuel. The combustion air for the fuel being fired sweeps over and cools those parts of the burner for firing the other two fuels. A changeover can be made almost instantly.

The gaseous fuel is admitted to the furnace throat in an annular stream issuing from the inner periphery of the ring-shaped gas chamber immediately adjacent to the furnace throat opening. The gas impinges on the rapidly rotating column of air from the curved blades of the air register.

The pulverized fuel and carrier air are admitted tangent to the inner periphery of the rifled coal-burner body located coaxially and adjacent to the gas chamber. This stream is picked up and mixed with the secondary air from the register rotating in the same direction.

The liquid fuel issues from the wide-range mechanical-atomizer tip in a diverging conical sheet which just clears the furnace-throat surface. All the rotating combustion air from the register must pass through this sheet.

Fig. 3 shows a similar combined burner for lower capacities. In this burner the coal is admitted tangentially into a ringlike, volute-shaped coal chamber and delivered to the furnace throat through an annular slot in the inner periphery of the chamber. The gas chamber is located between the coal chamber and the furnace front plate.

In the commercial application of these combined burners for firing waste fuels numerous combinations of gaseous, pulverized, and liquid fuels of various types are encountered.

In addition to natural gas, many kinds of industrial gases are being fired by such units, among these being refinery-still gases. Such gaseous fuels sometimes have a heat content per cubic foot as high as 2200 B.t.u. When burning these gases, it is sometimes difficult to obtain the best-appearing furnace conditions, due to the presence of a large percentage of the heavier hydrocarbons, and also because there may be present considerable quantities of raw distillate in suspension. Of course, whenever possible, the raw distillate should be properly removed in a separator as its irregular entrainment in the gas continually changes the heat liberation of the burner and makes steady furnace conditions impossible. This is accentuated when operating with low excess air. It is obvious that for the proper combustion of such fuels, rapid and complete mixing of the fuel and air is essential.

Among the waste pulverized fuels being fired by these burners are various forms of petroleum coke. Depending upon the process from which the coke is derived, it may contain from 4 to 12 per cent of volatile matter and varying percentages of sulphur and ash. However, the ash content is normally low and its fusing point high, although in certain instances fuels containing ash having a fusing point as low as 2000 deg. fahr. are encountered, and proper provision must be made to handle these. Refinery coke is often less friable than ordinary bituminous coal, but it is burned readily in pulverized form unless its composition approaches that of a pitch.

When burning a low-volatile fuel particularly in a water-cooled furnace, the combined burner is very desirable as it provides

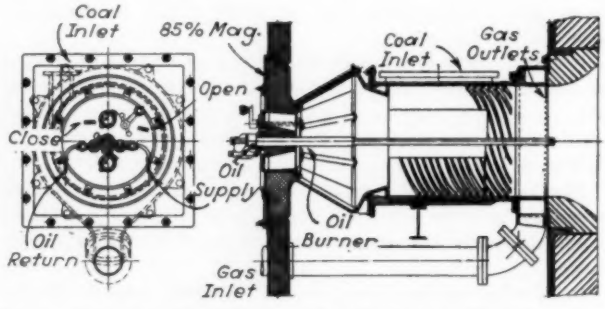

FIG. 2 COMBINED COAL, OIL, AND GAS BURNER OF HIGH CAPACITY

an auxiliary fuel which is available immediately, and in such a way that the control and operation of the plant are in no way complicated. In burning such pulverized fuels, it is necessary that proper combustion equipment be used, or else delayed ignition will occur and the combustible loss due to unburned carbon in the fly ash will be excessive.

The liquid fuels which are encountered often are of high specific gravity and contain a considerable amount of solid matter, carbonaceous or otherwise, in non-colloidal suspension. Mechanical atomization long has been recognized as the most economical method of burning liquid fuel, but not until recently has it been considered practicable for burning fuels of this nature.

Apparently one of the reasons for the previous inability to handle acid sludge in particular, and refinery sludges in general, in mechanical atomizers, was because capacity control

by the use of inlet pressure variation was employed. Furthermore, it had been taken for granted that the mechanical atomizer must handle the fuel under exactly the same conditions as the steam atomizer, and due to the high standard of operation expected from the mechanical atomizer, it was at the same time required to produce far better results before being considered successful.

It is well known that ordinary fuel oil cannot, in all cases, be handled with the mechanical atomizer with as little treatment as is required for the steam atomizer, and it is generally admitted that the slight additional preparation is warranted by the superior furnace conditions and better net economy with the mechanical burner. The proper procedure for economical sludge firing with mechanical burners for such fuels is therefore obvious.

Extensive tests indicated that with a little preparation refinery sludges could be burned satisfactory in the Peabody wide-range mechanical atomizer of the circulating type. As a result of these tests, an installation was made at the Louisiana Station of Louisiana Steam Products, Inc., at Baton Rouge, La., and the operating results have more than borne out the experimental data. The burners at this point are successfully firing crude or lubricating (acid) sludge, soda bottoms, neutralized sludge, acid tar, wax tailings, and flux bottoms, in addition to fuel oil. Combined burners are employed, as it also is necessary to fire pulverized and gaseous fuels.

The circulating type of wide-range mechanical atomizer is firing grades of asphalt pitch, which, while solid at atmospheric temperatures, melt at temperatures up to 125 deg. fahr., depending upon the source. When such pitches are delivered from the process to the burners at temperatures varying from 300 to 600 deg. fahr., their viscosity is sufficiently low to enable them to be atomized properly. The use of fuels delivered at the burners at such elevated temperatures has made it necessary to use special materials for the atomizer parts subject to pressure. Such atomizers also are firing other liquid residual fuels encountered in the petroleum industry.

The ability of this design of mechanical atomizer to handle such fuels successfully is due largely to the wide-range feature of control. This feature ordinarily is used to obtain a continuous and positive control (it is not a "high-low" burner) over a wide range of burner capacity, without reducing the fineness of atomization and without the necessity for changing atomizer tips. This is of particular importance in a plant with a widely fluctuating load when firing into a "black" furnace where the method of changing the supply pressure to take care of load range leads to coarser atomization at the lower capacities. Due to the existence at these lower capacities, of a lower heat liberation per unit of furnace volume, furnace conditions tend to become poorer under the best of circumstances, and coarse atomization seriously accentuates the trouble. When such conditions are coupled with increased burner capacities and the use of waste fuels which require the maximum fineness of atomization at all capacities to produce the best results, and which are far more sensitive to variation of supply pressure than ordinary fuel oils, it can be seen that the ability to operate over a wide range without affecting the atomization is almost essential.

In the case of heavy liquid fuels containing a considerable amount of foreign matter in non-colloidal suspension, the wide-range feature providing circulation has the very important added value that all of the fuel entering the burner is not necessarily sprayed. In this way a continuous circulation of fuel through the atomizer tip of the burner can be maintained at all times, part of the fuel supplied entering the furnace and part being returned to the tank. All dead ends are eliminated, the atomizer tip is cooled by the excess amount of circulating fuel, and the velocities can be kept sufficiently high to prevent such solid matter as is present from settling out and plugging. Tendency to carbonize in the atomizer tip is greatly reduced due to the additional cooling effect of the circulating fluid.

The mechanical-atomizing burner as an economical liquid-fuel-combustion unit has been discussed in various papers by E. H. Peabody, and this quality was brought forcibly to the attention of the engineering profession by data contained in the

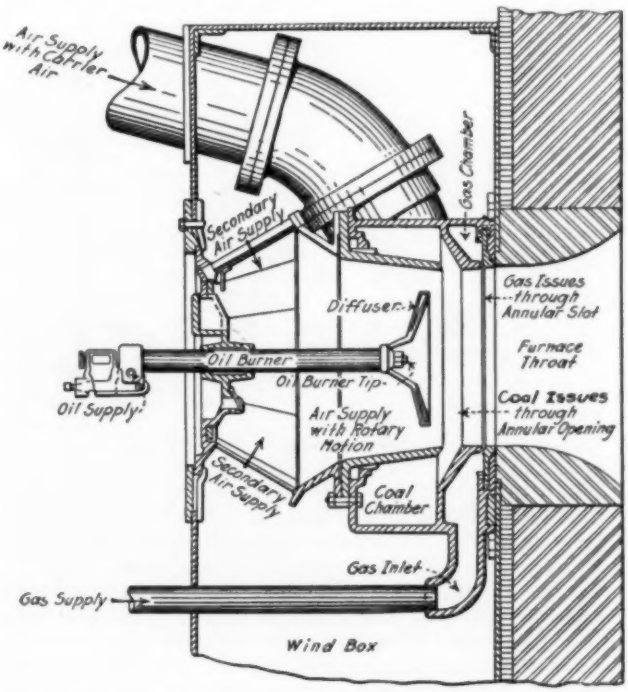

FIG. 3 COMBINED COAL, OIL, AND GAS BURNER OF LOWER CAPACITIES

paper on "Recent Developments in Oil Burning," presented at the forty-third convention of the National Electric Light Association, at Pasadena, Calif., May 18–22, 1920, by D. S. Jacobus and N. E. Lewis. While it is true that improvements have been made in both steam and mechanical atomizers since that time, the same general conclusions still apply as to the superiority of the mechanical atomizer. Whether the steam atomizer be of the flat-flame or round-flame type, there remains the objection that the amount of steam used for atomizing reduces the net efficiency below that possible with the mechanical burner and lowers the dew point of the exit gases. Furthermore, in the case of round-flame steam atomizers, the conclusion that the steam atomizer is less subject to stoppage than the mechanical atomizer, due to its larger passages, cannot be fully justified.

The wide-range mechanical atomizer of the circulating type can be changed to a steam atomizer merely by changing the atomizer tip. In this form one atomizer has fired successfully approximately 9000 lb. per hour of acid sludge. Gas atomization by the use of high-pressure refinery gas also has been used to produce corresponding heat liberations, but as an atomizing agent, gas is not quite so effective as steam. However, as this gas is often available at high pressure and must be disposed of, the quantity of atomizing gas is of relative unimportance, and every bit of atomizing agent acts as fuel contrary to conditions obtaining when using steam for this purpose. In the case of steam the most desirable furnace appearance often is obtained with an abnormal amount of atomizing steam, and if the operator is not careful, the quantity may reach an excessive figure.

Combined burners of the type shown in Fig. 4 have been purchased to fire two 600-lb. pressure boilers at the new steam station of the Humble Oil and Refining Company at Bayton, Tex. Each burner will fire approximately 4000 lb. per hour of fuel oil, and each boiler is to produce 350,000 lb. of steam per hour. In addition to this, there will be burned various refinery sludges and natural gas. These burners are combined gas and oil burners. They are similar to the three-fuel burner shown in Fig. 1, but Jackson & Moreland, of Boston, are the engineers for this project.

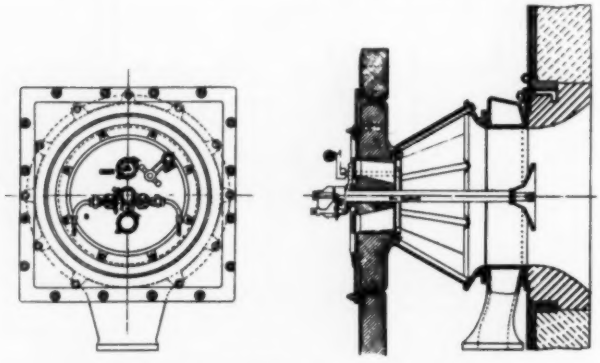

FIG. 4 COMBINED GAS AND OIL BURNER

An excellent example of a station in operation where various waste fuels are used to full advantage is the Louisiana Station. There combined burners similar to those shown in Figs. 2 and 4 are firing successfully various kinds of refinery sludges, petroleum coke, natural gas, and fuel oil, under four boilers, each having a capacity of 350,000 lb. of steam per hour, the boiler feed being treated Mississippi River water. Maximum operation represents about 850 per cent of rating based on the boiler heating surface. Stone & Webster Engineering Corporation, of Boston, are the engineers for this project.

This station is a typical public-utility plant, utilizing the waste fuels from a refinery and supplying to the refinery process steam and electric current, which previously the latter had produced in its own plant. It was described briefly in a paper presented before the Boston section of the A.I.E.E. on Nov. 18, 1930, by H. J. Klotz, Stone & Webster Engineering Corporation, and will be further discussed by him on Feb. 11, at the National Fuels Meeting in Chicago.

James F. Muir also has written a very interesting article[2] regarding the fuels at this plant. As this station is the first of its magnitude to be arranged for waste-fuel consumption in combined burners, its design and operation are of great interest to combustion engineers, and without a discussion of its fuel problems this paper would be incomplete.

The proportion of the heat supplied by the different fuels varies considerably, but averages about as follows, the fuel oil, which is used only for standby purposes, being neglected: 50 per cent natural gas, 33⅓ per cent refinery sludges, and 16⅔ per cent petroleum coke. About 85 per cent of the sludges contain from 30 to 50 per cent of dilute sulphuric acid, which gives them an actual acid content of about 12 to 20 per cent. Approximately one-half of the remaining 15 per cent of the sludges is strongly alkaline.

Some of the sludges fired at the Louisiana Station are more or less readily "burnable," but lubricating (acid) sludge, proper, has in many cases caused considerable difficulty, and the equipment heretofore developed in the refineries for burning it has been designed primarily for the purpose of disposing of the fuel and not with the main object of obtaining efficient combustion. The combustion of the sludge usually has been the most convenient means of disposal, and the mere ability to burn it has been considered an event.

This sludge is extremely variable in its characteristics, depending not only upon the initial crude stock, but also upon the method of treating that stock, including the amount and type of oil used for fluxing, as well as the method of agitating the flux with the sludge. Sludge often contains a large amount of suspended carbonaceous material, and one acid sludge may be practically solid and another rather fluid. It varies from day to day and from hour to hour. Some sludges have a heating value as high as 17,500 B.t.u. per lb., while others have a heating value as low as 8000 B.t.u. per lb. This wide variation is accounted for largely by differences in the amount of flux which must be added to make the material flow and by variations in the weak acid content. This latter often will run as high as 40 per cent. One sample of acid tar (which is considerably more fluid than the acid sludge) contained 54 per cent weak acid, i.e., acid and water, of which 38 per cent represented the acidity, which means that the tar contained 21 per cent of actual sulphuric acid.

The gravity of acid sludge may run from 5 to 14 deg. Baumé. The viscosity of the material cannot be determined, as the heavy and light components settle out in the viscosimeter, giving readings which are not at all representative of the true internal friction.

Lubricating acid sludge usually must be treated. This treatment ordinarily consists of fluxing with oil or tar to reduce its viscosity. Sometimes a sludge cannot be made "burnable" by fluxing in this fashion and must have a caustic material added to it. This process changes it from acid to neutralized sludge. The proper viscosity cannot always be obtained by additional heating, as some sludges tend to foam at a temperature slightly above 200 deg. fahr.

Sludges usually are kept in agitation in suitable lead- or brick-lined tanks by jets of steam or jets of steam and air. Quite possibly some method of mechanical agitation could be used instead of steam, but up to the present time this has not been done. In some plants it has been found impracticable to use tank heating coils, as the sludge carbonizes on the outside of the coils, reducing the heat transfer. Furthermore, agitation seems desirable, such as is now accomplished by the steam jets.

The preparation of the sludge varies with its character and u...ers in various refineries. No definite rules can be given for its treatment. As to whether it is properly fluxed or sufficiently agitated, only visual observation of experienced operators can determine. About the only definite statement which can be made about it is that a properly prepared sludge will be smooth and not too granular.

Improper treatment will cause coking. Any coke particles which are precipitated from the sludge tend to coagulate and form larger lumps of coke. The acid in the sludge appears to hold the coke in a sort of semi-colloidal suspension, and in certain cases, even if the sludge be boiled with heavy acid after the coke particles are precipitated, they will not again be absorbed by the fluid, but when boiled with a neutralizing agent, in some instances they can be made to return into suspension.

While the sludge itself is highly corrosive, due to its sulphuric-acid content, it often seems to be more so when mixed with steam, as is indicated by the wear on steam-atomizer nozzles. This may be accentuated by high velocity and the increased corrosive effect due to the presence of the steam at high temperature and to radiation from the furnace.

In firing boilers with acid sludge or acid tar it is necessary to keep the exit-gas temperatures above the dew point in order to prevent acid corrosion of the flues and certain portions of the air-heater surface. At the Louisiana Station no acid fuels are burned

[2] *Power*, Jan. 13, 1931.

when the boiler capacity falls below a value giving a final gas temperature below about 275 deg. fahr.

With some sludges slag is deposited on the furnace bottom and on the boiler tubes, similar to the deposit obtained when firing pulverized fuel with relatively low-fusing-point ash.

The alkaline sludges such as soda bottoms and neutralized sludge do not attack ferrous metals, so that the usual materials are satisfactory for piping and atomizer parts. Also, these sludges are generally more easily fired and less variable in their characteristics than the acid lubricating sludge. Brickwork difficulties when burning alkaline sludges sometimes are experienced. Furthermore, with alkaline sludges salt may be deposited on the boiler tubes, superheater, and air preheater. This may result in excessive draft losses unless ample soot-blowing equipment is provided.

In the installation at Baton Rouge, each burner is designed to handle approximately 2200 lb. per hour of liquid sludge or 1600 lb. of fuel oil. In addition to the acid sludge, acid tar, neutralized sludge, and soda bottoms, there also are burned wax tailings, flux bottoms, natural gas, petroleum coke, and fuel oil.

The liquid fuel piping on each boiler front consists of two sets of headers, one of steel for the neutral or alkaline fuels and one of brass for the acid fuels. All burners handling liquid fuels are piped to fire fuel oil which may be delivered in the steel header. The two bottom rows are piped to take their supply either from the acid or the alkaline header, while the top row takes its supply only from the alkaline header. Each burner is equipped to fire gas.

Each of two of the four boilers is equipped with 18 combined gas and liquid fuel burners in three horizontal rows of six each. The two lower rows of burners handle acid sludge. The top row handles neutral or alkaline fuels. All burners, of course, can be used for fuel oil or gas. The sludge supply header is

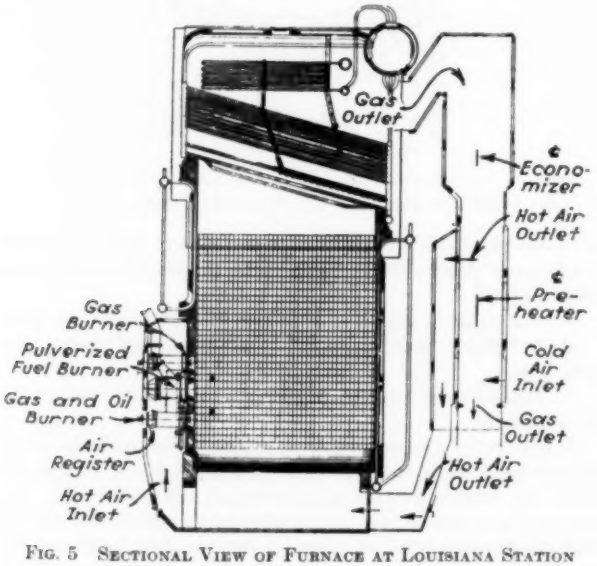

FIG. 5 SECTIONAL VIEW OF FURNACE AT LOUISIANA STATION

connected to the circulating pipe leading back to the tank to eliminate dead ends in the supply header and to prevent the deposition of coke therein.

Each of the second two boilers is fitted with 17 burners. There are six combined gas and liquid fuel burners of the usual size in the bottom row. In the second row are four of these combined burners and also two Toronto type combined pulverized-coke and gas burners in the center of the row. In the top row are five combined burners. The two lower rows are for handling acid tar, oil, and gas, and the top row for alkaline fuels, oil, and gas.

Gas is always fired in some of the burners. This is because the amount of sludge is insufficient to provide for the total steam output. Also previous refinery practice seems to indicate that it is better to fire gas and sludge together, although this is not always done. The burners at Baton Rouge fire through the vertical front wall of the furnace, and no ignition arches are provided. The interior surface of the furnace is water-cooled, part of the

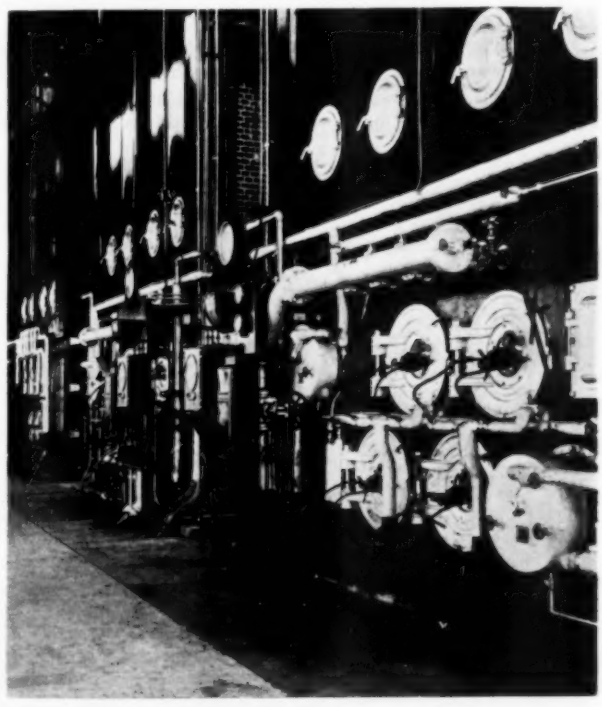

FIG. 6 PLANT IN WHICH DUBB'S RESIDUUM AND STILL GAS ARE FIRED

(The change from one fuel to the other is made many times a day.)

cooling tubes being covered with refractory material. Fig. 5 is a sectional view of the furnace.

As might be expected in a plant of this magnitude where the conditions are so new and the quantities so variable, some operating difficulties have been encountered. However, the author can say from his experience that they have been surprisingly few and far less than had been anticipated.

In so far as the combustion and furnace conditions are concerned, results are satisfactory. It sometimes happens when lighting "off" burners in handling a new batch of sludge that the first atomizers installed will plug due to material which has collected behind the stop valves connecting the burner to the fuel header. However, once in operation, the burners will stay clean for periods comparable with those between cleanings in a plant using ordinary fuel oil.

The question of the ideal material for burner tips has not been settled definitely. The difficulty of this problem will be realized when it is stated that, in one plant using steam atomizers, brass tips have been eaten away in 48 hours. The tips originally supplied seem to have given the best service, although this is not so good as is obtained when firing fuel oil. The burner tips are being used as a convenient "laboratory" in which to test materials for other parts of the plant subject to corrosion, such as pump liners, heater tubes, valve trim, etc. Substantial progress has been made, and new materials are in sight which give promise of being entirely satisfactory.

When it is considered that sometimes pulverized coke, sludge, and gas are being fired simultaneously in one furnace, it is obvious that the combustion problem is not a simple one. The fact that the operation has been carried on so successfully is a tribute, not only to the designers and builders of the plant, but also to the operators.

This plant is the only one of many plants where combined burners are being used for firing waste fuels. In other plants waste fuels which have been successfully fired in Peabody wide-range mechanical atomizers and gas burners are as follows:

1 Dubb's residuum, containing up to 30 per cent of base settlings and water and nearly 5 per cent of sediment by extraction.

2 Still gas, containing up to 10 per cent of hydrogen sulphide.

Both of these fuels (Dubb's residuum and still gas) are fired in the same plant, the change from gaseous fuel to liquid fuel being made many times a day. Fig. 6 shows the plant in which these fuels are fired.

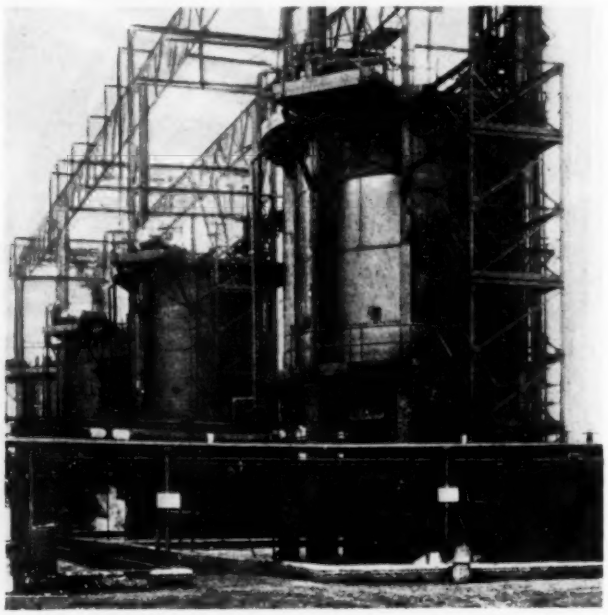

FIG. 7 VERTICAL HEATERS FIRED FROM TOP WITH COMBINED GAS AND OIL BURNERS

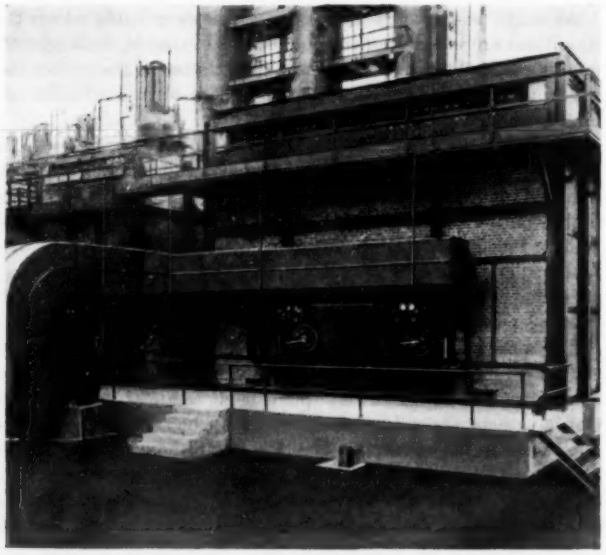

FIG. 8 SECTIONAL VIEW OF FURNACE FIRED FROM BOTTOM WITH SINGLE COMBINED STILL-GAS AND YARD-OIL BURNER

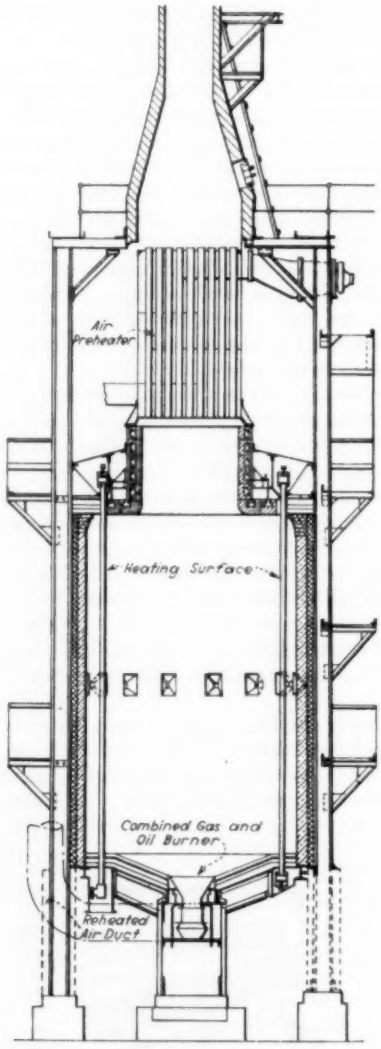

FIG. 9 COMBINED GAS AND OIL BURNERS FIRING A TUBE STILL

3 A mixture of gas oil and Holmes-Manley cracker bottoms.

4 A 125-deg. melting point asphalt pitch, delivered at 700 deg. fahr.

5 Distillate containing a considerable amount of solid matter in suspension.

It is extremely interesting to note that the oil refineries which usually have available large quantities of relatively inexpensive fuel, and which therefore are sometimes not particularly concerned about saving fuel, are turning to the circulating type of wide-range mechanical atomizer for their modern boiler and still installations. Control of heat distribution and furnace conditions and the saving of water for atomizing steam (an item of great importance to those plants so located that extensive feedwater treatment is required) are contributing factors.

Combined burners are being used for firing units of various types. Some of the newer types of oil stills are vertical cylinders as large as 25 ft. in diameter, the walls being formed by vertical tubes containing the fuel to be processed. Some of these are being fired from the bottom and some others from the top. The former method is now more widely employed.

Fig. 7 is a view of a bank of vertical heaters fired from the top with combined gas and oil burners. Fig. 8 is a sectional view of such a furnace fired from the bottom with a single combined still-gas and yard-oil burner of the type previously described. This burner liberates 40,000,000 B.t.u. per hour. When burning gas, two traverses at right-angles in a plane perpendicular to the axis and taken at 1-ft. intervals showed no CO and a CO_2 variation from 10.8 to 12 per cent, indicating the evenness of furnace conditions and the manner in which this single burner distributes the furnace gases. Fig. 9 shows combined gas and oil burners firing a tube still.

In closing, let it be said that the refinery engineers were presented with an enormous problem when they had to dispose of these fuels, and the fact that for years they have been burning them is a testimonial to their ingenuity. They have contributed a vast amount of information, and if this had not been available, modern installations of waste-fuel-burning plants would be far behind their present state of progress. No one can have had any contact with the oil-refining industry in this country without developing a profound respect for the intricate problems involved and the effective manner in which these are being solved.

The fact that refinery engineers have constructed many plants equipped with combined burners for the disposal of their waste fuels is an evidence of their foresightedness.

HYD-53-1

Federal Relations to Water-Power Development

By FRANK E. BONNER,[1] WASHINGTON, D. C.

With the amazing advances made in the production and distribution of electrical energy during the past decade, it is of interest to examine the part played by the Federal Government. This is particularly true of the water-power field where, through vast land holdings and constitutional authority in respect to navigation, the National Government exercises control over a large portion of the country's potential resources. During this period the administration of the law regulating the utilization of power sites involving Government interest has reposed with the Federal Power Commission. Although developments of many of the large rivers have been delayed by legislative embargoes and political controversy, the Commission has authorized the construction of many important projects, and about 2,600,000 horsepower of capacity is now operating under license from the Commission. The proper division of authority between the Government and the states has raised some complex problems which are pressing for solution.

IT IS UNNECESSARY to recount for the members of this Society the unparalleled progress made by the electric industry of this country during the past decade. The mechanical engineer has rendered such important aid in bringing about the astonishing economic and technical advances in supplying our people with cheap and dependable electrical service, that these achievements are already well known to your profession. The preeminent position that has been attained by the United States in the utilization of electrical energy for turning the wheels of industry and lightening the labor burden of the homes and the farms, makes it of some interest to consider what assistance or encouragement the Government may have contributed toward this result.

The primary relation of this industry is with the states. Under the system of regulated public utilities through which most of the electric energy is marketed in this country, the agencies of the state governments have highly important functions in the elimination of destructive competition, while at the same time safeguarding the public from unreasonable rates. The merit of this system has been amply demonstrated by the progressive lowering of the charges to consumers on the one hand, and the growth and stability of the industry on the other. The beneficial effects are especially conspicuous in the existing period of world-wide economic depression, when many basic industries are suffering from the effects of over-expansion and wasteful competition.

It has been recognized that electrical power must of necessity be consumed in the immediate vicinity of its place of production, and the matter of regulation has been viewed as a local problem properly within the authority of the states. With the growth of system interconnection, some problems of an interstate nature are beginning to arise, and proposals for their solution through imposition of Federal activity contemplate a minimum of interference with the existing machinery of the state agencies.

It is evident that the contacts of the Federal Government with the manufacturers and distributers of electrical energy have been confined mostly to those which are common to all industries. One prominent exception is in connection with the development of water power. Here through a combination of two factors the Government finds itself a shareholder in many potential water-power sites. These two factors consist of the Federal responsibility for navigation and the ownership of public land.

U. S. Government the Largest Real-Estate Holder in the Country

The fact is sometimes overlooked that the Government is by far the largest real-estate owner in the country. These holdings are concentrated chiefly in the western states, where vast areas of the original public domain have been reserved for national forests, national parks, Indian reservations, and other purposes. There are also millions of acres comprising the unreserved public domain for which no use, sufficiently profitable, has yet been found to justify private acquisition under the public land laws. Three-quarters of all the country's available water-power resources are found in the eleven most western states and, as might be expected, many of the potential sites involve United States land in greater or less degree. The national forests, which blanket the most of the great mountain ranges, harbor great power resources and have been an important factor in maintaining land useful for water-power purposes in public ownership. Even in these reservations, however, it is rarely found that a development may be made wholly on Government land. Through the operation of the public land laws prior to the establishment of the policies under which water power and other lands were reserved, the Government's holdings have been reduced to scattered and fragmentary tracts which serve to give merely a minority interest in many important developments. The Government, however, with its sovereign powers

---

[1] Executive Secretary, Federal Power Commission. Mem. Am. Soc. C.E. For the past 21 years Mr. Bonner has served continuously in the Government service. Upon completing his engineering training at the University of Montana in 1909, he entered the engineering department of the U. S. Forest Service and with that agency served as district engineer in charge of the engineering activities in several of the western field districts. For a time he had charge of the engineering work at the Research Laboratory at Madison, Wis., and later served several years as assistant chief engineer of the Forest Service at Washington, D. C., in the direction of water-power administration, highway construction, and other activities. In 1922 he was assigned as district engineer of the California District and in charge of the Federal Power Commission's activities of that region. He served in that capacity until transferred to his present position on July 1, 1929.

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

may not be disposed of through the ordinary process of condemnation like other small land holders, and therefore, even though its stake in the ownership of numerous sites is small, it is in a position to dictate the terms upon which the entire development may be allowed to proceed. In the exercise of this unlimited authority the Government becomes an important factor relative to many western projects which otherwise would be controlled solely by the state concerned.

Federal Jurisdiction Over Navigable Streams

The interests of navigation which supply the basis for the second element of Federal jurisdiction over certain water-power projects are derived from the fundamental law. The Constitution makes no reference to water power or navigation as such, but Section 8 of Article 1 embraces the following phrase:

> The Congress shall have power . . . to regulate commerce with foreign nations, and among the several States, and with the Indian Tribes.

By these few words the states surrendered to the central Government vast power under which many forms of Federal activity have grown up, including the control of the waterways used or useful for the transportation of persons or property in interstate commerce. The definition of navigable waters subject to the control of Congress has been the subject of much controversy. A long line of court decisions has failed to lay down a precise rule by which the jurisdictions of the state and national governments may be segregated with assurance. Whether a stream is navigable or not seems to be a mixed question of law and fact. On this point one of the clearest statements of the Supreme Court is that found in the decision in the case of United States vs. Holt State Bank (270 U. S. 49, 56) which said:

> The rule long since approved by this Court in applying the Constitution and Laws of the United States is that streams or lakes which are navigable in fact must be regarded as navigable in law; that they are navigable in fact when they are used, or are susceptible of being used, in their natural and ordinary condition, as highways for commerce, over which trade and travel are or may be conducted in the customary modes of trade and travel on water; and further that navigability does not depend on the particular mode in which such use is or may be had—whether by steamboats, sailing vessels, or flatboats—nor on an absence of occasional difficulties in navigation, but on the fact, if it be a fact, that the stream in its natural and ordinary condition affords a channel for useful commerce.

While uncertainty will arise relative to the navigable status of individual streams, it is evident that many of the country's waterways are subject to Federal jurisdiction, and by the act of March 3, 1899, Congress decreed that "any obstruction not affirmatively authorized by Congress to the navigable capacity of any of the waters of the United States is hereby prohibited." This law has been construed to apply not only to all structures placed in waters actually navigable, but also to such obstructions on non-navigable tributaries which have the effect of substantially impairing the use of "navigable waters" lower down on the stream.

From the foregoing, it is apparent that even though the separate states possess the right to control the use and development of waters within their borders, the National Government with its land ownerships and responsibility to navigation holds a basis for participation in the authorization of many water-power projects. Under existing law the administration of these interests is vested with the Federal Power Commission created in 1920. Prior to 1920 authorization for projects encroaching upon Government land or in navigable waters was obtained in various forms and from various agencies. Quite a number were sanctioned by direct grants from Congress. Many others were authorized under general legislation through permits issued by whatever Government agency happened to have jurisdiction over the property involved. These permits were of a revocable nature, and the difficulty of financing the cost of large works on leaseholds subject to bureaucratic vagaries led to a demand for legislation which would serve to promote the development of water resources.

Purpose of Federal Water-Power Act

After many years of discussion the Federal water-power act was passed in 1920. It aimed to provide a uniform policy under which all of the permissive actions of the Government might be managed. It authorized the granting of licenses which are in the nature of limited leases for 50 years. Development by private capital or public agencies was encouraged to the fullest extent practicable by limiting hampering restrictions and administrative fees to a minimum. Moreover the licensee was assured a stable tenure by the guarantee of reimbursement for the cost or fair value of improvements in case the lease should not be renewed upon its termination. The law thoroughly recognizes the principle that the exercise of Federal jurisdiction should be subordinated to that performed by the states in their rightful fields.

In preference to setting up an entirely independent agency for carrying out the functions of the law, Congress chose to have the work continued by the technical staffs of the departments. The necessary correlation of effort was accomplished by composing the Commission of the heads of the three departments concerned and providing it with a small headquarters staff. Pursuant to recommendation by the President, the last Congress authorized the substitution of full-time commissioners in order that the cabinet-officer members might be permitted to give undivided attention to the management of their departments.

The law has now had ten years of trial, and it seems appropriate that inquiry be made about what has been accomplished and whether it is serving to encourage water-power development as intended. As mentioned heretofore, this decade has been characterized by enormous growth and expansion in the electric industry. In this period the consumption of electrical energy has increased 137 per cent, while the population has grown only 16 per cent. Today we are using more than twice as much power per capita as we were ten years ago. The rapidly expanding demand has created the need for huge new sources of production, and many noteworthy water-power plants have been constructed.

Activities of Federal Power Commission

A substantial proportion of the new construction has been carried forward under the provisions of the Federal water-power act. Altogether the Commission has granted licenses for 449 projects, but only 107 of these are in the so-called major classification which embraces the developments larger than 100 hp. The rest relate to minor projects and segments of transmission lines crossing Government land. The geographical distribution of the licensed projects shows great concentration in the western states. California alone accounts for more than a third of the 449 projects, while the three Pacific Coast states together have just about half of the total number. Less than 10 per cent of the projects authorized are situated east of the Mississippi River. In most of the western cases the Government's jurisdiction arises from land ownership, while the limited number in the East are due almost entirely to navigation interest. Although few in number, the projects related to navigation are generally of large size.

The licenses of chief importance are those covering the 107 major projects. These range in magnitude from small plants of several hundred horsepower constructed to serve isolated

mining developments or small communities, to great public-utility developments of several hundred thousand horsepower. The giant generating stations at Niagara, at Conowingo, and on the Sierra Nevada streams of California furnish conspicuous examples of the large modern stations carried out under the existing Federal legislation. Obviously, many of the proposed projects involve questions of a highly controversial nature, but in handling applications the Commission has moved with such diligence and dispatch that no complaint has been made that construction has been unduly delayed on any legitimate project or that essential interests of the public have not been adequately safeguarded. During the past year the Commission has granted licenses which authorize the installation of more than 1,000,000 hp. It is anticipated that the immediate construction of these projects will contribute measurably toward the improvement of employment conditions and the stimulation of industrial development in the localities affected. During the same period, 30 applications were rejected pursuant to the Commission's endeavors to prevent favorable sites from falling into the hands of speculative enterprises which are unprepared to proceed with construction.

Aggregate Capacity of Water-Power Plants Under License

The aggregate capacity of plants under license which have been completed and placed in operation now amounts to about 2,600,000 hp. This comprises approximately 25 per cent of all the water-power capacity, and slightly less than 6 per cent of the total generating capacity in public-utility service. The Commission has no jurisdiction in respect to water-power developments other than the projects under license, and thus it is apparent that the scope of its authority in respect to the electrical industry as a whole is comparatively limited. Contrary to popular impression, the Commission has almost no jurisdiction in the field of rate regulation. The law specifically limits the exercise of such functions by the Commission to those licensed projects not controlled by state regulation, and since practically all the states embracing licensed projects are supervising public-utility rates, there has been little room for the Commission to engage in this business.

Since the authority of the Commission is by no means exclusive in respect to the licensed projects, the administration of the law has required close correlation with the activities of the state agencies. In general, these relations have been entirely harmonious and mutually helpful, but at times there has been complaint that the Commission was stretching its authority unduly. These complaints have related mostly to jurisdiction over projects located entirely on private land along non-navigable tributaries, where the Commission has assumed that the operation of the project works might serve to impair the use of navigable waterways lower down on the stream. The Commission's powers over such developments are rather vague and indefinite under the law, and a number of the states have challenged the Government's constitutional authority. They assert that the assumption of jurisdiction in such cases constitutes a serious invasion of the rights of the states, and interferes unnecessarily with developments of strictly local concern. For guidance in the matter the Commission has recently obtained an interpretation of the law from the Attorney General of the United States. This opinion holds that the Commission, in such cases, may grant licenses embodying terms restricted to those necessary for the protection of navigation. The states do not contest or object to reasonable exercise of the Government's functions in safeguarding navigation, and water-power licenses designed for this specific purpose will probably be acceptable to them. By thus harmonizing the respective jurisdictions of the State and Federal governments so that each may be effective in its proper field, a threatening shadow on the operation of the law will be removed.

With the extensive construction of new hydroelectric projects recently, it is somewhat surprising to find that the proportion of the energy requirements now generated from water power is practically the same as it was ten years ago. We are still producing only slightly more than a third of the country's public-utility needs from water power, and manufacturing the rest in fuel-burning stations. When the factors bearing on the situation are examined, some doubt is occasioned as to whether water power will be able to maintain as large a share of the increasing business of the future. We are in a period of great shifting of fundamental economic conditions. The tremendous production of cheap fuel supplies, the low cost of their distribution, and the remarkable improvements in machinery used for their transformation into electrical energy, have largely dispelled the popular notion about the advantages of water power. Even in the regions of abundant water-power resources there is a marked increase in the dependence placed on fuel-generated energy. Other factors which are restricting wider use of the water-power resources include the high cost of transmission to distant load centers, the deficient water supplies due to severe and repeated droughts, the increase of obstructive litigation, the tendency to make water-power developments the object of political controversies, and the imposition of special tax burdens on this particular form of power generation. It is evident that under present conditions the development of water power is faced with the keenest sort of competition by steam plants, and notwithstanding the encouragement extended by the Federal law the undertaking of new projects will depend largely upon a full measure of public cooperation.

Discussion

Guido H. Marx.[2] To the student of the conservation movement in our country familiar with the issues involved in the long campaign which culminated in Public Act No. 280 of the 66th Congress, known as the Water Power Act, this paper—emanating from the Executive Secretary of the Federal Power Commission, the executive officer primarily concerned with seeing that the act's provisions protecting the rights and interests of the general public are effectively exercised—is more than a disquieting one; it is one which should stir him to pro est and action.

To discuss in detail the departure of its philosophy from that of the act which the Power Commission is supposed to enforce would require space equal to that occupied by the paper itself. It is desirable, therefore, to limit th's discussion to two points only of the many which should be taken up.

(1) The author says, "It has been recognized that electrical power must of necessity be consumed in the immediate vicinity of its place of production," and upon this he rests his argument for state regulation with a "minimum interference" by Federal authority. To engineers possessing even the most elementary knowledge of present-day electrical transmission of power the statement is known to be the direct antithesis of the actual fact, and the argument based upon it is as invalid as the foundation is worthless. A large part of the admitted failure of state regulation of public utilities can be laid directly at the door of lack of coincident jurisdiction.

In a pamphlet issued by the Guarantee Trust Company of New York (surely not a Bolshevistic source) under date of Sep-

[2] Professor of Machine Design, Stanford University, P. O. Stanford University, Calif. Mem. A.S.M.E.

tember 15, 1920, entitled "Our Vast Unused Energy," and containing a reprint of the act in question, there is this interpretation of the regulatory powers conferred upon the commission:

> Public service enterprises are subjected to control of service and rates by state commissions where such exist, and where such a state commission is not in existence, the Federal Power Commission is authorized to regulate and control service, rates, and the issuance of securities. When the power or any part of it enters into interstate or foreign commerce, the rates of service must be reasonable, just, and non-discriminating. Briefly, this involves a degree of control in the field of power development and distribution between states comparable to that exercised over railways by the Interstate Commerce Commission.

In the present writer's mind the query arises whether the attitude of relinquishment shown in the paper by this executive officer does not amount to nonfeasance.

One minor question in passing; one wonders what is meant by the phrase "to prevent favorable sites from falling into the hands of speculative enterprises which are unprepared to proceed with construction." Is this the method employed by the Commission to encourage that sturdy individualism we have been hearing so much about? Among the unenlightened there might be some who would construe the words to imply that those not affiliated with the great pecuniary interests, popularly known as the "power trust," may more hopefully expend their efforts of initiative in some other line of "private enterprise."

(2) The discussion of the relative economic merits of water or fuel power which closes the paper, with an attempt to minimize the importance of the water-power issue, can scarcely mislead a group of engineers who are accustomed to analyze the differences between permanent real values and temporary pecuniary values. It is little less than tragic that a Federal administration from whom engineers, in general, had hoped so much in achievement and prestige should have no more dependable sources to inform them of the temper of the people, not to mention their will as expressed in their executed law. Some of the consequences can be seen in the results of the recent elections as shown in New York, Pennsylvania, Tennessee, Nebraska, and elsewhere.

NOTE: Following the presentation of Mr. Bonner's paper and the reading of the letter from Professor Marx, an oral discussion developed. The consensus of opinion expressed was strongly in support of the principles advocated in Mr. Bonner's paper. It was deemed desirable that the impartial and unbiased viewpoint of the engineering profession on these questions be made available to governmental bureaus desiring it, and to the public. This led to the preparation of the following resolution.

> *Resolved*, That the Hydraulic Division recommend to Council that it sponsor the formation of a committee to be known as the Engineers Water-Power Policy Committee, and that the committee be composed of five members, two of which are to be appointed by the American Engineering Council, one by The American Society of Mechanical Engineers, one by the American Institute of Electrical Engineers, and one by the American Society of Civil Engineers.

[The resolution was presented to the Council by Ely C. Hutchinson, and the Council voted to transmit it to the American Engineering Council with the suggestion that a committee corresponding to the one mentioned in the resolution be set up in the American Engineering Council to deal with this matter. Similar action was taken by the American Society of Civil Engineers and the American Institute of Electrical Engineers.—EDITOR.]

Calibration of a Large Nozzle

By JOHN R. DuPRIEST,[1] MINNEAPOLIS, MINN., AND JAMES H. POLHEMUS,[2] PORTLAND, ORE.

In testing large centrifugal pumps it is difficult to determine the amount of water that is being handled. In many cases the quantity is so great it is almost impossible to determine it by the ordinary field weighing system. The use of standard test nozzles offers a simple means of determining the capacity of large pumps, but the nozzles must be accurately calibrated. The authors made a test of three pumps by laying about 1000 ft. of pipe behind a dredge and attached standard nozzles to the end of the pipe line for calibration purposes. The quantity of water flowing was determined by the salt-solution method.

IN the testing of large centrifugal pumps one of the difficult tasks is to determine the amount of water being handled by the pump. In many cases the quantity is so great that it is practically impossible to determine it by any ordinary field weighing system.

J. R. DuPriest

There are several methods used to determine the capacity of large pumps, and each method has advantages and disadvantages, depending on the conditions under which the tests must be made. Standard test nozzles offer a very simple means of determining the capacity of large pumps, but the nozzles must be very accurately calibrated in order to insure trustworthy results.

Fig. 1 shows dimensions of a set of nozzles which have been used for many years for the testing of large hydraulic dredge pumps and which are considered standard for such work.

Some time ago the authors were engaged in research work to collect data on large dredge pumps preparatory to building the large Diesel-electric dredge *Clackamas* for the Port of Portland. When this work was under consideration the question arose as to the methods to be used for testing the pumps, and naturally the nozzle method was suggested on account of its simplicity.

Since the work to be done was of great importance, it was highly desirable that the results be as accurate as it was possible to obtain from field tests; therefore every phase of the work was very carefully studied.

J. H. Polhemus

One of the first questions therefore to be considered was the accuracy of the nozzle method for such tests.

Investigation showed that a coefficient of discharge of 0.94 had been established for this set of nozzles for all operating conditions and had been applied to many tests over a long period of years. No one seemed to know just when this coefficient was established or by whom.

The authors were not just satisfied as to the accuracy of this coefficient and decided to make an effort to recalibrate the set of nozzles. From the design of the nozzles one would hardly expect a very high coefficient, and also it did

[1] Professor of Mechanical Engineering, University of Minnesota. Mem. A.S.M.E. Mr. DuPriest was graduated in 1901 from Virginia Polytechnic Institute with B.S. in E.E. In 1901–1905, in charge of mathematics and shop work in high schools at Marion, S. C., and at Clearfield, Pa.; 1905–1906, drafting and design with General Electric Company, Ingersoll-Rand Company; 1906–1909, designer on steam and gas engines with the C. & G. Cooper Co., Mt. Vernon, Ohio; 1909–1911, chief engineer, Columbus Machine Company, Columbus, Ohio; 1911–1920, instructor at Cornell University and at University of Wisconsin, and professor at University of Idaho and Rensselaer Polytechnic Institute; 1920–1921, consulting engineer, Ellicott Machine Corporation, Baltimore, Md., and was sent abroad to study designs of special machinery; 1921–1927, consulting engineer for the Port of Portland, designing the main pump on the new Diesel-electric dredge *Clackamas;* 1927 to date, head of Department of Mechanical Engineering, University of Minnesota.

[2] General Manager and Chief Engineer, Port of Portland. Mr. Polhemus was graduated from Leland Stanford, Jr., University in 1910. He became connected with the Port of Portland in 1920 after having been the general manager and chief engineer of the Coos Bay Ship Building Company from 1917 to 1920, during which time this company built twelve ships for the United States Shipping Board. Prior to 1927 he served as an assistant engineer for the U. S. Engineer Department for some six years. During the last three years he was in charge of the river and harbor improvement work in southern Oregon, an interesting work in that district at that time being the dredging for the Coos Bay ocean bar with a seagoing dredge. This was the first successful bar dredging of this nature on the rough exposed North Pacific coast harbors. In his present position he has designed, built, and operated some of the largest and most modern hydraulic pipe-line dredges in this country.

Contributed by the Hydraulic Division and presented at the Semi-Annual Meeting, Birmingham, Ala., April 20 to 23, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

not seem reasonable that the same coefficient would hold for all nozzles of the set during wide variations in pressure and while L/D was changing so much.

Finally it was decided to lay about 1000 ft. of pipe behind the dredge and attach the nozzles to the end of the pipe line for calibration purposes. This procedure was used during complete tests of three pumps, and the results are given in this paper.

The quantity of water flowing was found by determining the pipe-line velocity by the salt-solution method, and it is believed that the results found in this way are as accurate as could be obtained under the circumstances. Data from these tests plot up in families of curves, which enables errors of observation to

be very easily detected. Pipe-line-velocity curves for the three tests are shown in Figs. 2, 3, and 4, and the results seem consistent.

The coefficients of discharge for the nozzles were found from the equation

$$Q = CA\sqrt{2gh}$$

where Q = cu. ft. of water per sec.
A = area of nozzle in sq. ft.
h = total head on nozzle at center line in ft.

Tables 1, 2, and 3 give observed and computed data for calculating values for C, and these data were obtained from curves shown in Figs. 2 to 10.

Total head on the nozzle was found as follows: Pressures were read just ahead of the nozzle, and line pressures just behind

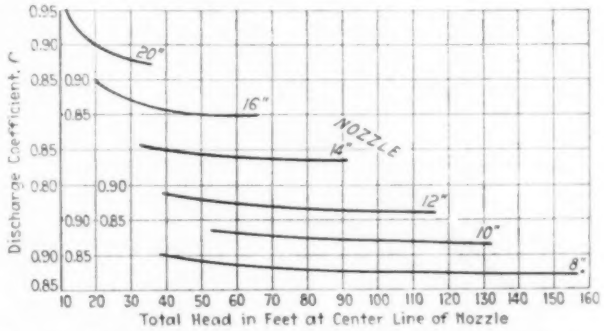

FIG. 17 NOZZLE COEFFICIENT CURVES DRAWN TO THE SAME SCALES

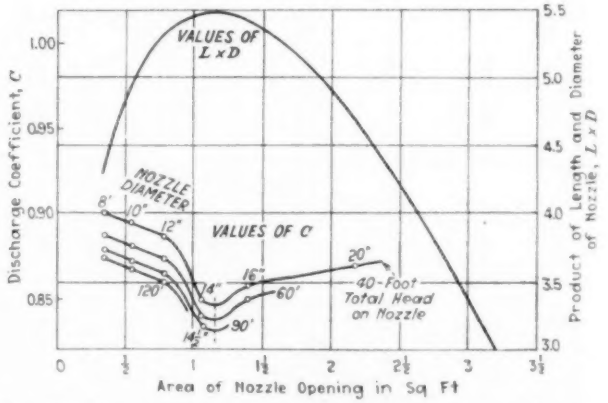

FIG. 18 COEFFICIENTS OF DISCHARGE PLOTTED AGAINST AREA OF NOZZLES FOR CONSTANT DISCHARGE HEADS ON THE NOZZLES

the dredge. These pressures were plotted up as shown in Figs. 5 to 10 to smooth out errors. Pressures were then read from the curves for chosen speeds, and to these values were added velocity-head and gage-elevation corrections.

Curves for the coefficients of discharge as a function of head on the nozzle for each nozzle are given in Figs. 11 to 16, and Fig. 17 shows curves for all nozzles plotted to the same scales, but displaced vertically.

The method of drawing the curves for the different nozzles was as follows: A pencil curve was drawn through each set of points for a nozzle as though only one set of data was available; values were then read from the three curves for selected heads, and the averages of these readings were used in plotting the final curves.

As was expected, the different nozzles gave different coefficients since L/D varied over a wide range and also the heads varied a great deal. The coefficients found are all much lower than the value 0.94 which has been used in the past, and it is interesting to note that the 14-in. nozzle gave the smallest coefficient.

The authors were a little surprised at the results when first obtained, but a careful review of all data and computations indicated that the work was free from numerical errors, and

further study of the question made the results seem more reasonable.

A nozzle placed on the end of a pipe will act in quite a different way from a nozzle attached to the side of a tank. If the length of a nozzle attached to a tank approaches zero, the result is an orifice in a thin plate, and the coefficient will be near 0.6, whereas with the set of nozzles attached to a pipe, of the same diameter as the largest nozzle connection, as the nozzle is shortened the

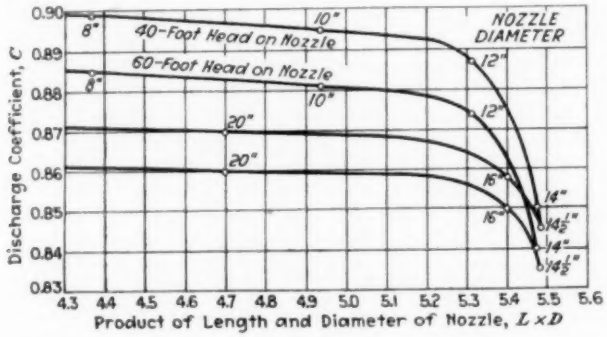

FIG. 19 DISCHARGE COEFFICIENT, C VERSUS $L \times D$
(For a 15-in. conical nozzle attached to a pipe 29 in. inside diameter.)

final result will be an open-end pipe with a coefficient approaching unity.

Inspection of Fig. 1 shows that the design of the set of nozzles is such that each nozzle is a frustum of a cone and that the exit side of each nozzle has a very sharp edge which would be expected to give a low coefficient of discharge. The nozzles cannot be changed to improve the bad exit conditions if they are to be assembled to form a set as in Fig. 1.

After finding by experiment that the lowest coefficient of discharge was for the 14-in. nozzle, further study was undertaken to determine the reason for this result and to find out if possible just where the lowest value might fall. Curves were plotted, as in Fig. 18, showing coefficients of discharge against area of nozzles for constant discharge heads on the nozzles, and it appeared that the minimum value for the discharge coefficient would occur for a nozzle slightly larger than 14 in.

With constant head on the nozzles, the only variables are L and D; therefore some relation was sought between these dimensions which might have a critical value when the coefficient was a minimum. After studies were made along several different lines, it was found that when the product of $L \times D$ was plotted against the area of the nozzle, the curve shown in Fig. 18 was obtained, which appeared to have a critical value just beyond the 14-in. nozzle point.

This result suggested an analysis by the calculus, and it was then found that the maximum value for $L \times D$, regardless of the nozzle angle, always occurred at a point where the diameter of the nozzle was one-half the diameter at the largest end.

Now since $L \times D$ was found to have a critical value and also the coefficients of discharge showed critical values, curves were plotted between these two sets of data, giving the very interesting results shown in Fig. 19.

The authors have no explanation just now to offer for these apparently unusual results, but it is believed, if sufficient data were available and all factors affecting loss through a nozzle were taken into consideration, that a satisfactory analysis of this problem could be made.

As mentioned, the coefficients found for this set of nozzles are much lower than the value 0.94 which has been used in the past; however, the data were very carefully observed, and in working up the results care was taken to smooth out errors of observation, and also numerical work was thoroughly checked. It is believed, therefore, that the results given are substantially correct for the conditions under which the nozzles were calibrated.

It should be noted here that in making comparisons with dredge-performance data, which have been obtained by using a value of $C = 0.94$, capacities and efficiencies will be too high for all such tests.

Another point of interest in this connection is that it is commonly stated that any nozzle is equivalent to a definite length of pipe line under all conditions of operation.

The curves shown in Fig. 20 give pipe-line lengths against static pressures for various size nozzles, and it was found that

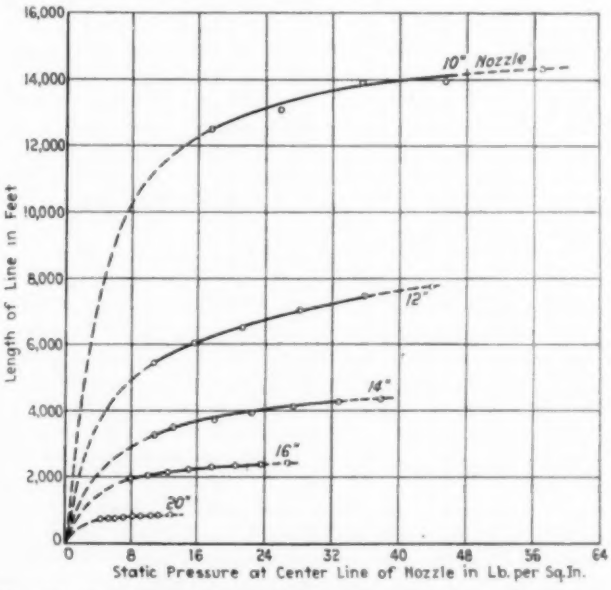

FIG. 20 PIPE-LINE LENGTHS PLOTTED AGAINST STATIC PRESSURES FOR VARIOUS SIZE NOZZLES

the length equivalent to a given size nozzle increased as the static pressure at the center line of the nozzle increased.

The authors realize that the nozzle discussed in this paper is of such a large size that very few engineers will have occasion to make use of the data and results presented. It is hoped, however, that this discussion will create some interest in the general subject of nozzles for measuring the flow of water and perhaps lead other engineers to follow up this work on perhaps smaller nozzles of similar design with the result that something of real value may soon be added to the meager literature on this subject.

The nozzle offers a very simple means of measuring the flow of water, and it would seem that it would be well worth while to develop a few standard sizes of the type discussed in this paper which could be calibrated and which would then serve as an accurate and rapid method of determining the flow of water over very wide ranges of operating conditions.

Discussion

SANFORD A. MOSS.[3] The authors are to be congratulated on the great gain in accuracy that they have secured by use of an actually determined coefficient of discharge, instead of the single uncertain value of 0.94 previously in use. No doubt the existing conical nozzles gave the best solution of the authors' problem. It seems, however, that a better method is possible, which will give still more accurate results, and that any future

[3] Mechanical Engineer, Thomson Research Laboratory, General Electric Co., West Lynn, Mass. Mem. A.S.M.E.

problem of this type will be better solved by the more accurate method.

This method is the use of a nozzle with well-rounded approach, and calibration by means of an impact tube traverse in the jet discharged from the nozzle. As an actual fact, enough data exist with respect to nozzles with well-rounded approach to give results accurate to less than 1 per cent, without any calibration whatever. Such nozzles with well-rounded approach have discharge coefficients which are very close to 0.99 for the conditions of the authors' problem, and an easily made calibration would give actual variation of values between about 0.985 and about 0.995.

The jet discharged from a conical nozzle usually has some contraction, so that there is a point of minimum diameter shortly beyond the nozzle end. If the authors have any photographs of the actual appearance of the jet, it would be interesting to include them in the paper, and there is no doubt that they would show this contraction. A proper nozzle with well-rounded approach ends with a throat having a parallel portion of sufficient length to properly size the jet, usually about half the diameter, so that the jet leaving the nozzle has the exact diameter of this parallel portion. It is furthermore to be assumed that the curve of the nozzle just preceding the parallel portion is very gentle and blends into the parallel portion smoothly. A curve with a radius equal to 4/3 times the nozzle diameter, and tangent to the parallel portion, gives a satisfactory profile. This curve need only extend for a length equal to $^1/_2$ the nozzle diameter preceding the parallel portion, and there may be a smaller radius preceding, such as $^1/_2$ the diameter. A nozzle practically of such a shape was used by the Bureau of Standards in some measurements of air flow (Bureau of Standards Research Paper, No. 49).

A series of such nozzles, each with a different throat diameter, could be independently bolted to the end of the 29-in. pipe. The cost of such a series, each to be used independently on the end of the 29-in. pipe, would be but little more than the cost of the set of successive cones which the authors actually used. The coefficients mentioned apply to cases where the nozzle diameter is about $^1/_2$ the pipe diameter or less. However, taking account of the contraction which must have existed with the conical nozzles, a 15-in. nozzle with well-rounded approach would probably have discharged the same quantity of water as the 16-in. nozzle that the authors used. This would leave only the 20-in. nozzle as being outside the range of the coefficients mentioned and with which fairly accurate results could be obtained without calibration. However, even a 20-in. nozzle with well-rounded approach could be used if complete calibration was made. With such nozzles with well-rounded approach, the nozzle pressure is most conveniently found by an impact tube in the jet discharged from the nozzle, situated at the center of the jet and a short distance ahead of the plane of the nozzle end. Such an impact tube is very easily located and gives the total nozzle pressure, including velocity head, without requiring any computation of the approach velocity in the pipe. The jet discharged by such a nozzle with well-rounded approach has a constant velocity throughout the cross-section, except for a narrow rim extending in a short way from the outer surface of the jet. The calibration of such a nozzle is made by making a traverse, with a very small impact tube, of this rim, finding the differential pressure between a point at a known distance from the edge of the jet and the impact tube in the center of the jet. This method was first used with nozzles by John R. Freeman, and it is described in a number of papers in the Transactions of the American Society of Civil Engineers.[4]

[4] Trans. A.S.C.E., no. 426, vol. 21, Nov., 1889; no. 479, vol. 24, June, 1891; and vol. 13, p. 382.

This method is also described in a paper in the Transactions of the American Society of Mechanical Engineers.[5] The same method was used in the Bureau of Standards paper quoted.

The authors may fairly be asked if such a type of nozzle and such a calibration would have been more accurate and easier to execute than the method they used, of course assuming that a proper set of nozzles was available.

J. M. Spitzglass.[6] The data disclosed by the authors bring to light a very interesting point in the behavior of fluid flow through a converging nozzle. The test nozzle of constant angle shown by the authors has the form of the approach side of the Herschel venturi. Here in the United States the term "venturi" designates a tube starting with a converging approach of a constant angle leading to a throat and terminating with a receding angle smaller than the approach. In European countries, especially in Germany, the approach side of the venturi is a well-rounded nozzle, so that the term "venturi" in that case has reference only to the receding part of the venturi, while the approach part is the same as any other well-rounded nozzle.

When the writer visited in Germany in 1927, he was surprised to find that the German engineers deviated from the Herschel type of venturi construction. Upon inquiry, he was told that such construction brings about a more uniform coefficient. A mathematical analysis of the case proved that the rounded approach of the same roughness will result in a smaller and more uniform drop of pressure through the approach to the throat of the venturi or nozzle. Since the friction drop through the approach is what reduces the value of the coefficient in proportion to the square root of that drop, any variation in this drop of pressure results in variation of the value of the venturi coefficient.

When the paper was read, the writer immediately realized the explanation for the results which the authors thought were unusual. In the analysis by the calculus the authors found "that the maximum value for $L \times D$, regardless of the nozzle angle, always occurred at a point where the diameter of the nozzle was one-half the diameter at the largest end." The same analysis carried farther indicates that, for a given flow through a nozzle, a maximum drop of pressure occurs when the diameter of the nozzle is one-half the diameter at the largest end. The product of $L \times D$ is also a maximum at the same point, as it should be, because the product $L \times D$ represents the effective rubbing surface or the criterion of frictional resistance in turbulent flow. The total drop through a constant angle converging nozzle is a summation of the increments of the product of $L \times D$. As we integrate these increments for a variable length of approach we find that the summation increases as L is increased to a point where D is equal to one-half of D_1. As D is further decreased, the summation gives a reduced total drop of pressure through the approach even though the length L is considerably increased.

It is of still further interest to note that this disclosure is in full contradiction to the statement made in paragraph C-65, page 67, of the 1931 issue of the American Society of Mechanical Engineers research publication, "Fluid Meters." The paragraph reads:

> When we come to applying this method, the first difficulty we encounter is that the available data refer to venturis of various diameter ratios between 2 and 3 and that there are not enough on any one design to be worth much by themselves. But it turns out upon examination that for a given value of D_2S_2, the value of C is very little affected by variations of the diameter ratio R between

[5] "The Impact Tube," paper 1554, 1916.

[6] Vice-President and Consulting Engineer, Republic Flow Meters Company, Chicago, Ill. Mem. A.S.M.E.

the above limits. This is not surprising; for the major part of the resistance which makes the actual discharge fall below the computed theoretical value must certainly occur in or near the throat, where the speed is highest and the ratio of circumference to cross-section greatest. And it is very probable that if D_2S_2 remained constant, lengthening the entrance cone and increasing the pipe diameter, so as to raise the diameter ratio to 4 or 5, would have very little influence on the value of the discharge coefficient. We therefore ignore the differences of diameter ratio and treat all the venturis on which data are available as if they belonged to the same series and were all geometrically similar to one another.

It is realized, of course, that the nozzle tested by the authors will have lower coefficients than a venturi with the smaller angle of approach and terminating with the rounded throat at the end. The fact remains, however, that the actual drop through the approach reaches a maximum at one-half ratio of throat diameter to pipe diameter. It appears, therefore, that for any given set of conditions the coefficient of the venturi will have a minimum value at the point where the throat diameter is one-half of the pipe diameter, increasing in both directions from that point.

Authors' Closure

As to Dr. Moss' interesting discussion, the authors realize that the set of nozzles discussed in this paper was not designed to give a high coefficient of discharge.

Nozzles made according to Dr. Moss' suggestions would give higher coefficients and also would probably be more accurate than the set discussed in this paper, but the authors' problem was to calibrate a set of nozzles which had been in use for many years so that data from previous tests could be compared with results obtained by other methods.

If a separate nozzle were made up for each size to be attached to the 29-in. pipe, they would cost considerably more than the ones now being used, and also it would require more time and labor for changing nozzles, as well as more space for handling. Large dredging equipment is costly to operate, and any unnecessary time spent during test periods is expensive.

The nozzles are used to determine pump characteristics under different operating conditions and with different runners, and it makes little or no difference what the coefficient of discharge is for any given nozzle if it is accurate. Nozzles of the type discussed in this paper are about as easy to make and use as any set that could be devised, and when accurately calibrated will give good results.

As to Mr. Spitzglass' interesting contribution, the authors have searched all accessible literature and have found nothing concerning nozzles of the type discussed in this paper. Many engineers with whom they have talked have expressed doubt over the findings presented in this paper, although they could find nothing wrong with the data or results, and it is very gratifying for Mr. Spitzglass to give an explanation for the results obtained. It is hoped that more engineers may be interested enough in this subject to do further research work along this line and check the results here presented.

HYD-53-3

A Method for the Standardization of Centrifugal Pumps

By JOS. S. STEPANOV,[1] HARRISON, N. J.

In the author's opinion, the combined application of the preferred-numbers idea and the law of similitude provides an effective means of eliminating unnecessary variety of sizes and of simplifying tool and machinery equipment in any field of industrial production.

In the application of this method to the standardization of centrifugal pumps, the author develops a set of geometric series conforming to the preferred-numbers table. The formation of the series, and their interconnection and use for treating the standardization problem, are illustrated by numerical tables, charts, and diagrams.

Standardizations of hydraulic and mechanical parts of centrifugal pumps are tied together by the use of the law of similitude, resulting in the formation of a set of interconnected geometric series applicable to both cases.

I—INTRODUCTORY

ENGINEERING of late has been making a more and more intensive as well as extensive use of scientific methods in the solution of its problems.

In recent years, and particularly during and since the World War, the problem of waste elimination has been given great attention. The standardization of industrial products, thus preventing the manufacture of an unnecessarily great variety of sizes and simplifying the tool and machinery equipment, has been an important part of the waste-elimination problem, and the subject of a thorough study in this country and in Europe.

As a result of such study it has been established that the development of sizes, to be economically and psychologically satisfactory, should follow a certain natural law of size variation which mathematically is expressed by a geometric series.

Such series of "preferred numbers" have been adopted by German and French industries and informally approved by the American Standards Association and recommended to our industries for a period of trial in practice.[2] A thorough survey of the problem[3] affords substantial evidence showing that the geometric series is most likely to be the natural law of size variation.

Working on the problem of standardization of centrifugal pumps, the author, before he had become cognizant of the preferred-numbers concept, was led to adopt the geometric series as the natural law of size variation. This fact is further evidence that a certain psychological law in human nature directs investigators. Most likely it is identical with the law of Weber-Fechner, which can be formulated as follows: "To produce sensations varying in intensity as an *arithmetic series*, the irritations causing them should vary as a *geometric series*."

II—APPLICATION OF THE LAW OF SIMILITUDE TO CENTRIFUGAL PUMPS

The conceptions and mathematical equations expressing the application of the law of similitude to centrifugal pumps are numerous, and sometimes confusing. Therefore it seems necessary to state here certain invariants which will be used in this paper.

A general inspection of these invariants calls for the following remarks:

Although the units n, q, and p have the same names (unit speed, unit capacity, etc.) as n_l, q_l, and p_l, they express quite different things, n, q, and p being constant for a definite size at different speeds, whereas n_l, q_l, and p_l, are for different speeds and different sizes of the same type. (For symbols used see p. 10.)

	Invariants in terms of H	Invariants in terms of H and D	Invariants in terms of Velocity $\sqrt{2gH}$	Specific speed
Speed..	$n = \frac{N}{\sqrt{H}}$	$n_l = \frac{ND}{\sqrt{H}}$	$K_u = \frac{u}{\sqrt{2gH}}$	$n_q = \frac{NQ^{1/2}}{H^{3/4}} = n\sqrt{q} = n_l\sqrt{q_l}$
Capacity	$q = \frac{Q}{\sqrt{H}}$	$q_l = \frac{Q}{\sqrt{H \times D^2}}$	$K_c = \frac{c}{\sqrt{2gH}}$	$n_{sp} = \frac{NP^{1/2}}{H^{3/4}} = n\sqrt{p} = n_l\sqrt{p_l}$
Power..	$p = \frac{P}{H^{3/2}}$	$p_l = \frac{P}{H^{3/2} \times D^2}$	.....	$m_s = N^2P = n_{sp}^2 H^{3/2}$

On another hand, the pairs n_l, K_u, and q_l, K_c, in spite of their different structures and different names, express the same physical relationship, differing in numerical values by a constant factor.

Capacity Q will be used in gallons per minute, therefore in

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

the denominator of the n_{sq} formula there appears a constant factor 21.2.

The law of similitude as applied to hydraulic machines involves certain assumptions, one of which is of special importance for the "mechanical" specific speed, N^2P, and the limitations caused thereby will be treated later in the chapter on mechanical standardization.

III—SET OF GEOMETRIC SERIES, THEIR FORMATION AND INTERCONNECTION

1 *Impeller-Diameter or D-Series.* This series is basic for the development of all the other series. It is the result of the assumption that sizes of the impeller diameters, as well as all hydraulically controlling dimensions, of a set of geometrically similar pumps should vary according to a geometric series.

Let us call the ratio of two successive terms of such a series $\lambda = \frac{D_n}{D_n - 1}$ or "length scale" of the pump series

Then the nth term of this D-series is $D_n = D_0\lambda^n$. The impeller diameter D_0 of the model pump being the same for all of the

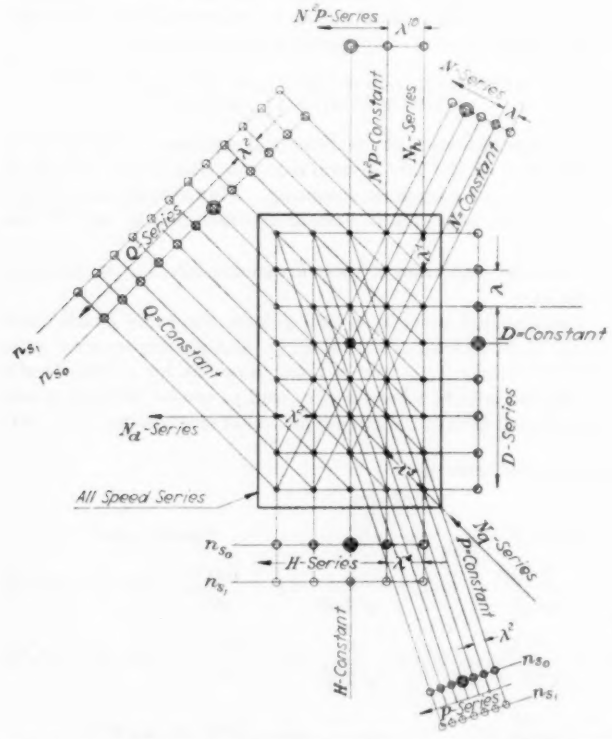

FIG. 1 SCHEME FOR THE INTERCONNECTION OF THE GEOMETRIC SERIES

D-series, can be omitted in further development, and the general term of the D-series reduces to λ^n or: $\lambda^{-n} \ldots \lambda^{-2}, \lambda^{-1}, \lambda^0, \lambda^1, \lambda^2 \ldots \lambda^n$, in which n can have negative as well as positive numerical values.

The number of variables involved in the problem makes it necessary to deal with the following ten series:

D-series	N-series	N_h-series
Q-series	N_q-series	N_α-series
H-series	N_p-series	PN^2-series
P-series		

The functional interconnection of all these series may to a certain extent be visualized by means of the scheme shown in Fig. 1. In this scheme the different rows of circles represent the different series as shown: Q, H, D, P, N, and PN^2. Each of these variables develops one series, whereas speeds N (included in the rectangle, Fig. 1), form the additional series N_α, N_q, N_p, and N_h, according to the row of the constant along which they proceed (D = const., Q = const., P = const., H = const.).

It may be also seen that in this arrangement any set of the corresponding terms of all series can be easily located, as, for instance, those shown on the scheme by the double circles.

Using this scheme we shall proceed with the formation of the various series.

2 *Capacity Series at H = Const. or Q-Series.* Proceeding through the successive terms Nh (H = const.), we pass through the corresponding successive terms of the Q- and D-series. From

$$q_l = \frac{Q_n}{\sqrt{H}D^2_n} = \frac{Q_{n-1}}{\sqrt{H} \times D^2_{n-1}}$$

it follows that

$$\frac{Q_n}{Q_{n-1}} = \frac{D^2_n}{D^2_{n-1}} = \lambda^2 \text{ for } \frac{D_n}{D_{n-1}} = \lambda$$

The term ratio of the Q-series is λ^2, and its general term λ^{2n}.

3 *Speed Series at H = Const. or N_h-Series.* The terms of this series run parallel to the D- and Q-series (Par. 2.). From

$$n_l = \frac{N_n D_n}{\sqrt{H}} = \frac{N_{n-1}\, D_{n-1}}{\sqrt{H}}, \quad \frac{N_n}{N_{n-1}} = \frac{D_{n-1}}{D_n} = \lambda^{-1}$$

The term ratio of the N_h-series is λ^{-1}; the series runs in a direction opposite to that of the D-series and its general term is λ^{-n}.

4 *Head Series at Q = Const., or H-Series.* Proceeding through the terms of N_q-series (Q = const.) we pass through the corresponding successive terms of the H- and D-series. From

$$q_l = \frac{Q}{\sqrt{H_n} \times D^2_n} = \frac{Q}{\sqrt{H_{n-1}} \times D^2_{n-1}}$$

it follows that

$$\frac{\sqrt{H_n}}{\sqrt{H_{n-1}}} = \frac{D^2_{n-1}}{D^2_n} \text{ or } \frac{H_n}{H_{n-1}} = \frac{D^4_{n-1}}{D^4_n} = \lambda^{-4}$$

The term ratio of the H-series is λ^{-4} the series runs in a direction opposite to that of the D-series, and its general term is λ^{-4n}.

5 *Speed Series at Q = Const. or N_q-Series.* The terms of this series run parallel to the D- and H-series (Par. 4). From

$$n_l = \frac{N_n D_n}{\sqrt{H_n}} = \frac{N_{n-1}\, D_{n-1}}{\sqrt{H_{n-1}}}$$

it follows that

$$\frac{N_n}{N_{n-1}} = \frac{\sqrt{H_n}}{\sqrt{H_{n-1}}} \times \frac{D_{n-1}}{D_n} = \lambda^{-3} \text{ for } \frac{D_{n-1}}{D_n} = \lambda^{-1}$$

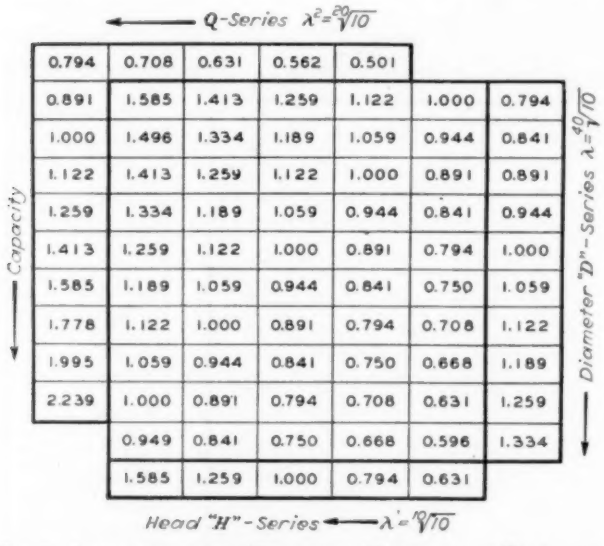
and

$$\frac{\sqrt{H_n}}{\sqrt{H_{n-1}}} = \lambda^{-2} \text{ according to Par. 4}$$

The term ratio of the N_q-series is λ^{-3} and it runs in a direction opposite to that of the D-series, and its general term is λ^{-3n}.

6 *Speed Series at D = Const., or N_α-Series.* This series

develops parallel to the Q- and H-series, D being constant. From



$$\frac{N_n D}{\sqrt{H_n}} = \frac{N_{n-1} D}{\sqrt{H_{n-1}}}$$

it follows that

$$\frac{N_n}{N_{n-1}} = \frac{\sqrt{H_n}}{\sqrt{H_{n-1}}} = \sqrt{\lambda^{-4}} = \lambda^{-2}$$

The term ratio of the N_d-series is λ^{-2}, it runs in the same direction as the H-series (λ^{-4}), and its general term is λ^{-2n}.

7 *Speed Series at Q, H, and D Variable, or N-Series.* Each

FIG. 2 ARRANGEMENT OF PREFERRED NUMBERS TO REPRESENT D-, Q-, H-, N-, N_h-, N_d-, AND N_q-SERIES ACCORDING TO SCHEME SHOWN IN FIG. 1

(The range is arbitrary and can be extended in any direction.)

term of this series represents a certain row of constant N, i.e., those common terms of the N_h- and N_d-series which have the same numerical values.

The term ratio of N_d is λ^{-2} and that of N_h is λ^{-1}. It is evident that if we pass one step along the N_d-series (λ^2) in the direction of decreasing terms and two steps along the N_h-series $(\lambda^{-1})^2 = \lambda^{-2}$ in the direction of increasing terms, we shall meet a term of the same numerical value. This gives the location of the row of N = const.

The ratio of the terms represented by each N = const., in other words, the term ratio of the N-series, is λ^{-1}, the same as for the N_h-series, for all successive rows of N = const. pass successively the terms of the N_h-series.

8 *Power or P-Series.* Proceeding through the successive terms of N_h we pass through the corresponding successive terms of the P-, D-, and Q-series, H being constant. From

$$p_I = \frac{P_n}{H^{3/2} D_n^2} = \frac{P_{n-1}}{H^{3/2} D_{n-1}}$$

it follows that

$$\frac{P_n}{P_{n-1}} = \frac{D_n^2}{D_n^2{}_{-1}} = \lambda^2$$

The term ratio of the P-series is λ^2, and its general term is λ^{2n}.

9 *Speed Series at Constant P, or N_p-Series.* Proceeding through the terms of this series we pass through the corresponding successive terms of the Q- and H-series, P being constant. As the ratio of the H-series is λ^{-4}, the ratio of this series will be found as follows. From

$$n_{sp} = \frac{N_n P^{1/2}}{H_n^{5/4}} = \frac{N_{n-1} P^{1/2}}{H_{n-1}^{5/4}}$$

it follows that

$$\frac{N_n}{N_{n-1}} = \frac{H_n^{5/4}}{H_{n-1}^{5/4}} = (\lambda^{-4})^{5/4} = \lambda^{-5}$$

The N_p-series runs in a direction opposite to that of the D-series, and its general term will be λ^{-5n}.

10 *PN^2-Series.* Each successive term of this series corresponds to a certain term of the H-series, for PN^2 = constant is equivalent to H = constant ($PN^2 = n_{sp}{}^2 \times H^{5/2}$). The term ratio of this series is:

$$\frac{(PN^2)_n}{(PN^2)_{n-1}} = \frac{H_n^{5/2}}{H_{n-1}^{5/2}} = (\lambda^{-4})^{5/2} = \lambda^{-10}$$

The PN^2-series runs in a direction opposite to that of the D-series, and its general term is λ^{-10n}.

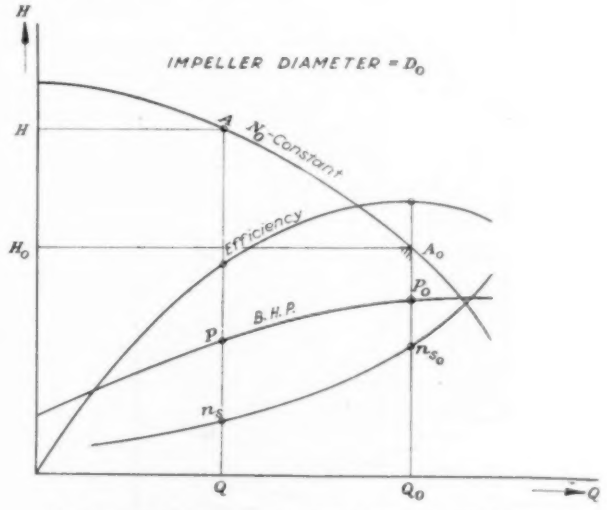

FIG. 3 RELATION OF THE RATING CURVE TO THE SERIES

Arranged in the order of the ratio powers, these various series are given in the following table:

Series	D	N	N_h	Q	N_d	P	N_q	H	N_p	NP^2
Ratio	λ	λ^{-1}	λ^{-1}	λ^2	λ^{-2}	λ^2	λ^{-3}	λ^{-4}	λ^{-5}	λ^{-10}
General Term...	λ^n	λ^{-n}	λ^{-n}	λ^{2n}	λ^{-2n}	λ^{2n}	λ^{-3n}	λ^{-4n}	λ^{-5n}	λ^{-10n}

Neglecting the plus and minus signs, which only show the directions of the series' development, we have only six series, with the ratios λ, λ^2, λ^3, λ^4, λ^5, and λ^{10}.

It is obvious that all the terms of all these six series are included in the first one, with ratio = λ; omitting certain terms of this series and taking only those corresponding to the power of λ, we can get any other series. This fact immensely simplifies the further treatment of the problem; for, in terms of the preferred-numbers idea, all these series are nothing else than different "orders of preference" of the same table of the preferred numbers.

IV—METHOD OF APPLICATION TO THE STANDARDIZATION OF CENTRIFUGAL PUMPS

1 *Numerical Values of the Series.* Tables of preferred numbers recommend the ratios: $\sqrt[80]{10}$, $\sqrt[40]{10}$, $\sqrt[20]{10}$, $\sqrt[10]{10}$, $\sqrt[5]{10}$.

It seems to the author that $\lambda = \sqrt[40]{10}$ can be adopted as ratio of the D-series. If, for certain types or certain services, the sizes appear to be too close to each other, λ can be easily changed to the next order of preference by simply omitting every alternate term from this series.

Preferred numbers having a ratio $\lambda = \sqrt[40]{10}$ are arranged in Fig. 2 according to the scheme shown in Fig. 1, excluding, however, the P- and N^2P-series.

Inspection of Fig. 2 shows that no numbers are used except from the series $\sqrt[40]{10}$, yet in the arrangement of the scheme all derivative series, with their ratios, appear in the expected places.

Another check on the table is the fact that any set of corresponding values of the H-, Q-, and N-series substituted in the expression of the specific speed $n_{sq} = N\frac{\sqrt{Q}}{H^{3/4}}$ should always give the value unity.

Similar tables can be arranged also for P and N^2P, following the indications of the scheme shown in Fig. 1.

2 *Application of the Preferred-Numbers Table to a Concrete Type of Pump.* Let us assume that the test curves of one of the sizes of a certain type of pump to be standardized are as given in Fig. 3. These show that a pump of impeller diameter D_0 at the speed N_0 delivers Q_0 against H_0 and calls for P_0, the maximum efficiency being right at this point of operation and the figured specific speed being

$$n_{sq0} = \frac{N_0 Q_0^{1/2}}{H^{3/4}}$$

Using the table of Fig. 2, we can construct another table simply by multiplying the terms of the capacity, head, speed, and diameter series by Q_0, H_0, N_0, and D, respectively.

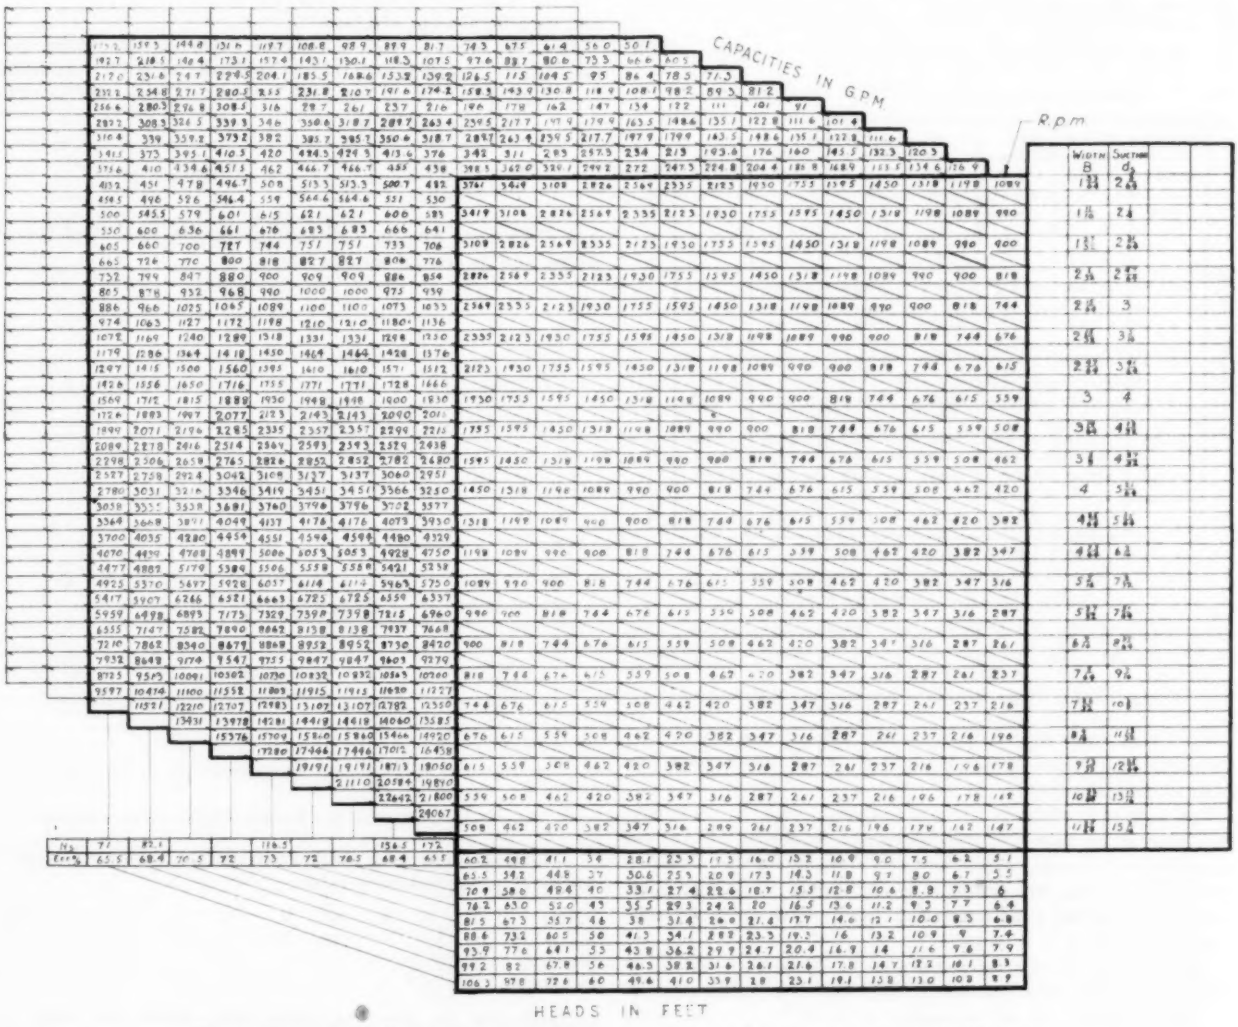

FIG. 4 TABULATION SHOWING STANDARDIZATION OF A PUMP ACCORDING TO AUTHOR'S METHOD

The specific speed for all sets of the corresponding N's, Q's, H's, and D's in such a table remain the same: $n_{sq0} = \frac{N_0 Q_0^{1/2}}{H^{3/4}} \times 1$, for, as was stated in the preceding paragraph, the corresponding values of the preferred numbers substituted in the specific-speed formula always give 1 as the result.

For another point A of the head-capacity curve, the same impeller D_0 at the same speed N_0 delivers Q and generates H at a specific speed n_s and a lower efficiency. Obviously, for this point the N- and D-series remain as for the previous case (point A), and only new Q- and H-series should be added by multiplying the capacity series (Fig. 2) by Q and head series by H.

In a similar way the Q- and H-series may be added for as many points of the head-capacity curve as desired.

Fig. 4 is a tabulation showing the standardization of a pump according to this method, the numerical values of the impeller D being omitted.

The blank spaces in the N- and D-series show that it was decided for the time being to actually develop only every alternate term of the series, i.e., to use the next order of preference.

The number of terms of all the series (Fig. 2) is theoretically unlimited. Conforming to the special given type, the range of the H-, Q-, D-, and N-series and even the order of preference should be selected according to the field to be covered, the demand of the market under consideration, and the lowest acceptable efficiency.

3 *Graphical Presentation.* The developed geometric series may be presented in convenient graphical form on logarithmic paper, as shown in Fig. 5, which includes all the series given in Fig. 1.

Using the scheme of Fig. 1 and keeping in mind that the logarithms of the terms of a geometric series form an arithmetical

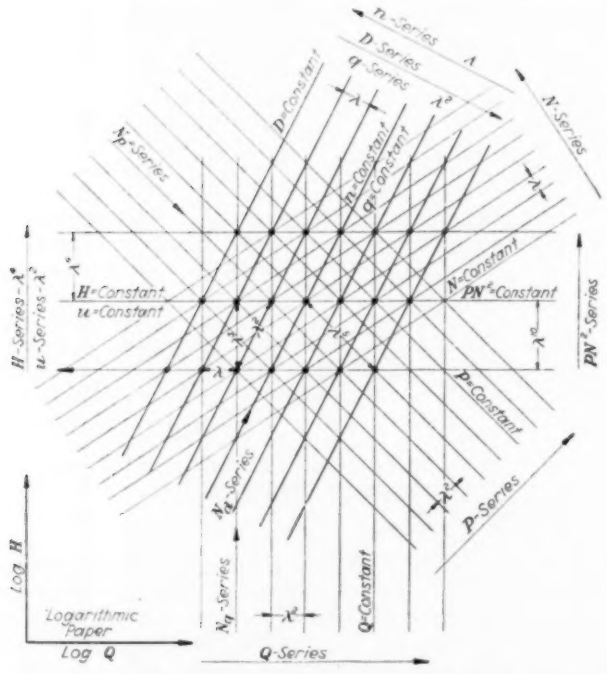

Fig. 5 Graphical Method of Presenting All the Series, on Logarithmic Paper

series, and therefore the distances between the terms of each series on logarithmic paper are equal, it seems to the author that no further explanations are necessary.

However, attention is called to the fact that certain other derivative series are presented on the same chart, namely,

(*a*) *Unit Speed or n-Series:* $n = \dfrac{N}{\sqrt{H}}$. The terms of this series are located along the D = const. line, for the same line is n = const. The ratio of this series is derived from the relationship $n = n_1/D$. As n_1 is constant for all sizes of the type, it follows that the ratio of this series is the same as for the D-series, i.e., λ^{-1}.

(*b*) *Unit Capacity or q-Series:* $q = \dfrac{Q}{\sqrt{H}}$. The same reasoning shows that the terms q = const. coinciding also with D = const., form a q-series with the ratio λ^2 for $q = q_1 D^2$, q_1 being constant for all sizes.

(*c*) *Peripheral Velocity or u-Series.* This series runs parallel to the H-series, H = const. being also u = const., for $K_u = \dfrac{u}{\sqrt{2gH}}$ is, like n_1, constant for all sizes. The term ratio of this series follows from the relationship:

$$\frac{u_n}{\sqrt{2gH_n}} = \frac{u_{n-1}}{\sqrt{2gH_{n-1}}} \quad \text{or} \quad \frac{u_n}{u_{n-1}} = \frac{\sqrt{H_n}}{\sqrt{H_{n-1}}} = \lambda^{-2}$$

4 *Simplification of Plotting.* The plotting of the chart is highly simplified if all regularities of the series relationship are

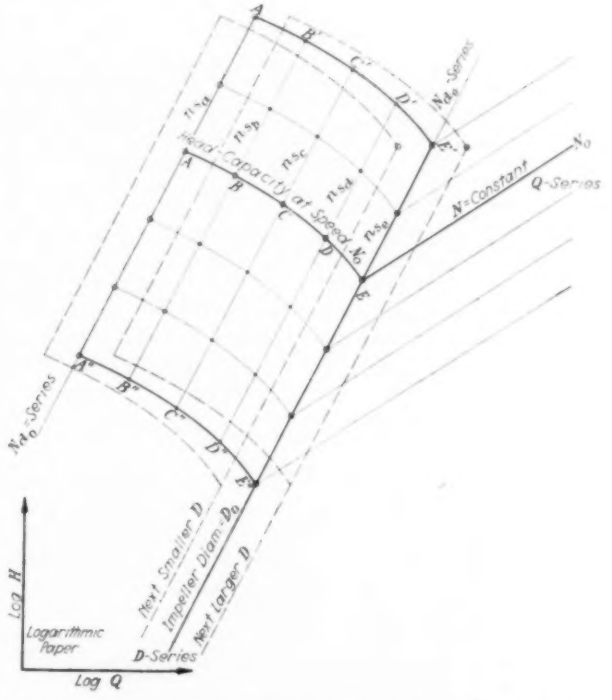

Fig. 6 Method of Plotting Field Covered by Impeller of a Given Size

fully utilized. The method of plotting is shown diagrammatically in Fig. 6.

It is not necessary to plot all the points given in the table of the numerical values, Fig. 4.

To plot the field covered by an impeller of size D_0 (model impeller), in the selected range of the head-capacity curve (range of efficiencies and specific speeds) $ABCDE$ at speed N_0, it is sufficient to plot only the points shown in Fig. 6 by circles.

This means the plotting of $Q_0 - H_0$ points along the N_{d0}-series, first for the highest specific speed n_{se}-points along $E' - E''$, and, second, for the lowest specific speed n_{sa}-points along $A' - A''$. This will give extreme points A and E of the selected range of the head-capacity curve at the speed N_0.

The intermediate points B, C, D of the same curve should be plotted, using the pairs of values Q and H for the corresponding values n_{sb}, n_{sc}, and n_{sd} at the same N_0. Thus the shape of the $ABCDE$ curve is determined. As the shape of the curve on the logarithmic paper does not change along all speeds (and all sizes), it is sufficient to transport this curvature between the points given on $A'A''$ and $E'E''$.

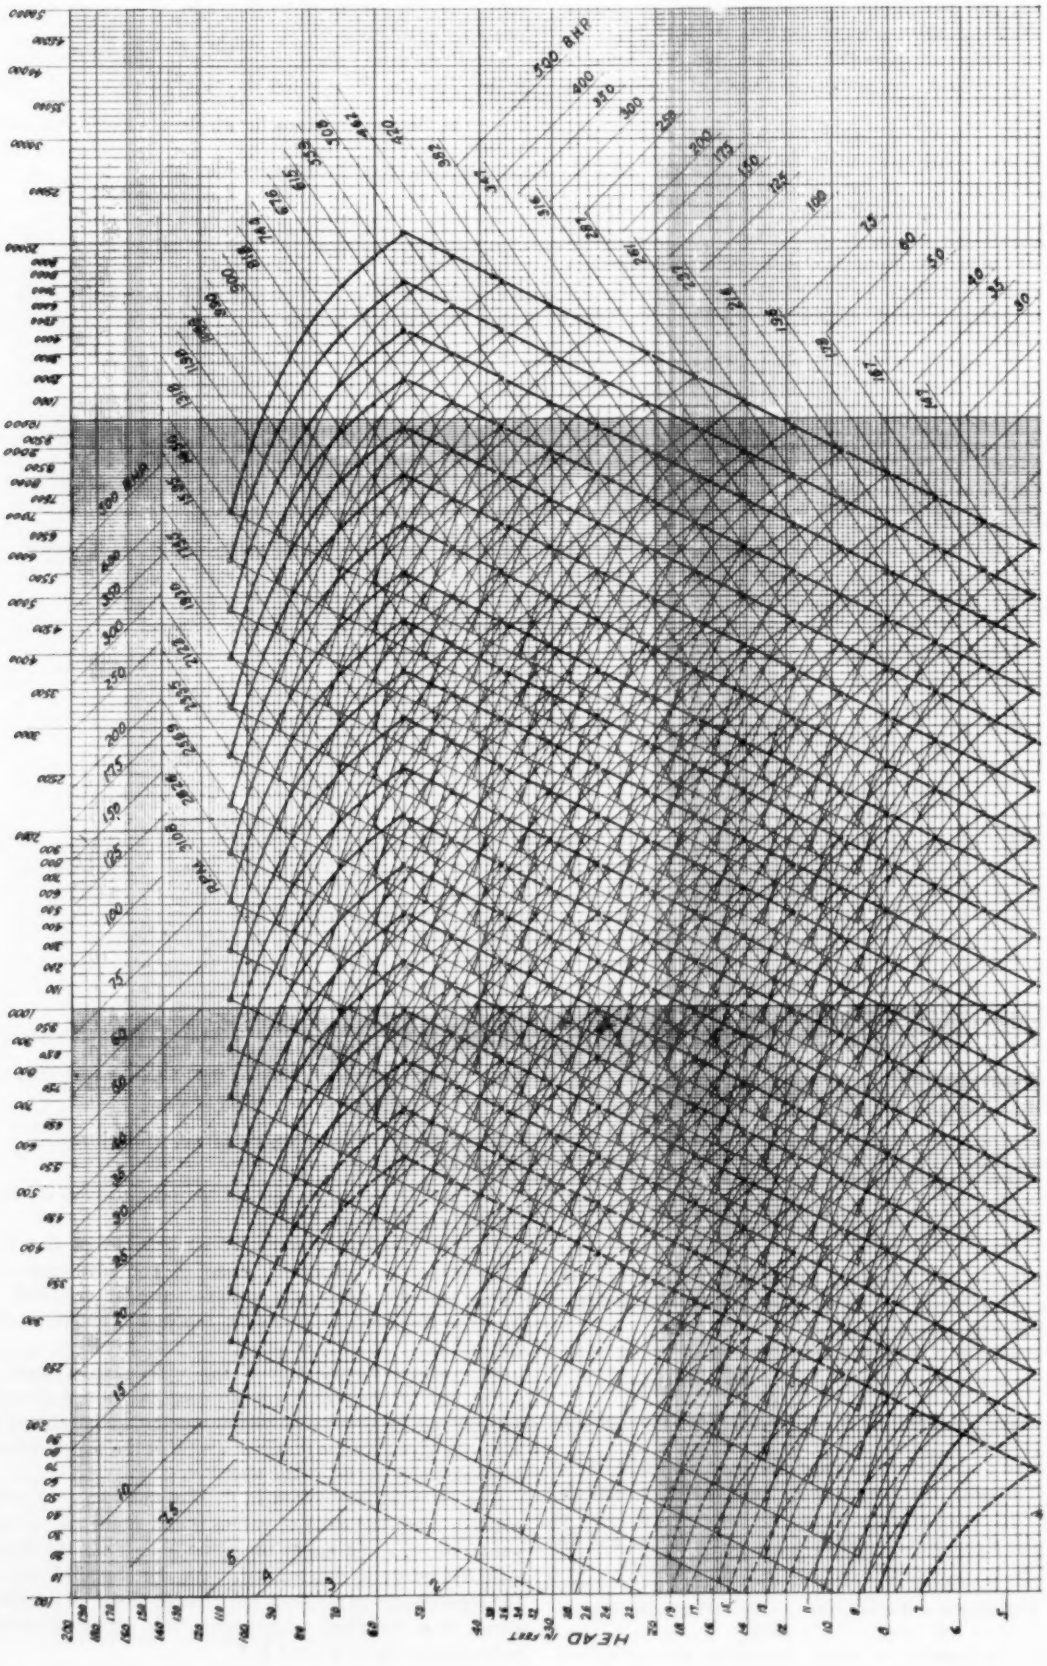

FIG. 7 TYPICAL EXAMPLE SHOWING STANDARDIZATION OF ONE OF A SERIES OF PUMPS FOR MANUFACTURE

The points of these head-capacity curves, such as B', C', D' or B'', C'', D'', corresponding to the points B, C, D of the model curve, are located on the n_s = const. lines $B'B''$, $C'C''$, $D'D''$ which are parallel to $A'A''$ and $E'E''$ and pass through the points B, C, D.

The intersections indicated by dots are corresponding to B-, C-, D-points, and can be checked by the numerical values given on the table (like the one in Fig. 4).

Thus the field covered by the D_0 impeller is plotted showing 6 head-capacity curves, corresponding to 6 different speeds N from the N-series.

For other sizes of impeller (D-series) it is sufficient to move the field $A'A''E''E'$ parallel to itself in the Q-direction by equal spaces, corresponding to the location of the D-const. lines, for instance, along the Q-series.

The corner point E' will move to E'_L for the next larger size, or to E'_s for the next smaller one.

The accuracy can be checked by using the numerical values from the table, as above.

Similarly, using the same method, the b.hp.-curves can be plotted, the difference being that the location of corresponding points on these curves should be determined by the pairs of numerical values of P and Q along the N_{s0}-series.

As example of such a plotting, the chart, Fig. 7, is given which presents the standardization of a type of pump. On this chart, for clarity's sake, the intermediate points of the curves, like B, C, D, in Fig. 6, are not emphasized by lines like $B'B''$, $C'C''$, and $D'D''$.

Corresponding to the numerical values of the table, Fig. 4, the D-series and N-series are of the next order of preference, any second term of the original series being omitted.

The numerical values of the D-series, being unnecessary for the purpose, are also omitted.

The b.hp.-lines, shown only at their ends, represent standard motor sizes, at the lowest efficiency of the pump under consideration, i.e., any condition point located on a certain line calls for maximum b.hp. indicated at the ends of this line.

V—USE OF THE METHOD FOR STANDARDIZATION OF DIFFERENT SERVICES

1—Specific-Speed Series

In the preceding pages the term "type" has been used to connote the constancy of the specific speed for all sizes of the particular class of pump being considered, i.e., all pumps of the series being geometrically similar.

To cover the field required by a certain kind of service, several "types" in this sense of the word are usually necessary, i.e., impellers of different specific speeds.

In deriving all the preceding series, the specific speed n_s has always been kept constant. This is equivalent to saying that only the impeller diameters D and speeds N have been varied to obtain all the variety of capacities and heads.

In practice it is frequently necessary to reduce the number of impeller diameters (casings) or speeds (drivers) to certain limits dictated commercially.

Therefore, variation of specific speeds, generally necessary to reduce variety of sizes and speeds, represents the only means of best utilizing certain expensive casings or certain motor speed (high-pressure multi-stage casings).

Specific-Speed Series at Constant Speed, or N_s-Series. All the speed series (N, N_h, N_d, and N_q) represent the variation of speed, with different variables being kept constant, needed to deliver a corresponding Q and generate a corresponding H, the specific speed being always constant.

The problem now is to deliver the same capacities Q and generate the same heads H, varying the specific speed n_s and keeping speed N constant. The specific-speed formula shows what will happen:

$$n_s = \frac{NQ^{1/2}}{H^{3/4}}, \qquad \text{or} \qquad \frac{n_s}{N} = \frac{Q^{1/2}}{H^{3/4}}$$

As Q and H are assumed to remain the same, evidently n_s/N should remain the same. This means: if n_s = constant and N forms a series with ratio λ^n, the result will be the same if N = constant, and n_s forms a series with the ratio λ^{-n}, for

$$\frac{n_{s0}}{N\lambda^n} = \frac{n_s\lambda^{-n}}{N_0}$$

This relationship justifies the following statements: *Speeds N and specific speeds n_s in all speed series are interchangeable*, with the change only in the direction of the variation, the ratios remaining the same. Lines of N = const. at variable speeds and constant specific speeds turn into lines of n_s = const. at variable n_s and constant N.

Let us investigate a field $ABCD$ (Fig. 8) covered by 4 impeller diameters and 8 speeds, all impellers being geometrically similar, i.e., n_s, n_l, q_l = const. Let us assume that all speeds are constant and that the N-series is replaced by the n_s-series directed as shown in Fig. 8. We then see that for AB impeller (as for each of the rest) there is only one speed, but two specific speeds are used. Unit capacities q and q_l remain the same as before, but unit speeds n and n_l vary:

$$\frac{n_n}{n_{n-1}} = \frac{N}{\sqrt{H_n}} \times \frac{\sqrt{H_{n-1}}}{N} = \sqrt{\frac{H_{n-1}}{H_n}} = \lambda^2$$

for both series, D being constant. This shows that n_s is changing only on account of change of unit speeds (n, n_l), unit capacities being constant.

Inspecting now the N_h-series, we see that along this series speeds are constant; i.e., corresponding terms of the D-series should also be constant, for these two series have the same ratio running in opposite directions, whereas the specific speeds in this direction is varying with ratio λ.

Along the same direction (AC) n is constant $\left(= \frac{N}{\sqrt{H}}\right)$ and $n_l \left(= \frac{ND}{\sqrt{H}}\right)$, but q and q_l form a series with λ^2. Therefore it can be stated that keeping D = constant in the direction n_{sh}, we should vary q and q_l at constant n and n_l.

As a final result it can be seen that all the field $ABCD$ can be covered by one impeller diameter at one speed, but using eight different specific speeds.

It is interesting to note here that the lines of constant specific speed do not always represent geometrically similar impellers: both the shape of the vanes (n_l) and the width of the impellers (q_l) are varying. This may indicate that the shapes of the operating curves are not necessarily the same, and this fact may call for a certain overlapping of the range of the separate impellers to cover completely the field under consideration.

The number of specific speeds can be reduced to any extent if a certain variation of impeller diameters and speeds is possible. For instance, a certain field (Fig. 9) equivalent to 9 parallelograms like one shown in Fig. 8 can be covered by 3 impeller diameters, 6 speeds, and 4 specific speeds. In the arrangement shown here, the same speeds and specific speeds are used for several impeller diameters and the same diameter is also used at several speeds and several specific speeds.

Such combinations of speeds (N), diameters (D), and specific

speeds (n_s) provide a flexible means of reducing the number of terms of any one of these series to one, correspondingly increasing the numbers of the terms of other series.

It can easily be seen that the problem is always how many terms of the D, N, or n_s-series should be omitted and how many used—in other words, what order of preference should be selected for each of these series.

Treating the actual problems of standardization of centrifugal pumps for different services covering different fields, it is usually necessary to reduce the number of impeller diameters, conforming to the number of casings, which latter should be reduced to a minimum, or to reduce the number of speeds, conforming to the standard speeds of the motor drivers.

In addition to the shape of the efficiency and the head-capacity curves, the lowest competitive efficiency, as affecting the operating range of the curves, is to be considered in the final selection from all possible combinations.

In the multi-stage pumps, the number of stages is an additional variable which, in combination with n_s-series, provides still further facilities for reduction of the number of impeller diameters and speeds required to cover a definite field of service.

Hydraulic engineers are familiar with the exceptional flexibility of centrifugal pumps. This feature is clearly expressed in the multitude of the series, in their various interrelations: 3 fundamental series (N, D, n_s) and their derivatives provide an almost unlimited variety of the Q and H.

The method developed in this paper furnishes a means of utilizing this feature intelligently for the elimination of an unnecessary variety of impeller diameters and specific speeds, and for unification of the chief dimensions, thus avoiding unnecessary variety of different parts.

Using when necessary different orders of preference, it is possible to establish *a single set of impeller diameters, a single D-series, for all kinds of services and designs, i.e., for the entire range of output* of a centrifugal-pump manufacturing company.

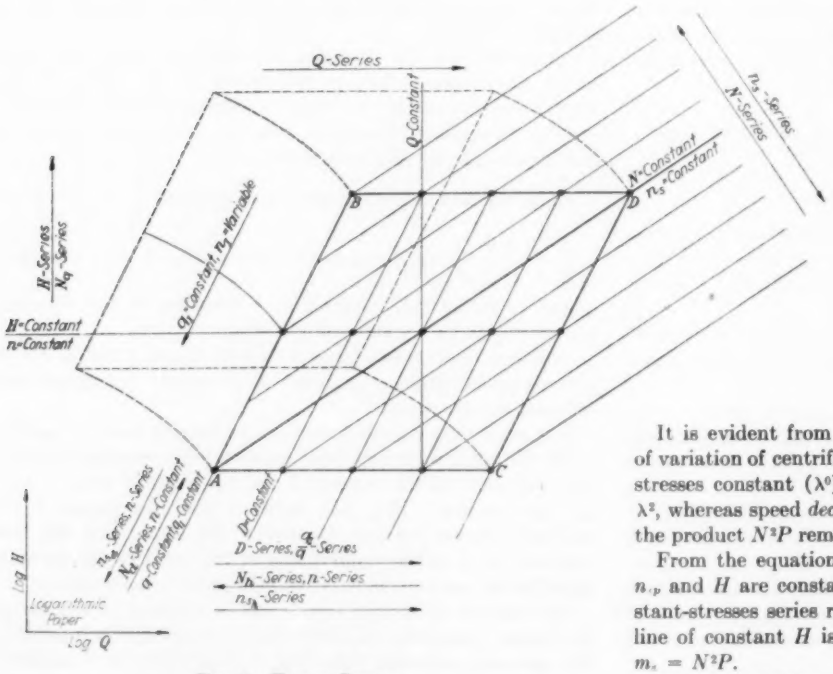

FIG. 8 THE n_s-SERIES

2—CONSTANT-STRESSES OR N^2P-SERIES AND MECHANICAL STANDARDIZATION

The specific speed in terms of power absorbed by pump is

$$N_{sp} = \frac{NP^{1/2}}{H^{5/4}}$$

It can be proved that the numerator $NP^{1/2}$ is a mechanical invariant of the centrifugal pump. Let us call it $m_s = N^2P = n^2_s H^{5/2}$. This invariant can be called also "mechanical specific speed" of a centrifugal pump, and is characteristic for the mechanical properties of similar pumps.

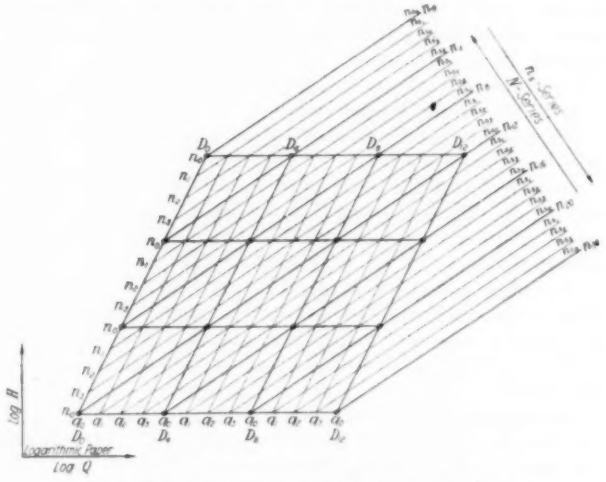

FIG. 9 COMBINATION OF THE D-, N-, AND n_s-SERIES

Using the same "length scale" as before, the ratios for the mechanical properties of geometrically similar centrifugal pumps will be as follows, for:

Sectional areas ... Surfaces	λ^2
Masses	λ^3
Velocities	λ^0-const.
Speeds	λ^{-1}
Accelerations	λ^{-1}
Mass forces	λ^3
Working pressures	λ^0-const.
Working forces	λ^2
Stresses	λ^0-const.
Power	λ^3

It is evident from these ratios that at the "length scale" λ of variation of centrifugal pumps, with velocities, pressures, and stresses constant (λ^0), power *increases* directly proportional to λ^2, whereas speed *decreases* directly proportional only to λ; i.e., the product N^2P remains constant.

From the equation $m_s (= n^2_{sp} H^{5/2} = N^2P)$ is constant when n_{sp} and H are constants, i.e., it indicates that the m_s- or constant-stresses series runs parallel to the H-series and that each line of constant H is the line of constant stresses, or constant $m_s = N^2P$.

The ratio of this series can be derived from the relationship:

$$\frac{P_n N_n^2}{P_{n-1} N^2_{n-1}} = \left(\frac{H_n}{H_{n-1}}\right)^{5/2} = \lambda^{10}$$

If $\lambda = \sqrt[60]{10}$, $\lambda^{10} = \sqrt[6]{10} = 1.778$. This means if we pass

from one term of the H-series to the next, the stresses will increase or decrease 1.778 times as much.

Certain limitations of the application of the mechanical invariant are due to the fact that the law of similitude neglects gravitational forces. For instances, the stresses due to the weight of the parts themselves in similar pumps do not remain constant, for weights increase with λ^3 and sections only with λ^2. The difference is caused by the fact that the acceleration due to gravity (g) remains constant, whereas the acceleration of the moving masses decreases with λ^{-1}. For the case of centrifugal pumps, *this deviation from the mechanical invariant is of importance only for the shaft deflections and critical speeds.* Let us therefore find the law of variation.

Deflections:

$$\frac{f_n}{f_{n-1}} = \frac{W_n}{W_{n-1}} \times \frac{L^3_n}{L^3_{n-1}} \times \frac{d^4_{n-1}}{d^4_n} = \lambda^3 \times \lambda^3 \times \lambda^{-4} = \lambda^2$$

Critical speeds:

$$\frac{N_{cn}}{N_{cn-1}} = \sqrt{\frac{f_{n-1}}{f_n}} = (\lambda^{-2})^{1/2} = \lambda^{-1}$$

This shows that the critical speeds decrease when the sizes of shafts, as well as of pumps, increase according to the D-series. But along the constant-stresses (m_s) or H-series or N_h series, the operating speeds, N_h-series, decrease in the same ratio (λ^{-1}): this means that along the constant-stresses series the *margin of safety against the critical speeds is also constant.*

The deflections increase with λ^2, whereas all dimensions increase with λ, and there is no compensation to cover this difference in the variation ratios. Therefore the following is of importance in designing the bearings: If the dimensions of the shaft are kept similar to all other dimensions of the pump, the *limit of deflection allowed by the type of bearings should not be exceeded.*

Thus we see that along the lines of constant stresses everything remains equally safe except the deflection. But when we move from one such line to the next, the stresses vary according to the stresses series in the enormous ratio λ^{10}, and this calls for special attention if the same pump is to be used for higher r.p.m.

Out of the above-stated relationship between the mechanical and the operating properties of centrifugal pumps, an interesting problem arises in the mechanical standardization of pumps.

As in the hydraulic standardization the range of the efficiency fluctuations (range of operating curve and range of operating speeds) is of paramount importance, so in the mechanical standardization the range of stresses (efficiency of utilization of the material) is a controlling factor.

To keep the *constant stresses* along all size series we should have not only as many sizes as there are impeller diameters, but for each impeller size as many mechanical dimensions (wall thicknesses, shaft diameters and lengths, etc.) as there are terms in the constant-stresses series.

On the other hand, if we do not change these dimensions from one line of constant stresses to another, it will mean a poor utilization of the strength of the material according to the range of heads (or terms of the N^2P series), the stress variations may be many times 1.778.

This is a case frequently encountered in engineering practice when certain contradictory requirements find their reconciliation in a properly selected compromise. This can be done by introducing certain series of constant stresses at constant dimensions.

Torque, or T-Series. The conception of unit torque and its formula $t_l = T/HD^3$ provide a means of forming a torque series and finding its term ratio. Proceeding through the terms of the N_h-series (H = const.) we pass through the corresponding successive terms of the T- and D-series.

From

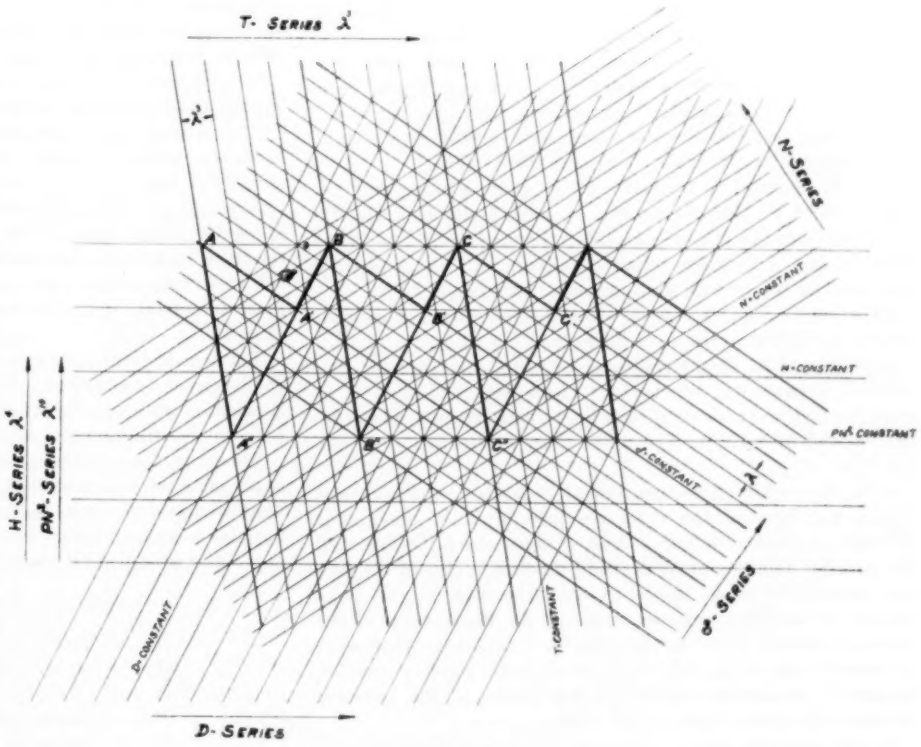

FIG. 10

$$t_l = \frac{T_n}{HD_n^3} = \frac{T_{n-1}}{HD_{n-1}^3}$$

it follows that

$$\frac{T_n}{T_{n-1}} = \frac{D_n^3}{D_{n-1}^3} = \lambda^3$$

The term ratio of the T-series is λ^3, it runs parallel to the D-series, and its general term is γ^{3n}.

The location of the lines of T-const. (Fig. 10) is determined by the relationship: T = const. $\times$ P/N. This relationship shows that the lines of constant torque should pass through each alternate term of N-series (λ^{-2}) and each term of P-series (λ^2).

The lines T-const. are simultaneously the lines of constant torsional stresses at constant shaft diameters.

Constant Wall Thickness or s-Series. In a similar way, using, for example, "the boiler formula" for the stresses in casings due to the internal pressure (σ = const. $\times$ $HD/2s$), we can form a series of constant casing stresses (σ = const.) at constant wall thickness (s = const.).

Proceeding through the terms N_h-const. (H = const.) we pass through the corresponding successive terms of the s-series and D-series. From

$$\sigma = \text{const.} \times \frac{HD_n}{2s_n} = \text{const.} \times \frac{HD_{n-1}}{2s_{n-1}}$$

it follows that

$$\frac{s_n}{s_{n-1}} = \frac{D_n}{D_{n-1}} = \lambda$$

The term ratio of the s-series is the same as that of the D-series, i.e., λ, and its general term is λ^n.

The location of the lines of constant thickness s = const. at constant stresses is determined by the same relationship σ = const. $\times$ $HD/2s$ at s = const. Obviously these lines pass through each term of the H-series (λ^{-4}) and each fourth term of the D-series (λ^4), Fig. 10. Along these lines of s = const., the stresses σ are constant at *constant* wall thicknesses, in spite of the casing size variation, following the D-series.

Now, in addition to lines of *constant stresses* along N^2P = const., where all dimensions *vary* in accordance with the D-series, we have the lines of constant stresses (T-series, s-series) where certain dimensions (shaft diameter, wall thickness) are kept *constant* in spite of the pump-size variation.

Referring to Fig. 10, we can state the following results concerning, for instance, the shaft diameters:

1 If the shaft diameters *vary* following the D-series, the torsional stresses will be constant along each line of N^2P = const., but *different* for each such line; thus, stresses along the line AB will be $1.778 \times 3 = 5.334$ times as great as along the line $A'B'$.

2 If the shaft diameters remain constant, the torsional stresses will be constant along the lines of T = const., but different for each such line; thus, stresses along the line AB' will be 1.995 times as great as along the line BB''. In the first case, using four shaft diameters, corresponding to the same number of impellers, we should expect the fluctuations of the torsional stresses to be in the ratio of 1 to 5.334, whereas in the second case, using *only one* shaft diameter for four impeller diameters, we should expect the fluctuation of the torsional stresses to be in the ratio of 1 to 1.995.

Similar reasoning leads to the same conclusion concerning the stresses in the casing.

The number of impellers (casings) to be included in each group with the same shaft diameter and wall thickness depends on the stress fluctuation which is considered commercially permissible: *The greater the fluctuation in stresses allowed, the smaller the number of different sizes needed.*

This conclusion is similar in all respects to the one derived for the hydraulic standardization. A statement expressing the same relationship for both hydraulic and mechanical standardization might read as follows: *The greater the fluctuation in the stresses as well as in the pump efficiency that is allowed, the smaller the number of different sizes needed to cover a definite field of service.*

At any rate, whatever selection is made following this method of standardization, all the dimensions of the mechanical parts will be included in the original table of preferred numbers if the dimensions of the model pump are preferred numbers.

VI—CONCLUSION

The law of similitude and the relations used in the development of this method are well known to hydraulic engineers. Therefore the author will confine himself to calling attention to certain points only. The method is accurate to the extent to which the law of similitude, as expressed in the equations used, accurately describes the actual performance of centrifugal pumps.

It is known that efficiency does not remain constant at constant n_s, but changes following the variation of sizes and speeds. The capacity is inclined to increase at the same n_s with the increase in size.

The deviations from the law of similitude are the greater the further the dimensioning of the pump, or its operating conditions, is from the normal state of a smooth channel flow and uniform distribution of velocities and pressures (versus shocks, cavitation, etc.).

Whereas these deviations are not of importance as regards the standardization itself, they should nevertheless be taken into consideration if the standardization chart is used as a rating chart for the preliminary selection of the size of pump to meet definite operating conditions.

In such cases correction factors based on the tests should be applied to the readings on the chart.

This method can be used for the standardization of other kinds of turbo-machines, properly adjusted to the individual peculiarities of the case.

The author's strongest conviction is that the method can be applied to the standardization of any industrial product if the relations expressing the law of similitude are established, for the preferred-number idea and the law of similitude are the most completely generalized principles which have ever been known.

The law of similitude was used for standardization of steam engines as early as 1894 by Normand.[4] At the present time, in connection with standardization problems, the subject deserves much more attention and study[5] than ever before.

Therefore the purpose of this paper has been not only the application of this method to the standardization of special kind of machines, as in the present case of centrifugal pumps, but also to arouse interest in its further study and application to any object of industrial production.

SYMBOLS USED IN THE PAPER

H	=	head in ft.
Q	=	capacity in cubic feet per second
N	=	r.p.m.
P	=	horsepower
T	=	torque in foot-pounds
D	=	diameter of impeller in feet
n, q, p, t	=	unit speed, capacity, etc., for the same size
n_1, q_1, p_1, t_1	=	unit speed, capacity, etc., for different sizes
n_{sq}	=	specific speed in terms of capacity
n_{sp}	=	specific speed in terms of power
m_s	=	mechanical invariant
u	=	peripheral velocity of the impeller in feet per second
C	=	flow velocity in feet per second
N_h, N_q, N_p, etc.	=	speed at constant H, Q, P, etc.
γ	=	length scale, term ratio of D-series
σ	=	stress in pounds per square inch
s	=	wall thickness

Discussion

J. W. Macmeeken.[6] The exceedingly clear presentation of the subject by the author is refreshing. The mathematical relationships of all the functions of the variables which come under the laws of dynamic similarity are treated throughout from the viewpoint of infinite series, of which any one pump or particular machine is merely one example. The interrelation of these series as functions of the same fixed ratio is expressed with a clearness and consistency that are new in pump literature covering these aspects of centrifugal-pump variations. This method of formulating the laws of variation is applied by the author with great advantage in showing the relationship between "the linear ratio" in its hydraulic aspects and its significance in design for strength of materials.

Diagrams on logarithmic paper such as the author uses have been employed by designers for many years past as a guide for consistent reasoning and comparison of results. This period of their use has seen us through the perfection of the hydraulic turbine and the development of the centrifugal pump to a degree of perfection at last equal to that of the turbine in several important types, but the period of development so far as pumps are concerned is far from completion. Later information acquired in the last few years has afforded the designer unexpected knowledge of limitations of application of the laws of type similarity applied to centrifugal pumps. For instance, a large pump which gives a satisfactory performance with high efficiency has been found to give exceedingly poor results in a geometrical model of considerable size reduction. Conversely, a conveniently dimensioned model when stepped up to a very large pump has been known to fail to perform according to the law of type similarity in some instances, and in others has given a slightly different performance from that expected from calculations. The known difference in dimensions between a satisfactory large pump of economical design and a satisfactory small pump of economical design is so great in the case of a linear multiplying factor of 4 that there must obviously be a continuous variation in the best proportions in all intermediate multipliers in a series of the same type. This is explainable by considering that the laws of type similarity are assertive in maintaining similar ratios in these elements of the machine which involve dynamic effect; for instance, in the proportioning of the maintenance of a forced vortex as a means of generating head. Certain parts of the hydraulic field of fluid flow in a centrifugal pump are not subject to dynamic effort on the part of the rotor; for instance, the approach to the impeller by any of the usual designs of suction casing or the distance through which the fluid travels between the impeller and the exit of the casing are elements that should scarcely be subjected to factor multiplication. In the impeller itself there are flow passages which operate under a different Reynolds number for different pump sizes. Dynamically, an impeller characteristic type is one which is dynamically suitable for a certain maximum total dynamic head with certain concomitant velocities. Therefore the numerical value of $DV\rho/\mu$, known as the Reynolds number, must be different for each pump size for the same fluid. The variation of radii of curvature in different sizes for the same velocity of flow as determined by type characteristics results in great variations in "radiating current" and "induced vortices." For example, an irrigation ditch with water flowing under a velocity of 4 ft. per sec. at a bend will produce elbow flow free from independent vortices. The same channel proportions in a large river with the same velocity of flow have been known to result in a complete circular whirlpool, with severe loss in head.

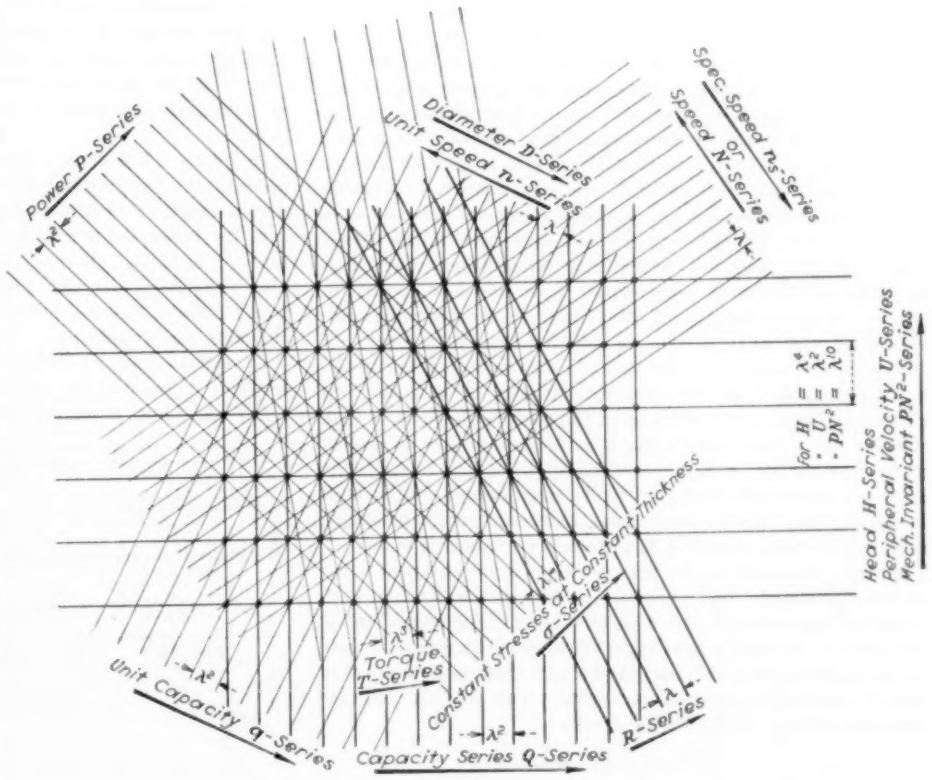

Fig. 11 Reynolds' Number or *R*-Series

The intensity of competition among centrifugal-pump manufacturers today makes the strict use of type multiplication diagrams prohibitive except for the purpose of preliminary comparison through a short range of multiplying factors in the series. A complete standardization based on the law of similarity would result in a series of standard pumps very likely to be satisfactory between certain limits and far short of the best possible above and below these limits. The study of this situation is being gradually advanced by different designers, and valuable knowledge is gained by occasional disappointments and the means that are found effective in their remedy. When this is completed, one important further step in the knowledge of pump standardization will have been reached. The principles outlined by the author remain important as a means for preliminary comparison and first approximation.

[6] Hydraulic Engineer, Byron Jackson Pump Mfg. Co., Berkeley, Calif. Mem. A.S.M.E.

The author's suggestion of the use of preferred numbers in the choice of multiplying factors and ratios is a happy one. Every designer has, however, developed certain preferred numbers of his own, based on actual experiences and arbitrary past selections, which have been fortuitously successful or which have some particular mental association. Many of these are not the result of psychological selection, but are fundamentally dependent on the natural laws of hydraulics, which in their application to power machines have a margin of possible variation. For instance, the ideal multiplying ratio for two consecutive machines of the same type should be such that a small-capacity impeller of the larger machine shall deliver only a slightly greater capacity than a high-capacity impeller in the smaller machine. This ratio has been determined experimentally, but is still possible of further modification.

The series developments used by the author and which plot as straight lines to logarithmic scales in the Cartesian diagrams illustrated by him are not really all straight lines in actual practice. For instance, the brake horsepower used by a power machine varies with size, not in accordance with the laws of similitude assumed by the author. Power losses in different-sized machines of the same type nearly always vary with multiplying factor as a transcendental function of the size of machine. This is true of steam turbines, centrifugal pumps, rotary compressors, etc., and such functions do not plot as straight lines to logarithmic scales. In addition, the combination of varying Reynolds-number indices in centrifugal pumps of different sizes has an effect on the unit capacity and unit speed which causes their deviation from the logarithmic straight-line rule. This variation is very marked in certain types and less marked in others. A knowledge of such effects is of the utmost importance to the designer in proportioning different sizes of machines of the same hydraulic type, not only in order to obtain the anticipated output and the best possible efficiency in each size, but also to enable him to so dimension the various elements of each size that the lowest possible manufacturing cost may be arrived at by economizing in space and material. There exists today fairly conclusive evidence that really large pumps can be built to substantially smaller dimensions than small pumps belonging to the same series, and by so doing their performance is improved. The larger the machine, the better it may be proportioned to hydraulic advantage—a second reason why in standardization work a multiplying factor should be regarded as a "type factor" which requires for maximum advantage important changes in dimensional proportions of the machine for each size, as long as every size of machine is required to operate with uniform physical characteristics of the fluid to be pumped.

Author's Closure

Deviations from the law of similitude were briefly treated in the conclusion of the paper and the attention of readers was called to certain points liable to raise questions. That the discussion of Mr. Macmeeken has been directed to these points should be welcomed, as obviously they need further elucidation.

If the Reynolds number be of such importance, as Mr. Macmeeken seems to believe, its effect could be easily taken into consideration.

Using the diameter D as representative of the size, the peripheral velocity U as representative of the flow velocity, and ν as the kinematic viscosity of the water, the Reynolds number R is proportional to DU/ν, or $R = \text{const.} \times DU/\nu$.

The kinematic viscosity being constant for the case considered, this relationship permits us to form the R-series in the usual way. Proceeding through each term of H_h-series along $H = \text{const.}$ and $U = \text{const.}$, we pass through the corresponding successive terms of the R-series and D-series. We have

$$\frac{R_n}{R_{n-1}} = \frac{D_n U}{D_{n-1} U} = \frac{D_n}{D_{n-1}} = \lambda$$

The term ratio of the R-series is γ and its general term λ^n.

The location of the lines $R = \text{const.}$ is determined by relationship $R = \text{const.} \times DU/\nu$; obviously the lines of constant R pass through each term of the u-series (λ^{-1}) and each alternate term of the D-series (λ^2). The R-series is shown in Fig. 11. It indicates that the Reynolds number increases with the size and capacity of the pump, a fact which to a certain extent explains the better efficiency of the larger-size pumps.

Unfortunately we can not make more use of the Reynolds number in the standardization of centrifugal pumps than to state its relation to the other variables and its effect on the pump efficiency. That the Reynolds number is not the controlling factor as regards pump efficiency follows from the fact that there are large pumps (large Reynolds' numbers) with low efficiency as well as small pumps with high efficiency.

The Reynolds number has not been taken into consideration not only because the similitude, simultaneously geometric and dynamic, cannot exist for motion in a *viscous* liquid, but chiefly because in the application to turbo-machines the friction forces are negligible as compared with the mass-acceleration (inertia) forces.

In addition, the friction losses, along with the other hydraulic losses (shock, conversion, etc.), were found to follow very closely the assumption involved in the relationships used, namely, that the losses are proportional to the square of the flow velocities, or heads. But in the law of similitude as applied to centrifugal pumps, further assumptions are involved, i.e., regular flow, uniform distribution of pressures and velocities, filled channels, no cavitation.

In endeavoring to design pumps of better efficiency, we certainly approach the assumptions required by the law of similitude. Fig. 12 shows results of tests of a pump running at

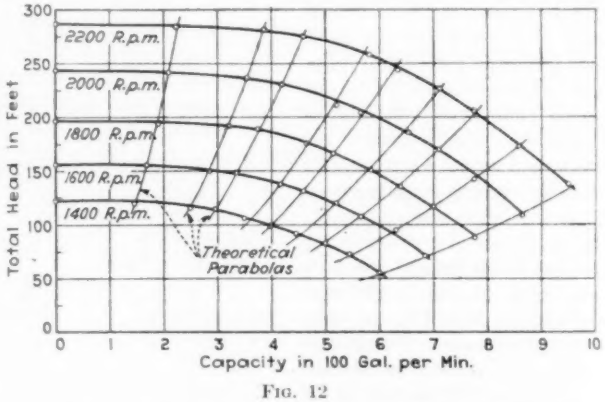

Fig. 12

different speeds and at constant openings of the discharge valve. The high efficiency (best, 86 per cent) of a comparatively small pump and the almost exact location of points of the N_s-series on the mathematically determined parabolas are not a mere coincidence, but seem to indicate a closer relationship between the high efficiency and the fulfilment of the assumptions of the law of similitude.

Using the standardization method presented in the paper, it is possible to handle any information about the pump in question, and to evaluate any new factor which may appear and take it into consideration when selecting the range of the D-, N-, and n_s-series to be used for a given service (see Chap. V on the n_s-series).

The selection of the n_s-series is especially connected with

the matter of efficiency, and here is where the designer can utilize all information like that given in Mr. Macmeeken's discussion. As a means of presenting all the variables with all their interrelations, the standardization method may also be helpful in this stage of the work, but its task is, as a tool, to develop and incorporate in the standardization chart all the series involved, with their multiple interrelations, utilizing any information which is of value for the purpose of standardization. The method can do that, using not only the series already developed, but also adding, if necessary, series of new variables, which it may appear desirable to evaluate, as was done at the beginning of the closure with the Reynolds numbers.

Application of Hydraulic Laboratory Researches

By IREAL A. WINTER,[1] BIRMINGHAM, ALA.

This paper presents results of laboratory investigations made in connection with hydroelectric power-plant designs, the problems encountered leading up to the establishing of a policy of conducting research, the method of testing, and comparisons of laboratory and field results. The object is to illustrate the many advantages of model investigations and to point out the deficiency of scientific knowledge incidental to power-plant design, with the hope that interest will be stimulated in pure-science research. Hydraulic research may be classified under two subdivisions: complex flows created by natural active and reactive forces, such as river channels, harbors, estuaries, tidal effects, etc., and, second, manufactured structures, such as spillways, canals, penstocks, hydraulic machines, etc., where the active and reactive forces should be definitely predicted by the designer. This paper deals with the latter, principally in connection with hydraulic turbines and their associated parts. Results will be shown where slight changes in shapes raise or lower the efficiency of hydraulic machinery as great as 1 per cent. No attempt is made to specifically account for the results obtained, but the apparent inconsistency of performance of water passages designed according to the limited knowledge of positive and negative acceleration will be evident to hydraulic engineers engaged in the utility field.

THE keen appreciation for a need of engineering facts in the preparation of designs for hydraulic structures has given impetus to research in this country to a great extent in the past few years. The self-sufficient attitude of the engineer of the old school has been supplanted by a desire to prepare designs in accordance with results established by laboratory tests on homologous models. This attitude has been brought about mainly by economic necessity, supplemented by engineering difficulties due to a deficiency in materials.

Many engineers are aware of the fact that new and improved methods are being fashioned in the laboratory, challenging the existence of every industry. A casual observation of the rapid change in importance of various industries today is sufficient acknowledgment of these facts. No group of utilities has been more aware of these conditions than the hydroelectric group. This new and energetic industry has grown to great economic importance by untiring efforts in developing its properties and markets through research, its very conception being a laboratory product.

The Mitchell Dam Plant

When designs were being prepared for the Mitchell Dam development of the Alabama Power Company, several engineering problems became evident as the work progressed.

The topography at the dam site limited the space available for spillway capacity when using gates of a depth considered safe for spilling on the river-bed foundations. The rock bluffs forming the abutments presented unsuitable conditions for a hillside spillway. The channel immediately below the site caused a rise in backwater of over 25 ft. during flood periods. As the normal operating head was only 68 ft., the loss in effective pressure at times of freshets, a frequent occurrence on the Coosa River, amounted to an appreciable loss in turbine capacity.

These conditions brought to maturity the conception of the Thurlow backwater suppressor.[2] This type of plant utilizes the hydraulic jump to lower the static pressure over the draft-tube orifice, thereby maintaining full pressure head on the turbine at all times. It also enables the plant to be laid out so that the full width of the river can be used as a spillway. This is accomplished by placing the units upstream of the spillway and discharging the draft tube through the main dam. Fig. 1 illustrates the general arrangement of the plant. Many secondary advantages resulted from the design, and it is considered by the operators as one of the most satisfactory generating stations on the system.

The performance of the backwater suppressor has been as predicted from experimental research. The average increase in kilowatt-hours per year has been substantially 4 per cent. This is the amount of energy actually sold, and is not the available generation had the load been equal to the plant capacity. The possible increase is 7.5 per cent without the influence of the Jordan Dam backing tailwater over the draft tubes. It is expected that a substantial increase over the present generation will be realized when the full efficiency of the spillway water is used in neutralizing the effect of a rising forebay at Jordan Dam.

Of equal importance to increase in yearly generation is the ability of the plant to carry full load at all times.[3] The maximum increase in plant capacity has amounted to 45 per cent, which may not account for a substantial increase in kilowatt-hours, but as a means of reducing capital investment, is of great moment.

---

[1] Hydraulic Engineer, Allied Engineers, Inc. The author was born on July 31, 1894, in Belvidere, Tenn. His engineering activities began in 1912 in the drawing room of the By-Product Coke Oven Plant of the Tennessee Coal, Iron and Railroad Company at Fairfield, Ala. From 1913 to 1914 he was engaged with the Alabama Power Company on the design of hydroelectric stations, resigning in the fall of 1914 to accept a position with Ford, Bacon & Davis at New Orleans, to be engaged in the design of cotton warehouses and grain elevators. In the summer of 1915 he returned to Birmingham with the Alabama Power Company on design of steam and hydroelectric generating plants. During the World War he served with the 37th Engineers, U.S.N.A., with the grade of Master Engineer. From 1919 to date he has at various times been connected with the Dixie Construction Company, Allied Engineers, Inc., and Corps of Engineers, U.S.A., on general design and laboratory investigation of hydraulic machinery and structures.

Contributed by the Hydraulic Division and presented at the Semi-Annual Meeting, Birmingham, Ala., April 20 to 23, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] Trans. A.S.M.E., vol. 44, p. 361.

[3] N.E.L.A. publication No. 267–10.

All features of this new type of plant were developed by models to a scale of $^1/_{24}$ and $^1/_{10}$ full size. No laboratory facilities were available in the Birmingham district; consequently the work had to be done on a very modest scale. The first working model was demonstrated in a flume costing less than one hundred dollars. The results were so convincing that the management appropriated a substantial sum for carrying the investigation to a conclusion.

Since 1921 all major developments of the Alabama Power Company have been the subject of laboratory research covering structural, electrical, and hydraulic problems. The field of hydraulics has been investigated in connection with spillways, spillway gates, energy dissipators, penstocks, scroll cases, draft tubes, turbines, expansion joints, cofferdams, backwater curves, etc. The results of laboratory tests have been checked in the field where a check has been feasible.

Draft-Tube Tests

When Mitchell Dam was under construction, the new improved concentric type of draft tubes was coming into general use, and it was thought desirable to investigate tubes best suited for the suppressor type of plant.

A series of experiments were conducted at the Alden Hydraulic Laboratory of the Worcester Polytechnical Institute, using a 12-in. homologous runner and various types of draft tubes.[4] The result of these tests was the adaptation of two units using the White hydraucone[5] for good efficiency at all loads and two units of the elbow type modified to use the long downstream leg incidental to the suppressor design. The latter type offered considerable saving in construction cost and equally good peak efficiency, being well adapted to base-load generation.

Fig. 1 View of Mitchell Dam Plant Showing Three Suppressor Gates Open
(Flow is 15,000 cu. ft. per sec.)

A comparison of the laboratory and field results is shown in Fig. 2. No efficiency tests were made on the plant due to the difficulty of measuring the water quantity. The kilowatt output against the gate opening in per cent is used as the criterion for performance. It will be noted that the two machines have identical capacity for the same per cent of gate opening from 16,000 to 18,000 kw. This is in substantial agreement with the model tests indicating that the efficiency of the two units should be the same between 0.20 and 0.235 hp. at 1 ft. head for $D_2 = 12$ in.

The importance of draft-tube design to construction costs and turbine efficiency was well illustrated by the Worcester tests In this same series a model of the old-style elbow-type draft tube used at Lay Dam (lock 12)[6] was built and tested. The interesting results of this work are shown in Fig. 3.

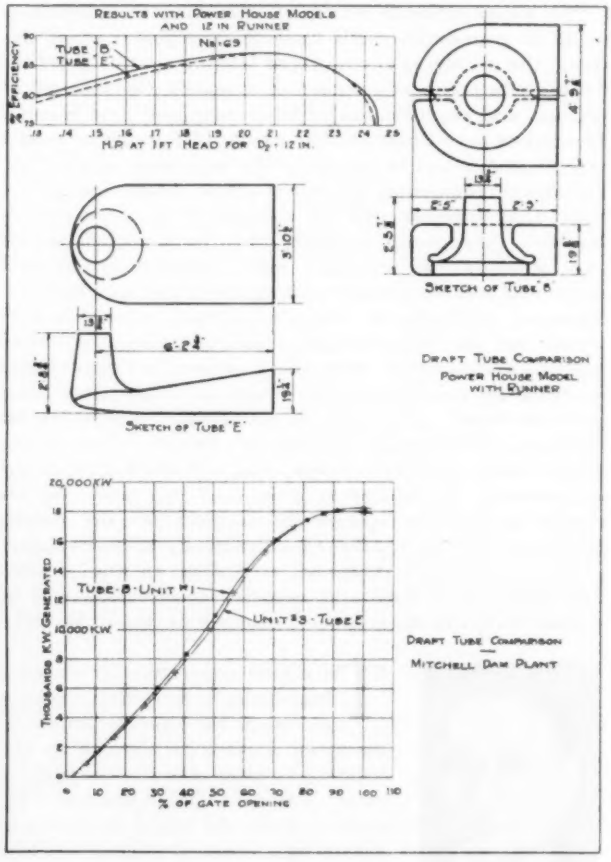

Fig. 2 Comparison Curves for Mitchell Dam Draft Tubes

Comparisons of tests from several angles are given in this figure. Starting with the experiments on a 4-in. model without a runner, the general characteristics for various angles of whirl are shown. Contrary to the general belief that an elbow tube is poorer in efficiency with an increase in angle of whirl, the reverse is true in this case. A draft-tube efficiency of 33 per cent is obtained at 8-deg. angle of whirl and increase to a maximum of 52 per cent at 40 deg. By plotting the area curve of the vertical barrel with sections taken in a horizontal plane, rather than normal to the center line of the tube, the reason for this apparent inconsistency is seen. The rate of expansion is much greater than can be obtained without considerable centrifugal force to effectually fill the tube. Alteration D, Fig. 3, is a semicylindrical fillet blocking off 40 per cent of the outflow area. The efficiency at zero angle of whirl is increased 10 per cent to a value of 46, and to a value of 63 per cent at 38-deg. angle of whirl. A comparison of the rate of diffusion normal to the center line for the two tubes will show that the alteration more nearly approves the possible rate determined experimentally

[4] Trans. A.S.C.E., vol. 87, 1924, p. 893.

[6] Trans. A.S.C.E., vol. 58, 1915, p. 1505.

for a conical diffuser than the original design which was based on negative acceleration obeying the law of positive acceleration.

The same characteristics for the alteration are shown when tested with a runner, the peak efficiency being raised a full 1 per cent and the maximum power 3.5 per cent.

The performance of the model runner using the Mitchell Dam hydraucone is shown for comparison. It was thought quite significant that a simple alteration in the old-style elbow tube would raise the efficiency of the runner to within 0.5 per cent of the value obtained with the improved hydraucone. Results of research to develop the quarter-turn tube are included in the paper.

The field alteration of the draft tube at Lay Dam apparently

It was assumed that the increase in capacity was due to an increase in negative head within the draft tube. The Holyoke test on the model runner was used as the criterion for change in efficiency, all points being based on a percentage of power in both cases. A new gross head was computed that would produce the equivalent increase assuming the power to vary as $H^{3}/_{2}$. A new quantity of water was computed on the basis of the $\sqrt{H}$. The new quantity was substituted in the efficiency equation, using the actual head and kilowatt output. The resulting curve is shown in the figure. It is believed that this method of determining the effect of alteration in the field is legitimate, although it has been questioned by several engineers. The author has had unfortunate experiences in attempting to check field results

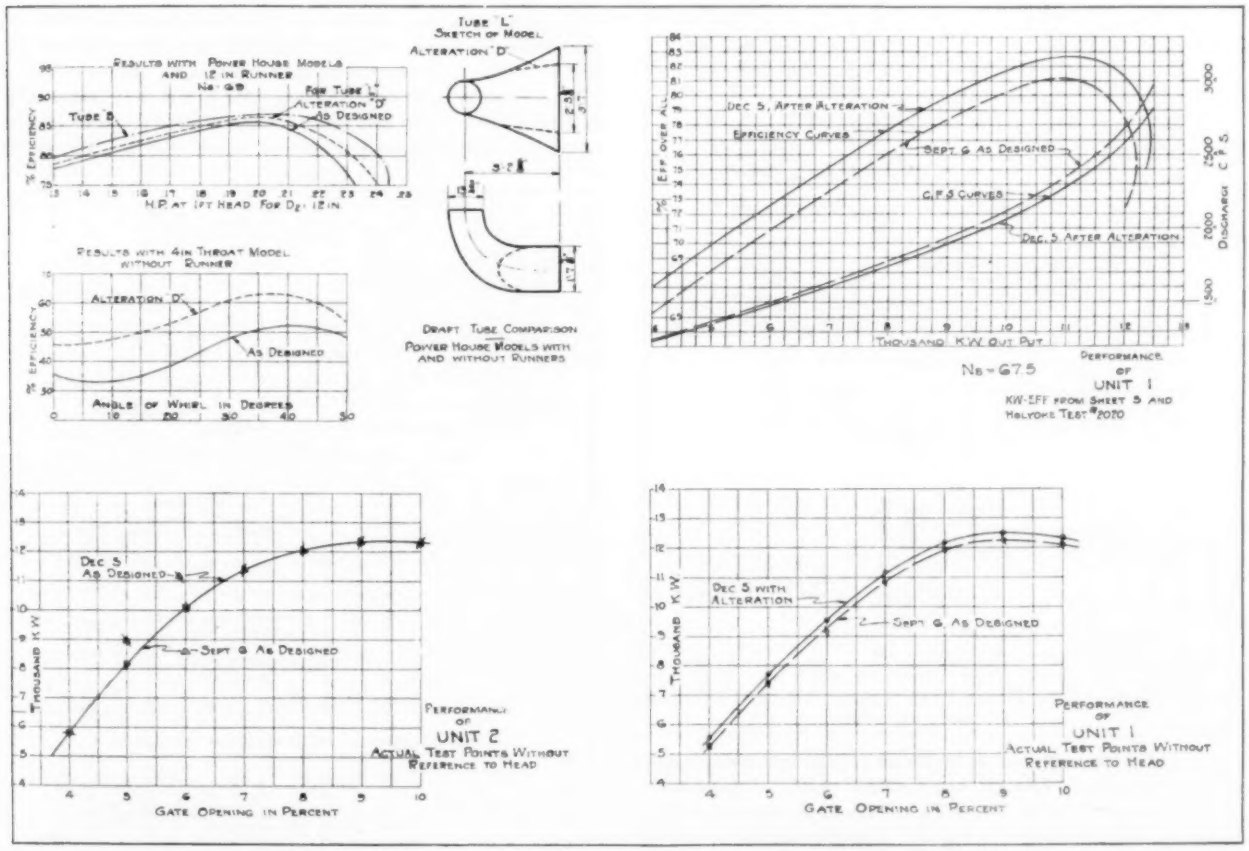

Fig. 3 Comparison Curves for Draft-Tube Alteration at Lay Dam

agrees with the results obtained in the laboratory. The peak efficiency was raised 1.4 per cent and the maximum power 2 per cent. The power output was used to arrive at these figures.

A test of capacity against gate opening was made on units 1 and 2. The head was kept constant for all readings. The switchboard instruments were used to determine the output and were sealed to prevent being altered before a check test could be made on the units after the draft tube change. Unit 2 was used as a pilot unit, the draft-tube alteration being made on unit 1.

The curve sheets show the agreement of the tests before and after alteration. Unit 2 shows consistent agreement of power for gate opening for both tests. These readings were remarkable inasmuch as the actual readings checked as close as 10 kw. in 12,000. Unit 1 showed a constant increase in kilowatts for all gates, the curves being parallel.

with portable instruments. The best criterion for changes in turbine performance in the case just cited is the piston stroke of the guide-vane servomotor in inches and the revolution of the kilowatt-hour meter disk, with due respect for accurate head readings and the relation of piston stroke to actual gate opening in inches.

Martin Dam Tube

The general idea of the modified elbow tube developed for units 3 and 4 at Mitchell Dam was incorporated in designs for the Martin Dam plant. The units at this plant are rated at 45,000 hp. at 145-ft. head. Due to the relatively lower specific speed of the wheels, it was thought that draft-tube efficiency was not as essential as in the first cases cited. The designs were prepared to meet structural conditions to the best advantage.

A series of laboratory tests were made to determine the hy-

draulic performance of tube *N* and *Na* as shown in Fig. 4. Tube *F* is used as a pilot tube for comparison. It will be noted that tube *N* gave a peak efficiency equal to tube *F*, but at other loads the performance was decidedly inferior. From paint experiments made to determine the flow lines within the tube, it was evident that at axial flow an eddy developed in the heel of the tube causing a reversal of flow up into the vertical barrel. A half-cone fillet was placed in the heel which proved effective in removing the reversal flow and improved the performance of the runner to a marked degree as shown by curve *Na*.

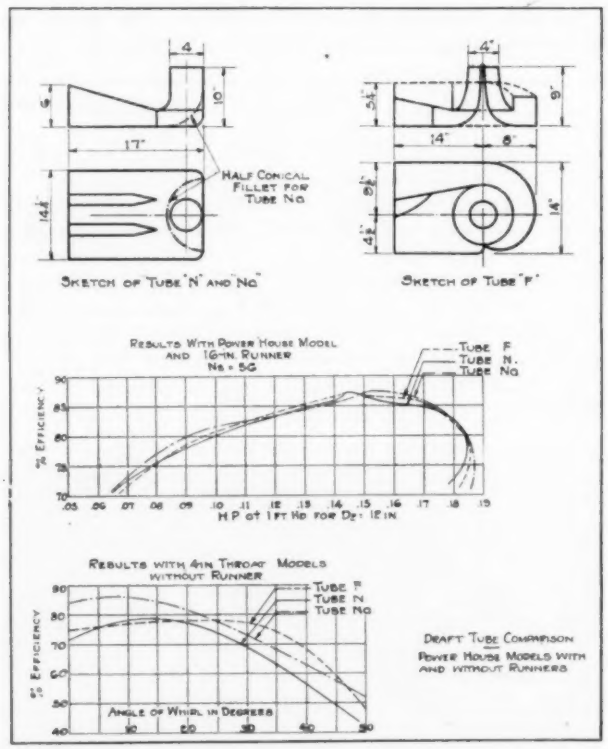

Fig. 4 Martin Dam Draft-Tube Tests; Models With and Without Runner

The importance of draft-tube design for the low-specific-speed runner was clearly brought out in these tests. A comparison of performance of tubes *N* and *Na* at various heads using a 13½-in. model runner is shown in Fig. 5. The effect of the alterations is interesting, as they indicate the necessity of making a laboratory test to determine the effect of any change that might be made to suit field conditions.

Jordan Dam Tubes

The similarity of the cross-section of tube *Na* and the results obtained on the draft-tube alteration at Lay Dam suggested a reversion of type to the old quarter-turn tube. A series of experiments were made to determine the characteristics of the true elbow type. The method adopted was purely experimental. The limiting dimensions were taken from tube *F*, and the outer radius was made to equal the depth of the draft tube. The inner radius and roof line were estimated from designs of earlier types.

The first results showed poor performance as was expected. Paint experiments indicated that the trouble was due to eddies and reversal flows around the inner radius and along the roof of the horizontal diffuser. The regions of ineffective areas were filled in, and the paint test was repeated. This work was carried on in a manner similar to a mechanic spotting a bearing. As the dead area were eliminated, the efficiency improved, until a point was reached where the elbow was filled at all angles of whirl. The final design is shown as tube 1810 in Fig. 6.

The closeness of performance of tubes *F*, *N*, and 1810 showed that the three general types represented in this series were all capable of delivering good efficiency, with the advantages in favor of the elbow tube.

Inconsistent Performance of Tubes

In general, it can be stated that a good draft tube for one wheel will also prove efficient for another, but to risk the design of a major installation without laboratory investigation is not justifiable. The following illustrations are offered:

From tests shown in Fig. 4, it would appear that tube *Na* would be the better tube for comparison with 1810 and *F* in Fig. 6. This test was made, with the results shown in Fig. 7. The increase in draft-tube efficiency due to the installation of the half-cone fillet in the heel netted a loss of 0.75 per cent in peak efficiency, but registered a gain of 8 per cent in horsepower.

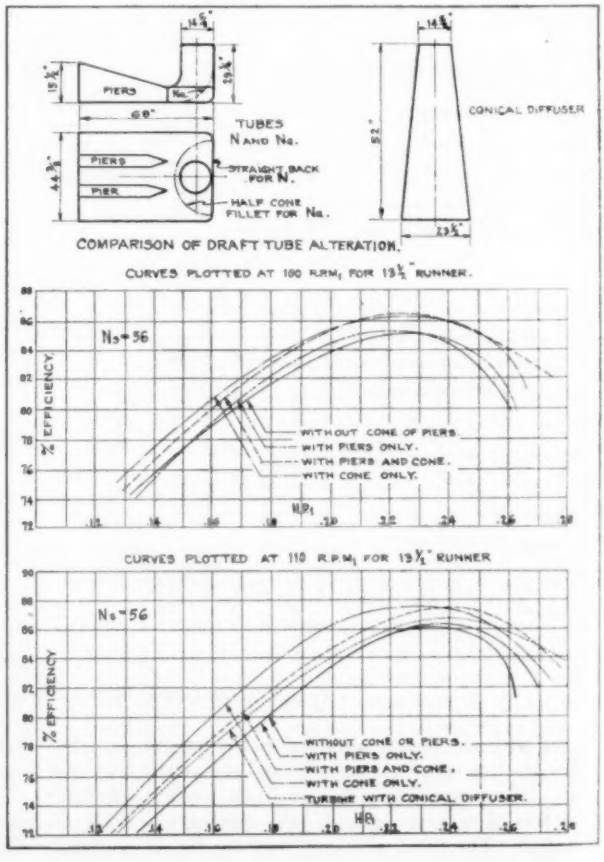

Fig. 5 Experiments With Alteration on Martin Dam Type of Draft Tube

The additional regain in velocity head pulled more water through the runner, but failed to improve the performance at point of best efficiency. The author has no explanation for this fact, as other test data indicate the same inconsistency in a negative way.

Fig. 7 shows the draft-tube efficiency for tube 1810 and a 4-deg. conical diffuser. The conical diffuser has a superior efficiency of from 10 to 20 per cent throughout the range of 45 deg. of

whirl, but no increase in turbine efficiency was found when tested with a 16-in. model runner, although the horsepower did move out a small percentage. The second curve in this figure is a little more encouraging, as the peak efficiencies move up and out as the draft-tube performance improves.

The upper and the second curves in this figure were obtained with runners of different designs, but which were of the same specific speed.

General

With the exception of the cases cited in Figs. 5 and 7, it has been the author's experience that the tube giving the greatest horsepower also gives the best performance curve. This is only stating that the tube with the best regain of velocity head will perform better with a runner.

The illustrations showing the results obtained with 4-in. models without a runner give considerable prestige to this method of testing.

It has been generally understood that the 4-in. models were usable only for rough approximation. This idea is no doubt the result of the method of testing and the failure to appre-

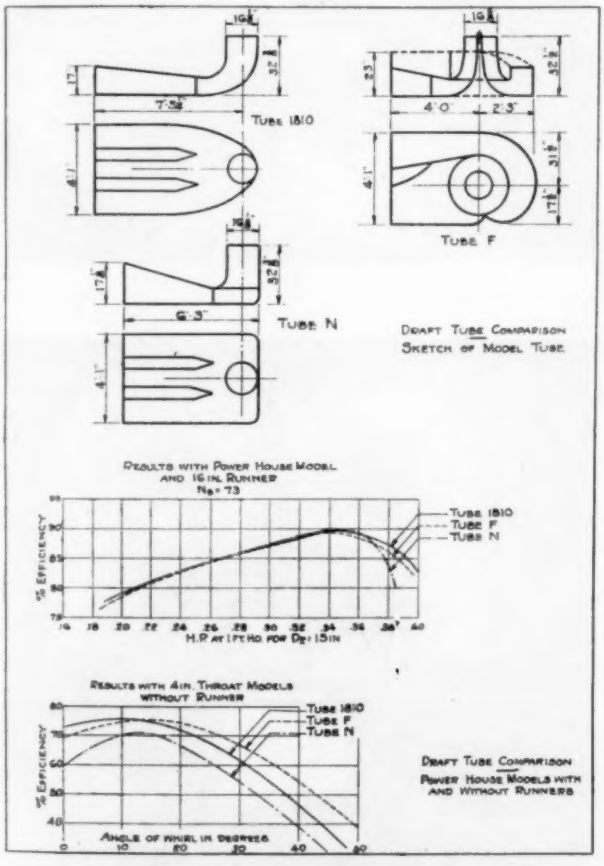

Fig. 6 Jordan Dam Draft-Tube Experiments

ciate the necessity of making a suitable flume where accurate observations could be made.

The power-house type of tubes being designed today leaves very little to be desired in the way of efficiency if we are to be guided by results shown in Figs. 5 and 7. This suggests the idea that the runners are deficient in delivering the water to the diffuser in order that the superior ability of this type of water passage can be utilized.

Scroll-Case Experiments Without Runners

Extensive research in connection with scroll-case design was carried on in conjunction with the draft-tube investigations. The results obtained have indicated that if full benefits are to be realized from tests, complete use of the laboratory facilities should be made. The later plants of the Alabama Power Company have been designed from data obtained by tests on homologous turbines, speed rings, draft tubes, scroll cases, and pen-

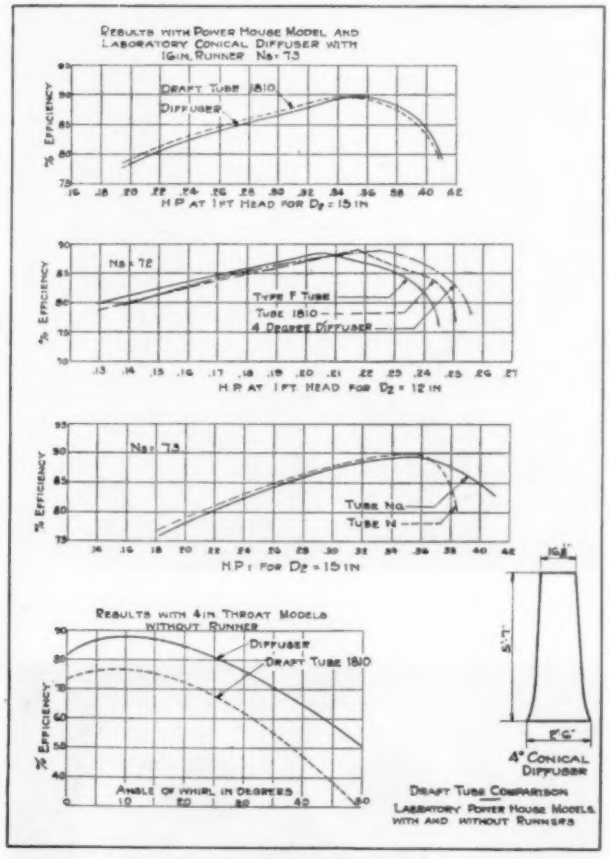

Fig. 7 Comparison Curves for Martin Dam and Jordan Dam Draft Tubes

stocks. The plant has been set up in the laboratory as completely as possible. New runners, speed rings, and guide vanes have been cast to reproduce the actual plant conditions. This is essential if correct values are to be obtained regarding speed, horsepower, and expected efficiency.

The first research in this connection was on the Martin Dam plate-steel scrolls and penstock. This work was done in the Birmingham laboratory on 4-in. models without a runner. The difficulty of obtaining usable data by such a procedure was fully appreciated, but in view of the remarkable performance of the 4-in. draft-tube models, a try seemed justifiable.

Three scroll cases with speed rings to match were built. The turbine proper was complete in detail, except that the buckets on the runner were omitted. The turbine gates were fixed at the point of best efficiency for all tests, the only variables being the scroll case and speed ring. The coefficient of discharge based on the throat discharge area of the runner D_2 was used as the criterion of performance. The flow line within the case and turbine was determined by paint tests.

The installation of the model in the laboratory is shown in

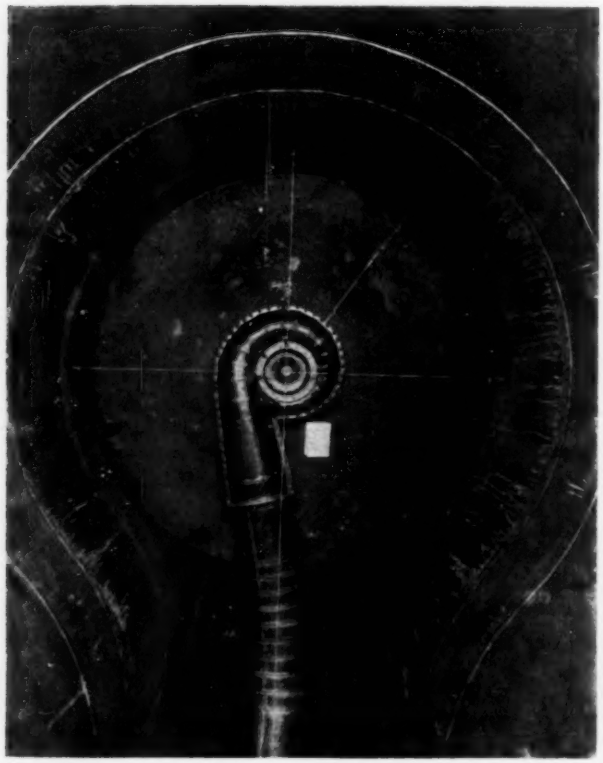

FIG. 8 FLUME ARRANGEMENT FOR EXPERIMENTS ON 4-IN. MODELS OF PLATE-STEEL SCROLL CASES

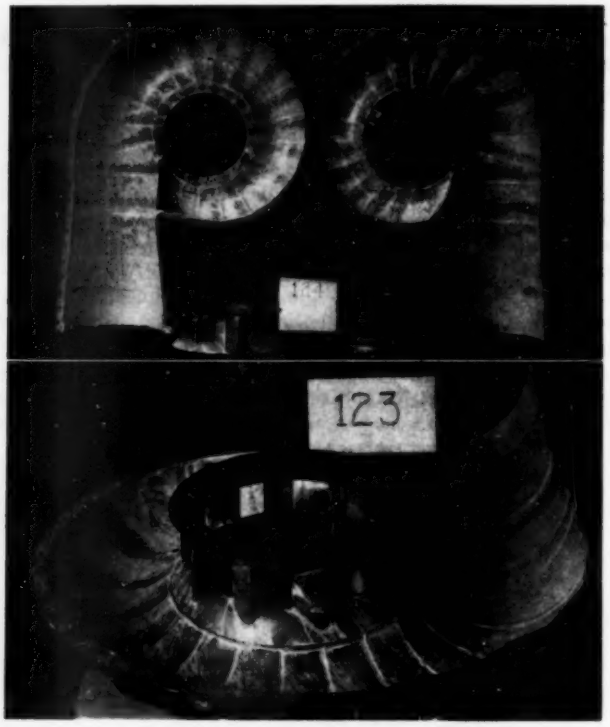

FIG. 10 FLOW LINES WITHIN SECOND 4-IN. MODEL SCROLL CASE

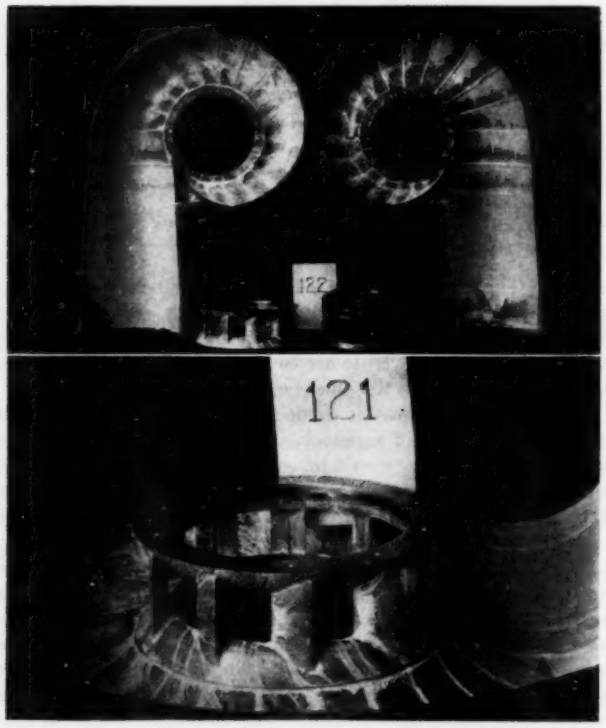

FIG. 9 FLOW LINES WITHIN FIRST 4-IN. MODEL SCROLL CASE

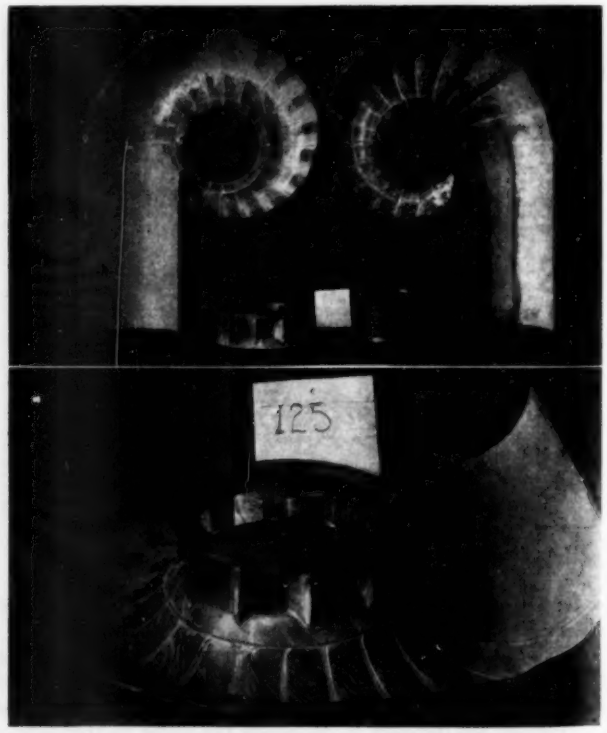

FIG. 11 FLOW LINES WITHIN THIRD 4-IN. MODEL SCROLL CASE

Fig. 8. The flow line for the first scroll designed with increasing velocity around the turbine is shown in Fig. 9. It is interesting to note that the water entering the turbine adjacent to the speed-ring surfaces is flowing radially inward while the water at the center of the distributor is flowing more tangentially and in line with the turbine gates. The failure of the water to follow the speed-ring stay vane is shown by the eddies developing on the turbine edge of the vane.

The second case, shown in Fig. 10, is designed for constant velocities around the turbine, the initial velocity being determined arbitrarily as a percentage of the spouting velocity of the water. The same general characteristics of flow into the turbine are found as in the first case. The speed-ring stay vanes are slightly better in line with the water currents.

The third case was designed along different lines from either of the first two cases. The moment of momentum was deter-

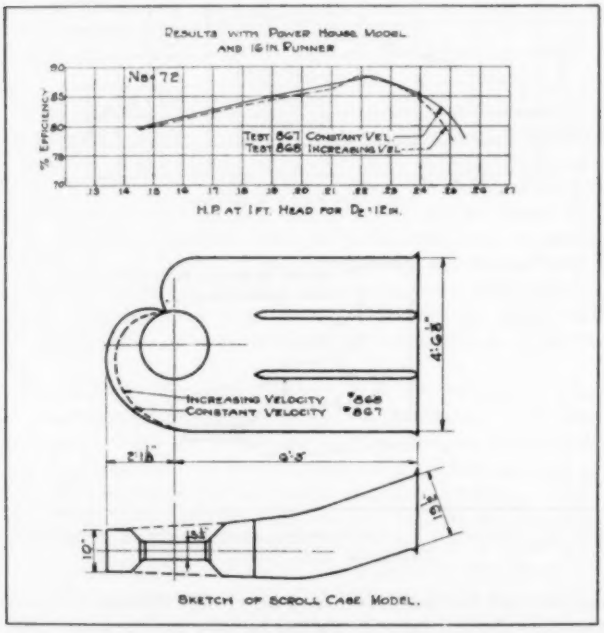

Fig. 12 Scroll-Case Tests Showing Effect of Velocities Within the Scroll

mined for the increment of flow passing the discharge tips of the turbine guide vanes when at the point of best wheel efficiency. All sections of the scroll were then made to conform to the full moment of momentum law. This gave a definite value for all dimensions of the scroll as well as establishing the initial scroll velocity. The speed-ring stay vanes were placed more radially than in the first two cases. These vanes were duplicates of the turbine guide vanes and placed substantially in line with the guide vanes at the point of best runner efficiency. Fig. 11 shows the flow characteristic for this case. The radially inward flow still persists on the upper and lower speed-ring surfaces, but the stay vanes are more in line with the water stream than in either of the first two cases. It will be noted that the eddy has moved to the entering edge of the stay vane, indicating that a slightly less angle would have given better results.

The influence of a 100-ft. radius elbow in a 20-ft. penstock immediately above the scroll intake was included in these experiments. The angle of the elbow was 32 deg. The intake to the penstock was bell-shaped to eliminate the influence of the usual design of penstock entrance. An equivalent length of straight penstock was built as a guide to the losses within the elbow. The tests indicated that the elbow lowered the coefficient of discharge a slight amount. The flow lines in the scroll case did not change, indicating that the elbow did not set up an appreciable roll affecting to any great extent the distribution of the water to the turbine.

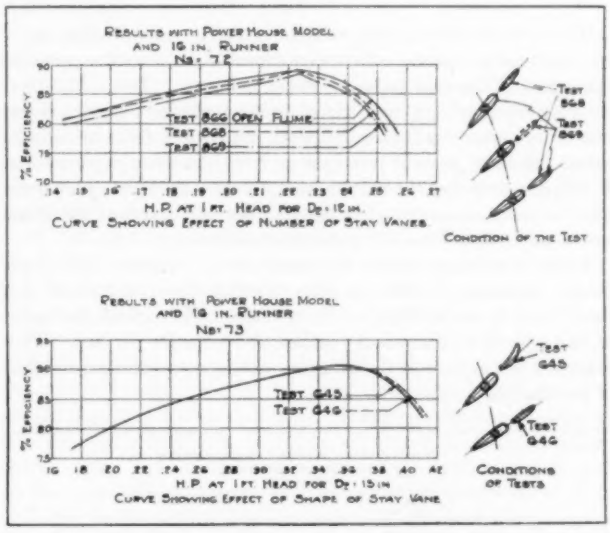

Fig. 13 Comparison Curves Showing Effect of Types of Stay Vanes

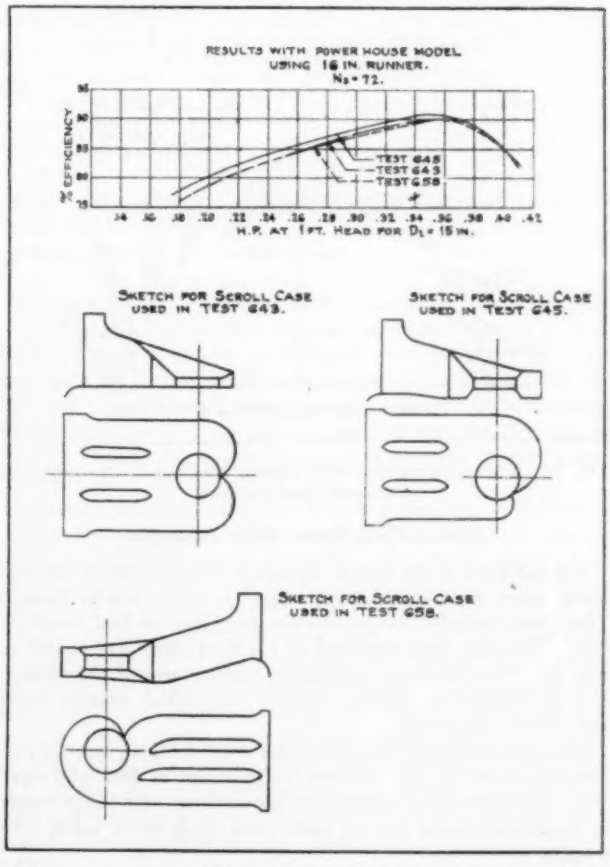

Fig. 14 Comparison Curve Showing Results Obtained With Various Designs of Scrolls

A comparison of the test results for the various conditions given is as follows:

Coefficient of discharge based on runner D_2:
Case 1 = 0.3178 with elbow in penstock
Case 2 = 0.3180 with elbow in penstock
Case 3 = 0.3190 with elbow in penstock
Case 1 = 0.3188 with straight penstock.

These tests were not as conclusive as the experiments on 4-in. draft-tube models. This was expected, due to the opposite functions of the two types of water passages. The author has no definite records of tests on plate-steel scrolls using a runner, but he is under the impression that subsequent tests have indicated the same general relations as found in these experiments. It will be noted that the maximum difference in efficiency between any two cases amounts to less than 0.5 per cent and that the elbow accounts for less than 0.1 per cent in efficiency.

These small models were to a scale of $^1/_{12}$ full size. The indicated discharge based on the coefficients determined by model test is about 3800 cu. ft. per sec The actual discharge of the wheels at the plant reached 3860 cu. ft. per sec. This is a good criterion as to the accuracy of the tests and the precision of the models.

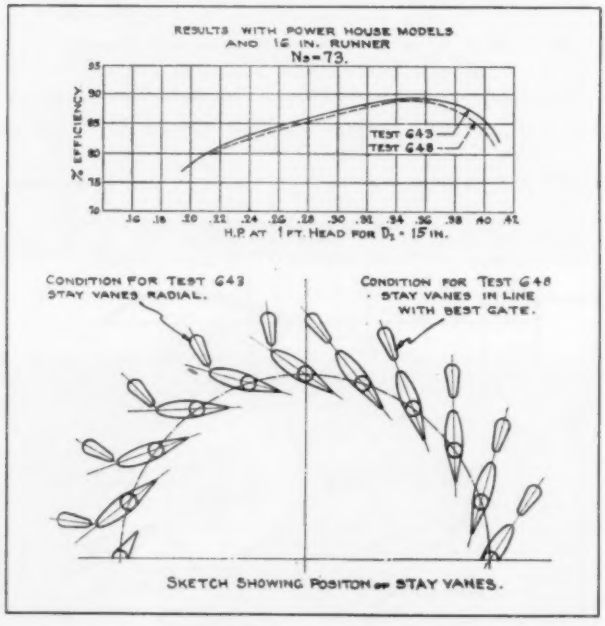

FIG. 15 TEST CURVES SHOWING EFFECT OF STAY-VANE ANGLE ON TURBINE PERFORMANCE

SCROLL-CASE TESTS WITH RUNNERS

The influence of the rate of change of velocity within concrete scroll cases was investigated, using a 16-in. model runner. These tests included the penstock as proposed for field construction. The test data obtained in the first series are shown in Fig. 12. Test 868 is for increasing velocity around the runner, and test 867 is for constant velocity, the initial velocity being the same in both cases.

The peak efficiencies for both tests were identical, but the performance curve for the constant velocity case is decidedly superior. The increase in horsepower is consistent with the increaser in coefficient found on the plate-steel scroll tests, using 4-in. models.

The speed-ring stay vanes used in these experiments were of the guide-vane type. It was thought that the use of a speed-ring stay vane for every guide vane would improve the hydraulic efficiency as well as lighten the upper and lower distributor rings. This did not prove true, as is shown in Fig. 13. The use of 24 vanes instead of 12 lowered the peak efficiency 0.6 per cent, and the entire performance curve proved to be decidedly inferior.

The lower curve in the figure shows the effect of the shape of the speed-ring stay vane on turbine efficiency. The straight-sided vane slightly increased the maximum efficiency and horsepower, and is an economic factor in construction. This is consistent with results found in the paint test made in connection with the 4-in.-plate scroll-case tests.

A comparison of performance of the two general types of concrete scrolls and a third radical design is shown in Fig. 14. Design for test 643 was based on 4-in. models without a runner, assuming that the water should flow radially into the guide vanes. Test 645 is for a scroll with constant velocity, and test 658 is with increasing velocities. Here again the constant-velocity scroll proved the better design, the peak efficiency being raised 0.75 per cent and the general performance curve being improved. The empirical scroll, with a symmetrical discharge and radial speed-ring stay vanes, proved equal to the increasing velocity scroll in peak efficiency, with better performance at part gate.

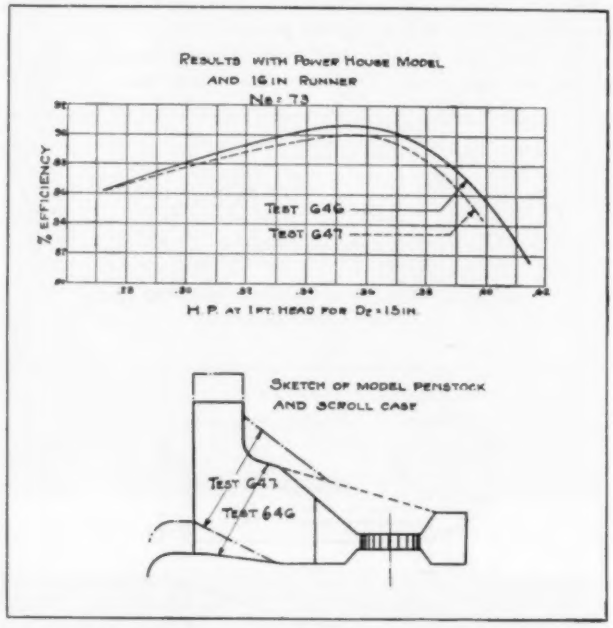

FIG. 16 PENSTOCK EXPERIMENT SHOWING EFFECT OF STEEP SLOPE ENTERING THE SCROLL CASE

An interesting sidelight on the consistency of test data is shown in Fig. 15. This design of scroll was determined in the flume used for testing 4-in. draft-tube models. The only limiting dimension given was the gross width and depth of penstock. A galvanized-iron form was placed around the turbine entrance to conform to the limits of the vertical walls of the penstock and scroll case. The scroll end was semi-circular and without a central baffle. Water was passed through the model to a depth corresponding to the roof of the penstock, and the resulting flow was noted. Two sheets of iron were bent to a shape approximating the outer surface of a scroll and placed in the flume while the test was under way. The two eddies forming about the downstream center line of the turbine entrance were greatly reduced by this procedure. The two sheets were then shaped by hand until all surface indications of ineffective areas were eliminated. The flume was then drained, and all metal parts were painted with white lead and oil. A test with a constant flow of water

was run for two hours. When the flume was drained, the flow lines showed with remarkable contrast, indicating the rate of reduction of area required in the scrolls. The limits of flow were calibrated from the iron sheets and transferred to a working drawing for the 16-in. turbine tests.

It was assumed that radial flow into the speed-ring stay vanes was desirable. Accordingly, a set of radial stay vanes was used in making the preliminary paint test. A set of corresponding vanes was built for the 16-in. runner. To check the effect of stay-vane angle on scroll design, a run was made with the symmetrical case, using the conventional vane angle of about 45 deg. Test curve 643 is for the condition of design, and curve 648 is for the conventional stay-vane angle. A drop of 1 per cent in efficiency resulted from the use of the sloping vane.

The influence of a sharp angle in the penstock immediately above the turbine entrance is shown in Fig. 16. This test was made using a 16-in. model turbine. The steep-shaped penstock for test 647 is not usual in power-plant design even with its penalty of 0.75 per cent on the plant's output.

Conclusions

Data presented in the paper are necessarily limited. The main object has been to point out the many potential mistakes in resorting to individual judgment without thorough laboratory tests. It is of equal importance to know what not to do as well as what to do. Throughout the paper it will be noted that many attempts have been made to use definite laws of motion to effect a proper design. The consistent failure of these attempts to produce the desired results is evident. A closer understanding of the application of fundamental principles to design will be realized when more scientific data are available to point the way.

The necessity of making field tests is of first importance if the full advantages of experimentation are to be realized. It is most gratifying to note the steady increase in field tests being made. Only by experience can we learn the art of measuring flows up to 7000 and 8000 sec-ft. with a fine degree of accuracy. Companies that have withheld their support because of the uncertainty of obtaining reliable results are now making plant tests and contributing their share to the general knowledge of the art. The measurement of the electrical output has not received the sincere attention that it should, no doubt due to the apparent ease with which these readings can be obtained. This is unfortunate, as many cases of conflicting results of overall efficiency measurements have resulted from indifferent output readings.

It is seldom possible to check the effect of various phases of turbine design in the field. The plant is tested, and the results obtained are for one condition only. This fact emphasizes the necessity for obtaining accurate absolute values if progress is to be noted by reference to other plants.

A review of the effect of altering parts of the water passages generally considered non-essential gives encouragement to the idea that substantial increases in efficiency and simplification of structures are to be had by continued effort along the lines of research.

The work outlined in the paper was done under the direction of Mr. O. G. Thurlow, Vice-President, Allied Engineers, Inc., with the author in responsible charge. Acknowledgment is made of the valuable assistance of Messrs. G. J. Hornsby, R. R. Randolph, Jr., Roy E. Davis, and E. B. Coleman, whose efforts were responsible for the precise execution of the work, and to Allis-Chalmers Manufacturing Company, I. P. Morris & De La Vergne, Inc., and S. Morgan Smith Company for their splendid cooperation in contributing their time and information to much of the data presented in the paper.

Discussion

R. V. Terry.[7] Experimental results obtained by the writer on 4-in. draft-tube models are in agreement with the author's in showing that, to a certain extent, the efficiency of most elbow draft tubes increases with whirl.

As a matter of record the writer would suggest that the author include a statement regarding how the efficiency of the 4-in. draft-tube models was determined; i.e., whether it is expressed as a regain in percentage of the throat velocity head or a percentage of the difference in throat and discharge velocity heads; also a statement regarding how the whirl was introduced and where the angle was taken. The angle of whirl of course varies across the throat of the tube.

The writer also has found some inconsistencies such as pointed out by the author. Slight errors are likely in the construction and testing of small models; also our simple theories do not completely cover the complex nature of water flow.

The writer has always used the constant-velocity method in designing turbine spiral casings. The method which increases the velocity toward the small end of the casing is based on the simple theory of free vortex flow. However, the flow conditions in a hydraulic turbine between the casing inlet and the runner are far from free vortex conditions. This space is subdivided by the speed-ring vanes and wicket gates. It is also quite probable that the runner indirectly affects the flow conditions in the casing to some extent. The writer considers that water flow in a spiral casing is more nearly analogous to flow in a pipe bend.

Certain previously published information is misleading in intimating that there is practically no loss of head in a well-designed spiral casing. The writer has found that there is appreciable loss of head in even well-proportioned casings and agrees with the author that casings should be the subject of laboratory investigation.

It is a little startling to find that radial speed-ring vanes give slightly improved results. This could never have been found by theory. The more one studies water flow the more he is convinced that it is far better to consult the water first, as the author has done, and then investigate a theory to correspond.

E. Brown[8] and L. B. Stirling.[8] The paper shows that tests of model turbines and their settings can be relied upon in forecasting the performance of full-sized homologous units. An increasing amount of confidence in such work will lead to the appropriation of funds for test purposes, and the results of studies undertaken over a wide field by various organizations should result in improvements in efficiency and reliability of hydroelectric units.

The Shawinigan Water and Power Company established a turbine testing plant at Shawinigan Falls a few years ago, in which model runners could be tested under heads varying from 55 ft. to 75 ft. or more, the tailrace level being adjustable over a wide range to facilitate studies of the effect of "setting" of the runner. It was thought that tests under such heads would bring to light unfavorable characteristics of runners which would not appear from tests under lower heads. The experience of many operating companies shows that modern high-speed runners, of both Francis and propeller types, exhibit a marked tendency to pitting, both on their under blades and on the draft-tube liners. A considerable amount of testing work has been done in studying the conditions under which such pitting occurs and in efforts to minimize it. These tests include the effect of

[7] Hydraulic Engineer, Newport News Shipbuilding and Dry Dock Company, Newport News, Va.

[8] In charge Experimental Turbine Plant, Shawinigan Water and Power Company, Shawinigan Falls, Quebec, Canada.

form of draft tube, and studies of the power-efficiency characteristics of propeller runners with differently shaped blades, and the influence of the setting of the runners on these characteristics. Many other allied problems have also been investigated.

Like the author, the writers have found the use of paint to be most helpful in certain kinds of work. To study the conditions resulting in pitting in the draft tube, the surface of the draft tube was painted with red or yellow duco and overlaid with a coat of soft white paint. After the paint had dried for about 12 hours, the turbine was operated under some predetermined condition for half an hour. The extent to which the painted surface was affected gave a comparative measure of the tendency of the conditions to cause pitting. In some cases no changes occurred; in others only the paint was removed; while in others both paint and duco were removed. In some cases the pitting was very severe and localized, and in other cases was scattered lightly over large areas. By such tests on a propeller runner it was established that serious pitting occurred over a comparatively small range of gate opening and that a very small change in the shape of the trailing edge of the blades made considerable change in the intensity of the pitting. Some unexpected results have been recorded, as in the author's experiences. Thus, for example, severe pitting occurred at a certain gate opening and speed, under 60-ft. head. The tailrace was lowered 5 ft., and the pitting was almost nil, other conditions being unaltered. A similar experience occurred with two service units on the system. The unit in which the runner appeared to have a safe setting, as judged by general principles of hydraulics, showed considerable pitting. The other runner, which was installed to replace one which had shown mechanical weakness and inefficiency, had a poor setting as judged by the same standards. It shows no pitting after two years of operation. The two runners are not of the same size, but their specific speed is the same, they operate under practically the same head, and they are similar in design.

During the summer of last year an extended series of tests was made in conjunction with the manufacturers who supplied a number of models of propeller runners, so designed that the inclination of the blades could be altered, thus providing for a number of variations at reasonable cost. The settings were altered by variation of tailrace level, and the performance of different models was thus related to the cavitation factor. After selecting the form and inclination of blade which gave the most desirable power-efficiency characteristic, the model was tested for resistance to pitting by using the paint method described. The model runner thus selected was used as the basis of design for the fifth unit of 30,000 hp. recently installed at LaGabelle, where the normal operating head is 60 ft.

Tests made some years ago on the effect of cones of different heights in the draft tube proved that no one cone showed to advantage over the others at all gate openings, when tested over a wide range of speeds. For small gate openings the smallest cone gave best results at all speeds, whereas at the larger gate openings the highest cone had the advantage up to certain speeds, beyond which the advantage lay with a cone of intermediate height. These results are mentioned briefly, to show that small changes have distinctly measurable effects and that it is sometimes dangerous to generalize from the experience of individual tests. The explanation of results is sometimes difficult or impossible, but the facts are of great importance and only appear as the result of tests.

RALPH L. THOMAS.[9] It is particularly notable that the author and his company have had the courage to apply the results of their model tests in actual installations, involving expenditures of large sums of money, sometimes in the face of the skepticism usually met in pioneering work, and that their expectations have been amply fulfilled.

There is one feature of the design of the hydraulic turbine water passages, as shown by the drawings with the paper, concerning which it would be interesting to have additional information. Was the shape of the bell mouth of the turbine intakes as shown in Figs. 14 and 16 the result of model tests? In particular, has the author made an investigation of the proper or most efficient curvature for the top of this bell-mouth entrance?

CARROLL F. MERRIAM.[10] The paper deals with an important phase of a subject which is being given serious consideration by power companies, particularly those constructing important hydroelectric plants. It is a well-established fact that these companies cannot afford to build modern plants without carrying through an extensive testing program comprising experiments such as those the author describes.

There is always present danger of accepting results which are based upon too little testing and of the establishment of engineering dogma which may be blindly followed in the future. For this reason experiments should aim to give clear understanding of the fundamental causes of hydraulic phenomena, rather than to determine simply what designs may under certain circumstances give the best results. These circumstances may be entirely upset by a slight alteration, and conclusions which might be accepted as general may prove on further investigation to be fallacious. The problem therefore demands the finest talent available, as well as a free interchange of information between investigators.

It is interesting to compare our practice with that in Europe, where progressive work in hydraulic-turbine design is being conducted practically entirely by the turbine manufacturers. In this country, although it is true that all of the leading turbine manufacturers have well-equipped laboratories, a great deal of work is being done by the laboratories of educational institutions and by the power companies themselves. The chief engineer for a foreign manufacturer recently remarked that he wished that his clients took the same interest in hydraulic experimentation that we do in America.

It would be very desirable, in order that laboratories may exchange equipment, to standardize upon a particular diameter of runner, and it is therefore urged that 16 in. should be adopted, inasmuch as the following laboratories are equipped to handle this size model: I. P. Morris & De La Vergne, Inc., Philadelphia, Pa.; S. Morgan Smith Company, York, Pa.; Newport News Shipbuilding and Dry Dock Company, Newport News, Va.; Shawinigan Water and Power Company, Shawinigan Falls, Quebec, Canada; Pennsylvania Water and Power Company, Holtwood, Pa.; Alden Hydraulic Laboratory of the Worcester Polytechnic Institute, Worcester, Mass. The economies effected by having it possible to test a runner at any of these laboratories can be appreciated.

In one place the author mentions measuring the electrical output by timing the disk of the integrating watt-hour meter. Excellent results may be secured in this manner, particularly for informal tests. Precautions, however, should be taken to see that these permanent instruments should not be affected in any way by outside causes, such as the change of burden on the transformers caused by the use of other instruments in the same secondary circuits, difference in power factor, etc.

G. W. SPAULDING.[11] The author has clearly shown the need

[9] Assistant General Superintendent, Pennsylvania Water and Power Company, Baltimore, Md. Mem. A.S.M.E.

[11] Assistant to General Superintendent, Pennsylvania Water and Power Company, Baltimore, Md.

for model testing when dealing with hydraulic design problems and by numerous examples indicates what improvements are possible by this means. It is generally recognized that the field of model testing, with either turbine models or structures, is by no means exhausted, and while each engineering project has its own peculiar local problems, it is plainly evident that a wealth of general knowledge could readily be available if the various agencies would pool their information obtained by model testing. Last year a hydraulic laboratory was built at Holtwood, Pa., to study the problems arising in connection with the Safe Harbor project. Much of the data and information obtained will be of considerable interest, and it is hoped that this information can be made known at a later date to those interested.

The results obtained by the author on his scroll-case tests without runners were exceedingly interesting and emphasized the fact that it is indeed difficult to predict the direction of the actual flow lines. On similar tests which were made in connection with Safe Harbor, it was found that the angle of the speed-ring vane was not critical and that this angle could be varied appreciably without affecting either the power or the efficiency. The angle actually used on the Safe Harbor turbines is approximately 25 deg. with the radius. The vanes are symmetrical about a center line, and it was decided to use one stay vane for each guide vane in order to reduce the cost of the speed rings.

A number of different tests were made with the final draft tube chosen for the Safe Harbor plant, to determine the effect of sloping the horizontal leg of the tube upward, to determine the most efficient rate of diffusion in the horizontal leg of the tube, and to determine the most economical horizontal length of the tube.

It would be interesting to obtain additional confirming data for a wide range of conditions including various types of draft tubes and with runners of various types and specific speeds, before agreeing with the author's statement that "in general, it can be stated that a good draft tube for one wheel will also prove efficient with another wheel." This is a matter which has been the subject of many discussions. It is hoped to make certain comparative tests along this line at the Holtwood Laboratory in the near future.

The author points out that the necessity of making field tests is of first importance, if the full advantages of experimentation are to be realized. It is planned at the Safe Harbor plant to use two methods of index testing, each of which will first be used on the homologous setting at the Holtwood Laboratory, and it is hoped that the coefficients obtained on the model can be used for the actual unit. One of these index methods is the Winter-Kennedy principle, for which the author was responsible. In addition to the index testing, actual efficiency tests will be made, using a large bank of current meters. The engineers of this company have spent considerable time and money in studying the question of field tests, and we are going to be very critical of the results obtained with these current meters. It is recognized that these field tests will be of primary value in analyzing the conclusions reached from the model tests.

LEROY M. DAVIS.[12] Not only is this paper valuable for its positive information, but it clearly shows the danger of designing an important hydraulic structure from the known laws of hydraulics without substantiating this design with suitable model tests. The importance of model testing, as a cheap and accurate means of determining the action of an unprecedented hydraulic structure, is just beginning to be appreciated by the American engineer. It seems probable that in the future the laboratory will be considered a necessary medium for arriving at an efficient design.

[12] Pennsylvania Water and Power Company, Baltimore, Md.

Model testing in the hydraulic field is not limited to draft tubes and intakes. For years model tests have been used extensively on turbine design. Recently tests have been made on spillways and on piers, to determine the breakwater effect of dams and cofferdams, and also the effect of excavation in rivers.

It would be interesting to know how the models which the author used were constructed. The Alden Hydraulic Laboratory has developed a method of building draft tubes which is especially well suited for models. A skeleton of wood is made up composed of rings and longitudinal braces. The inside is then lined with sheet copper which is hammered into shape and soldered together. For convenience the tube is made in two sections, which are fastened with bolts. The copper lining can be accurately formed, the wooden frame giving the necessary strength. The tube is light and inexpensive, and experience has shown that there is very little distortion when the wood becomes soaked. This same construction could be adopted for intakes and scroll cases. Such construction is limited to models for comparatively low head testing with low draft heads.

J. B. CUTLER.[13] The author states that "a review of the effect of altering parts of the water passages generally considered non-essential gives encouragement to the idea that substantial increases in efficiency and simplification of structures are to be had by continued effort along the lines of research." The writer assumes that by non-essential parts of water passages the author refers more particularly to speed-ring vanes, scroll-casing layout, and details of draft-tube design. It is undoubtedly true that higher efficiencies than at present obtainable will be developed by improvement of these details. The margin for improvement, however, above the present high-efficiency values of approximately 94 per cent is not large, and it does not seem probable that an increase of more than 1 or 2 per cent in actual calculated efficiency will be obtained.

The author's reference to the Thurlow backwater suppressor, with which it is possible to maintain rated output from a unit under greatly reduced heads caused by excess stream-flow conditions, gives rise to the thought that possibly greater importance should be attached to investigations conducted along this general line. The Moody ejector turbine, like the Thurlow suppressor, and other features developed for the attainment of the high capacities under reduced heads have been used with very satisfactory results. Considering the excess water available to the power company as an additional source of energy apart from the machine itself and without cost, the efficiencies developed from the standpoint of net return to the company might be considered as being in effect appreciably in excess of 100 per cent.

In view of this possible greater net revenue to the power producer from such devices as these, it would seem that further research along this line should perhaps be of greater ultimate value than along the line of improving features of design within the established water passages of the turbine itself. This conclusion is in contradiction to the generally accepted understanding that development in turbine design is definitely limited by the small margin in actual net efficiency, yet remaining under 100 per cent. In the writer's opinion the proved performance of the Thurlow suppressor should suggest fields of research the limits of which are as yet undetermined.

H. A. HAGEMAN.[14] For a number of years it has been the practice of this corporation to do model testing in connection with the design of important structures of hydroelectric develop-

[13] Safe Harbor Water Power Corporation, Baltimore, Md. Mem. A.S.M.E.

[14] Chief Hydraulic Engineer, Stone & Webster Engineering Corporation, Boston, Mass.

ments. Recent work along this line includes a variety of model tests of the spillway dam for the Osage development in Missouri now nearing completion, and the Rock Island development on the Columbia River, near Wenatchee, Wash., at present under construction.

In connection with the latter development, a model was constructed on a scale of 1 to 100 which reproduces the entire power site over a distance of 6200 ft. An extensive series of tests have been made on this model which have proved of great value in determining the effect of the river flows in an unusually rugged section of river channel. The largest flow on record at this power site is about 740,000 c.f.s., and flows corresponding to even greater than this amount have been experimented with on the model. As a result of these model tests, it has been possible to measure headwater and tailwater levels for a wide range of flow conditions, to determine cofferdam heights for protection of the work under construction, and to study the effect of changes in location and alignment of the various structures. Certain of these model tests showed that, by directing the river discharge from a battery of large flood gates through a deep channel below the power house, a reduction in tailwater level during high flows could be obtained very similar to that obtained by the Thurlow suppressor. No special construction was used to obtain the ejector action, which was accomplished by an arrangement of structures in relation to the natural topography. It is expected that for flows of about 200,000 c.f.s., the minimum head on the plant can be increased by this means at least 3 ft., which for an installed capacity of 150,000 kw. will mean a very considerable increase in available power.

The writer is thoroughly in accord with the practice of conducting model tests and believes that much valuable information can be obtained relative to the flow of water through hydraulic structures at small expense.

S. O. Schamberger.[15] The author's description of laboratory work done and field results accomplished in connection with the various hydroelectric developments of the Alabama Power Company indicates that considerable distance has already been covered in determining the value of experiment whenever there is a reasonable doubt in the mind of the designer as to the adequacy of a structure or the value of a change in design or operation.

Recent years have seen real interest taken in the subject of model testing, and one need only refer to the report of the Committee on Survey of Hydraulic Research of the Hydraulic Division of the A.S.M.E. to be convinced that there must be some justification for the work. Publicity is lacking, however. There may be some justification for the withholding of test data by equipment manufacturers on the grounds of economic pressure, but certainly this is true to only a small extent in the consulting field and not at all with operating companies. The author is to be commended on the experimental data he has made available to all.

Losses of any kind in an operating structure cost money. The elimination of losses is therefore warranted if the cost of elimination is not too great. Model testing to determine the ways and means may be the first step in the elimination of these losses if one can depend upon the accuracy of the results obtained. This paper, if it has done nothing else, has pointed out to an extent (not, however, to the extent that it might be hoped for) that results obtained by model testing can be checked in the field. It is to be hoped that more data can be made available in the future which will give the designer and the operator confidence in his ability to obtain field results as obtained by model testing.

[15] Hydraulic Engineer, New York Power and Light Corporation, Albany, N. Y.

Experiments described in this paper are practically all of the type where a change in form or line results in improvement in operation without appreciable increase in cost. In this type of experiment, the exact relation between the model and the prototype is not absolutely essential, as a dollars and cents value need not be placed upon the gain obtained by the model. It is important, however, to know that the field installation will react to the change in the same way, if not exactly in the same amount, as in the model. The paper has shown conclusively that this is true.

There is another type of testing which has its value to the designer in that losses experienced in waterways can be determined and evaluated before the construction, and in this way

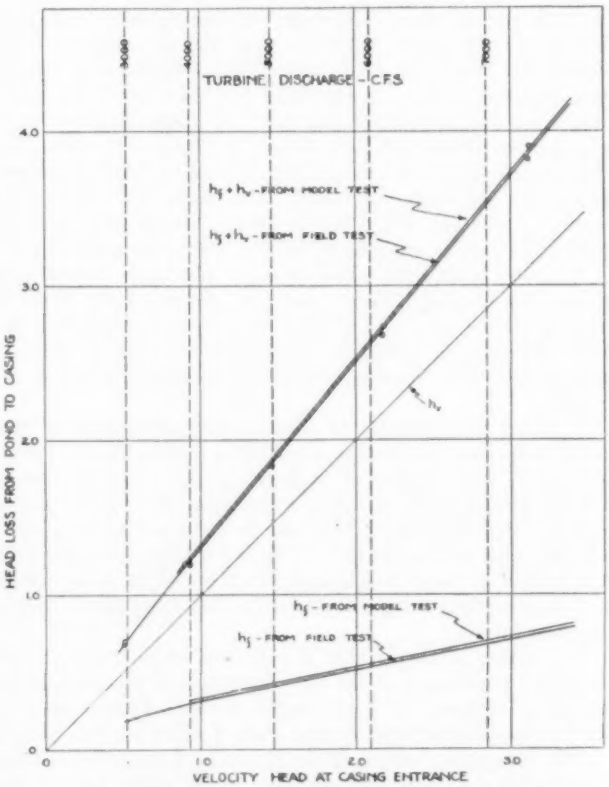

Fig. 17 Comparison of Lost Head as Determined From Model Test and From Field Test

(Conducted at New York Power and Light Corporation's Spier Falls hydro station.)

the most economic design be determined. With this type of testing, it is important to know the relation between the model and the prototype, and more data should be obtained from the field before confidence can be placed wholeheartedly in the model builder.

During the past two years, the writer has had opportunity to use a model on the scale of 1 to 48 to determine forebay and canal losses in a heavy rock cut, and also to determine the economic limit of increasing the velocities through an intake structure. These experiments were conducted at the Alden Laboratory at Worcester Polytechnic Institute in connection with the addition of a 37,500-kw. unit at the Spier Falls Station of the New York Power and Light Corporation. The test of these models has been briefly described in an article by C. L. Avery, published in the December, 1930, issue of the N.E.L.A. Bulletin.

The Spier Falls plant was built in 1902 and designed for an ultimate capacity of 9000 c.f.s. The characteristics and the

advantageous location of the plant with respect to the interconnected system made it desirable to increase its capacity for peak operation. The quantity of water through the forebay was to be increased from 9000 c.f.s. to more than 17,000 c.f.s. The enlarged forebay was in heavy rock excavation, so that dollars spent in taking out the rock should earn dollars in increased capacity.

Prior to the construction of the model, an actual test was conducted in the field to determine losses in the existing installation, and then that installation was set up in model form to determine the accuracy which might be expected from the model. The results were sufficiently convincing so that testing was continued to cover the entire construction project. After the model experiments for the determination of the final alignment of the forebay and the dimensions of the intake, construction was finished and a field check was made.

Because of the lack of time in testing the model before construction was actually under way, there were minor changes made in the design which resulted in a structure and water passages slightly different from those tested in the model. It is felt that the forebay model is as close a representation of the actual forebay as it is practical to make. There are, however, certain differences in the intake and penstock model, as follows:

1 The angle of the floor of the intake was 9 deg. steeper in the model.

2 The elevation of the stop-log sill was 2 ft. higher in the model.

3 The area of the head-gate opening was 3 per cent smaller in the model.

4 The percentage of the total acceleration produced in the transition section was 15 per cent less in the model.

5 The percentage of the total acceleration produced in the penstock bend was 13 per cent more in the model.

6 The model was tested without racks.

Of these variations, the first three tend to decrease the loss in the field, while the last three tend to decrease the loss in the model.

The curve shown in Fig. 17 indicates the agreement between the field test and the model test. For best gate capacity of 6200 c.f.s., the model indicated 0.56 ft. loss from pond to waterwheel casing entrance, while the actual field test showed 0.54 ft. The model test in this particular case indicated changes in design which resulted in a saving of some $80,000 in construction cost without appreciable increase in operating loss and unquestionably warranted the cost of the experimental work, which was in the neighborhood of $8000.

It is hoped that this comparison between the model test and the actual field check will help confirm the conclusion which the author has drawn—that model testing is a very great aid to the designer and may result in savings in construction and operation far in excess of the cost of experiment.

Author's Closure

Since presentation of the paper, field tests have been completed on the Lower Tallassee Plant, where identical turbines with different speed rings were installed. Fig. 18 shows results obtained on unit 1 with a 24-stay-vane speed ring and unit 2 with a 12-stay-vane speed ring. These results are in agreement with model tests as shown in Fig. 13.

The field tests define the shape of the performance curve more completely than is possible in the laboratory. It will be noted that the efficiency in model test 869, Fig. 13, shows a tendency to drop sharply after reaching the point of maximum efficiency. This characteristic is positively brought out in the field tests. The absolute difference in peak efficiency was found to be 1 per cent in the plant as compared with 0.6 per cent on the model. This difference is not due necessarily to inaccuracy in testing, but is inherent in the present laboratory methods. By selecting six or seven gate openings and covering a wide range of speeds, the performance curves are determined by intersecting the resulting horsepower-speed–efficiency-speed curves. The peak efficiency is established from the envelope. This method leaves considerable latitude in plotting the resulting performance curve. The need of laboratory apparatus whereby a constant speed on the turbine under test can be maintained is evident. This is only

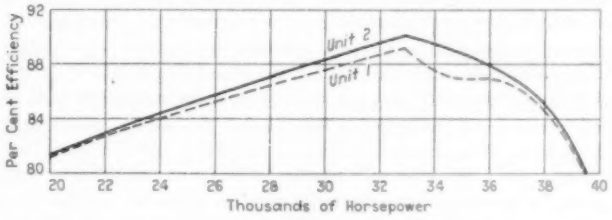

Fig. 18 Lower Tallassee Field Test, Over-All Plant Horsepower

(Comparison of 12 and 24 speed-ring stay vanes. Unit 2 has 12 stay vanes, and compares with test 868 of Fig. 13; unit 1 has 24 stay vanes, and compares with test 869 of Fig. 13.)

emphasizing the necessity of keeping all factors in model and prototype as similar as is practical.

Mr. R. V. Terry's comments regarding scroll cases is most interesting. The author is inclined to believe that the scroll case functions as a combination of vortex and elbow. By referring to test 121, Fig. 9, it will be noted that there are three separate streams of water entering the speed ring. The upper and lower streams tend to flow radially, following the elbow characteristics. The central stream tends to flow more tangentially and in agreement with the vortex law. Mr. William White, of Allis-Chalmers, emphasized this fact during an informal discussion of the paper.

In making the 4-in.-model draft-tube experiments, a turbine speed ring with guide vanes was used. The guide vanes were at various angles adjusted to produce whirl in the draft tube corresponding to 0, 15, 30, and 45 deg. with the vertical axis of the turbine. The angle was measured at the outer walls of the draft tube. The efficiency was completed by the formula $E = (C2/C1)^2 - 1/C2^2$ in which $C1$ = coefficient of discharge (based on runner D_2) without draft tube, and $C2$ = coefficient of discharge with draft tube attached. This formula is a function of external and internal head and has no factor for the inflow and outflow velocity heads.

The effect of cones in the draft tube, as noted by Messrs. E. Brown and L. B. Stirling, is of interest, as it was found in the Worcester tests that a large cone extending to the runner shaft increased the efficiency of the turbine. The function of the cone in this case was to fill a void under the runner rather than to correct areas within the draft tube.

The bell-mouth penstock entrance used in the plate-steel scroll case experiment was not arrived at experimentally. The object of the experiment was to determine the effect of the penstock elbow at the scroll entrance. The following table of plant tests, based on weighted values for all sections of water passage, will indicate to Mr. R. L. Thomas the combined head losses from forebay to turbine entrance to be expected in actual plant operation:

	Ratio L/R	Head loss, % H_v
Martin Dam	40.0	36
Upper Tallassee	21.8	65
Jordan Dam	7.6	33
Lower Tallassee	47.5	83

in which L = length from penstock entrance to net head piezometers in feet and R = hydraulic radius in feet. Martin Dam

has a plate-steel penstock in a single pipe. Upper Tallassee, Jordan Dam, and Lower Tallassee are three-pipe concrete penstocks. The Upper Tallassee water passages are comparable to the Safe Harbor design.

Mr. Carroll F. Merriam states the fact that conclusions should not be deduced from even a great number of repeated experiments unless the phenomenon is clearly understood. Hydraulic research as conducted by various operating companies in this country is of a defensive nature. Only limited funds are available for offensive research to point out the phenomenon, enabling the engineer to make a direct approach to the solution of his problems.

The position taken by Mr. G. W. Spaulding relative to the performance of draft tubes with various specific speed wheels is well founded. The author wishes to qualify his statement that "in general, it can be stated that a good draft tube for one wheel will also prove efficient with another wheel," to the Francis type runner, as he has had no experience with the propeller turbine.

The construction of draft-tube models in sheet copper, as described by Mr. LeRoy M. Davis, represents an advancement over the method used by the author. The models referred to in the paper were constructed of white pine and followed pattern-work practice. An average 16-in. model draft tube costs $350, while a scroll case may reach $500. Deterioration is rapid due to the wood swelling and joints opening, making constant inspection and repairs necessary.

As pointed out by Mr. Davis and Mr. Hageman, there is much to be gained by building a model of the complete project. In the case of Mitchell Dam, the plant arrangement using the Thurlow suppressor is equivalent to increasing the over-all turbine efficiency by 4 per cent.

A valuable contribution to the paper is offered by Mr. S. O. Schamberger in presenting the results obtained at the Spier Falls Plant. The agreement of head losses as determined on the model and at the plant is remarkable. An interesting comparison of intakes and entrance losses could be made by reducing the Spier Falls values to those shown in the table for various plants of the Alabama Power Company.

The author wishes to thank the contributors to the paper for their assistance in materially adding to the usefulness of the data presented.
